At this stage in the VA process, the team has undergone a joint learning process that "loads their minds" with a massive quantity of valid data about the product under study. Each team member is a decision maker in his or her area of specialization, and the information phase has required them to:

- Develop a common and unconstrained language (the FAST diagram)
- Develop an unprecedented understanding of the reason for the existence of each element of material and labor (the function-costing exercise)
- Relate each product function to the needs and desires of the users/customers (the function-worth exercise)

These three exercises prepare the collective minds of team members for the identification of ideas, concepts, and solutions.

Ownership in the Synthesis Phase. During the synthesis phase of the job plan, ideas and concepts arise. The team leader asks which of the team members will champion the idea or concept. If no one volunteers, the idea or concept is dropped. One who agrees to become a champion is charged with investigating the feasibility and economics of the idea or concept. The result of this phase is, thus, a series of proposals with all the explanations required to be able to select the solutions that are highly likely to be implemented. This includes a description of the present situation and of the proposed alternative, the advantages and disadvantages of the idea, the assumptions used for the calculations, the benefits and costs of the idea, the implementation efforts, and any other information required for a sound decision.

The Development Phase

During the three-week period of the development phase, each champion prepares a rigorously complete set of data on his or her proposals. Included are drawings, cost estimates, engineering calculations, test results, and any other material verifying the efficacy of the proposed change.

The Presentation and Report Phase

The final presentation of results is a brief, but concentrated, report to the management group that authorized the study. Such a presentation has been found to be an essential element in the dynamic of a VA study. It is the focal point toward which all previous activity is directed. It is also framed as "the first day of the implementation phase."

A final report, written by the team members, is issued to each attendee at the final presentation. It contains each of the VA proposal forms, as well as a summary of results and a set of Gantt charts scheduling each activity of the implementation process. This document is, in effect, a "blueprint" for the implementation phase. It should have the power of a sales document because this is the moment at which the champion of each idea will get the go ahead for his or her idea, budget included.

The Implementation and Follow-Up Phase

Without a rigorous system to transform synthesized designs into implemented design changes, an organization stands to waste its problem-solving effort. As noted earlier in this article, VA starts with a process of implementation planning, and this phase is intended to ensure that any proposal reaching this stage has the maximum opportunity for implementation.

A Gantt chart should be prepared describing the activities required to implement each proposal. The implementation plan, as in the example shown in Table 4, serves as a guide to the assignment of a specific person to accomplish each activity. Implementation and follow-up then become simply a matter of carrying out the plan.

Table 4 Possible areas of change for the coolant level sensor design

See Example 1 in text.

Possible change	Actions required to ensure implementation of change
Probe tip material change	Lab test immersed in coolant at high temperature and pressure
	Verify plan with customer release engineer
Relocation of assembly area	Discuss in advance with Human Resources
	Establish rigorous quality constraints
	Discuss with union
Change in sealing configuration	Accelerated life test to ensure 10 yr mean time between failures

---

Value Analysis in Materials Selection and Design

Theodore C. Fowler, Fowler & Whitestone

Examples

Value analysis techniques are described in this section through excerpts from case studies. Two case studies were selected as best exemplifying the materials-related aspects of the VA process. The first of these studies involves a coolant sensor probe, produced by a U.S. manufacturing company. The second focuses on the development of a helicopter gearbox.

Example 1: Value Analysis of a Coolant Level Sensor.

During the implementation planning phase, the team members created a list of possible areas of change in the coolant probe design, and they updated the list twice during their study. Three typical entries are shown in Table 4.

The coolant sensor contains two conductive probe tips that contact the liquid coolant when it reaches the proper level. This sends a signal to the system indicating that the equipment can be permitted to operate. The remainder of the sensor comprises insulating material and a method of mounting and sealing the assembly.

From the synthesis effort, the team generated several ideas and concepts. This example illustrates only one of them, which was championed by the materials engineer team member. The concept involved the injection molding of the probe body with two probe tips insert-molded in place. It required only a single O-ring. While this new design reduced the parts count from 10 to 4, it left several questions to be resolved in materials selection. Primed by their rigorous function-analysis effort, the full five-person team worked out the design led by the materials engineer.

The team determined that the probe must be conductive and corrosion resistant. Stainless steel (300 series) was chosen, with a cross section to lock into the injected plastic tube and with the required 19 mm ($\frac{3}{4}$ in.) exposed to match the previous impedance.

The team also determined that the body of the probe must resist the cooling chemicals and withstand temperatures from 1 to 315 °C (33 to 600 °F). The base threads will be molded in. A major concern with the hygroscopicity of nylon was turned into an advantage as a result of the team's focus on required functions and the materials engineer's previous knowledge. Nylon 6/6 was chosen because of its hygroscopic nature. The team eliminated the base O-ring because the nylon body would swell in the presence of water and ensure a seal. For assembly, the unit comes from the press in finished form requiring only deflashing. The seal around the probe tip resists leaks, again because of hygroscopic nature of the nylon.

Results. The new sensor was tooled at a cost of $30,000 and became the new standard for all of the products of the company. It had a failure rate of less than 10% of that of the purchased sensor, with essentially no leakage failures. The unit cost of the new sensor was $1.50, enabling a return on tooling cost in 4.33 months and saving the company $180,000 per year.

Example 2: Value Engineering of a Helicopter Gearbox.

The objective of this VE study was to reduce the weight of a new gearbox design for an aerospace company while maintaining or reducing the final cost. The design of the gearbox had not been finalized at the time of the study, so the study focused on weight reduction rather than on detailed design of the gearbox. Material composition and weight considerations were important because the gearbox was to be used in a rotary winged aircraft.

The VE team was composed of four university students along with engineers from the aerospace company. The results and recommendations of this example are presented in some detail to illustrate the level of rigor of the typical value analysis/engineering synthesis and development phases.

Gearbox Function Analysis. While a complete function analysis was done during the study, only the key functions of the gearbox are described below:

Function	Description
Basic functions	
Reduce speed	The gearbox reduces the power turbine speed so that it is suitable for driving the helicopter rotor. In this case, the speed reduction is from approximately 40,000 to 6,000 rpm.
Accommodate accessories	Contained within the gearbox housing are drive gears for mounted accessories that operate at different speeds. These accessories include the alternator, starter, generator, fuel pump, oil pump, hydraulic pump, etc.
Supporting functions	
Transmit signals	The gearbox sends information to the cockpit regarding torque, oil levels, drive speeds, etc.
Detect failure	A gear failure is detected through a metal chip detector installed inside the gearbox housing. This function is for safety only and does not affect the speed-reduction functions.
Simplify maintenance	Appropriate positioning of components facilitates maintenance.
Ensure safety	The gearbox must meet aviation industry standards regarding safety.

The creation, synthesis, and development phases resulted in the proposal and study of many solutions, each of which concentrated on the prime objective of weight reduction through proper material selection and manufacturing methods. A summary of the recommended changes is given in Table 5.

Table 5 Recommended changes to the helicopter gearbox design

See Example 2 in text.

Change	Current situation	Proposed alternative	Advantages	Disadvantages	Weight savings		Savings or (cost), $
					kg	**lb**	
1a. Aluminum investment casting	The present gearbox housing is produced via aluminum sand casting with a nominal wall thickness of 0.100 in. and tolerance of 0.020 in. The current material is aluminum alloy AMS 4219, strength class No.	Produce the housing via aluminum investment casting, which allows for thin-wall castings. It is also suggested that the strength class be increased to No. 12 for improved material properties.	Weight and cost savings. Improved geometric accuracy and consistency. Flexibility of design. Good surface finish for contoured air-passage areas, such as engine air-intakes. Components can be	Investment casting reduces the opportunity for concurrent engineering as final detailed drawings are required for tooling definition.	1.4[(a)]	3.0[(a)]	1275

	10 to 11.		cast with ultrasmooth surfaces. Performance is increased without resorting to expensive secondary operations. Indefinite tool life because investment casting tools are in contact only with wax.				
1b. Magnesium sand casting	Same as above.	Magnesium would be used to produce sand cast housings. Investment cast magnesium is not economical. However, the switch from aluminum to magnesium sand casting is very feasible and is commonly done in industry.	Magnesium has a density of 0.645 that of aluminum. The weight-to-stiffness ratio favors magnesium at engine operating temperatures. This is particularly important for a casting of a gearbox part. Magnesium has less loss of yield strength with time as temperatures approach operating conditions at 150 °C (302 °F)	Magnesium is prone to corrosion and requires the addition of a thick epoxy coating on the housing. This was estimated at $100. Due to castability issues, wall thickness was increased by 15% over baseline maximum wall thickness.	4.3	9.4	(100)
2a. Thinning of gear webs	On the preliminary design, the nominal thickness of the gear webs of accessory gear trains ranges from 3.05 to 3.81 mm (0.120 to 0.150 in.).	Preliminary stress analysis showed that it would be safe to thin down the webs to 1.91 mm (0.075 in.) for flat gears only. If the gears are thinned down, the pieces may bend, and for this reason, a minimum nominal web thickness of 2.223 mm (0.0875 in.) is assumed. Calculations of savings were made according to this value.	A weight saving of 0.29 kg (0.64 lb). It is unlikely that the removal of the extra 0.8255 to 1.5875 mm (0.0325 to 0.0625 in.) will require an additional cut during machining; therefore, no cost increase is expected to produce the thinner webs.	. . .	0.3	0.6	0
2b. Cross-drilling of gear webs	The thickness of the gear webs is stated above. They are all full webs.	Cross-drill holes in the gear web in order to remove material and thus weight. Requires extensive analysis because many options are possible. The size, number, and location (balanced, random pattern) of the holes are all variables, but a good disposition must sustain the stresses within a given factor of safety, must not induce vibrations (must not resonate in operating range), etc.	Weight savings. Conservative assumptions were made to give an idea of the possible weight savings, e.g., 3 holes per web, hole diameter of $\frac{1}{3}$ of the web's radial length, and accessory gears only (flat and conical).	The cost of cross-drilling three holes in all gears is calculated as: $8.50/hole × 3 holes/gear × 12 gears = $306.	0.75[(b)]	1.66[(b)]	(306)[(b)]
3. Optical torque sensor	The torque being transmitted by the gearbox is measured using a pair of acoustic	Use an identical configuration, but with photo-electric sensors. The fingers on the shafts are replaced with simple,	A weight saving is realized by replacing the acoustic sensors with optical ones	. . .	0.2	0.5	2000

	sensors directed at the intermeshing fingers of two coaxial shafts.	cross-drilled disks. Each disk has a sensor which "reads" the holes on the disks. Torque is measured as a change of phase between the two signals.	and the fingers with lightweight disks. Optical sensors are inexpensive, reliable, and require far less machining. The data processing requirements (to interpret the phase, and convert to torque) are essentially unchanged.				
Future option: optical strain gage[c]	Same as above.	An extension of the optical torque sensor proposal. An optic fiber would be mounted on or in the power shaft. A light source is then directed through the fiber, and a detector reads the signal at the fiber exit. As the shaft strains, the fiber is deformed, and the signal altered. Similar applications have been used in many cases, e.g., to measure the strains on the propeller and shaft of an icebreaker. The main requirement is the mounting of the fiber on/in the shaft in a permanent, repeatable manner.	Weight saving. The components used for an optical strain gage are very light. Because the strain is read from the output shaft, the concentric shafts presently employed for this purpose can be removed along with the associated bearings and supports. With the removal of the present torque sensor, the gearbox design can be more compact, thus saving on space and housing size as well. Once calibrated, this system would be simple and inexpensive.	. . .	. . .	. . .	. . .

(a) Assumes a 2.159 mm (0.085 in.) nominal wall thickness; the actual weight savings achieved will vary depending on the nominal wall thickness selected.

(b) Preliminary stress analysis permitted, with reserve, to assume up to 5 holes per gear. In such a case, the weight saved would be 1.22 kg (2.70 lb) at a cost of $510.

(c) The solution was thought feasible, but would require some development and thus was recommended to the company for future consideration.

Conclusions of the Helicopter Gearbox Study. The recommendations given in Table 5 considered different materials and casting methods, weight removal through material reduction in gear webs, and the use of an optical torque sensor. It was left to the company to select the most appropriate combination of options given the constraints of the final gearbox design.

A maximum weight saving of 5.2 kg (11.5 lb) with a corresponding cost reduction of $1594 was obtained with the following combination of recommendations:

Recommendation	Weight reduction	
	kg	**lb**
Magnesium sand casting	4.3	9.4
Cross-drilling of gear webs	0.7	1.6

A maximum cost reduction of $3275 with a corresponding weight saving of 1.9 kg (4.1 lb) was obtained with the following combination of recommendations:

Recommendation	Cost saving, $
Aluminum investment casting	1275
Thinning of gear webs	0
Using an optical torque sensor	2000

Conclusions

The popularity of the VA process as a tool for design optimization has consistently risen since the early 1960s. Many organizations have applied some version of the process. Wherever the rigor of the process has been maintained, the results are commonly dramatic. This invariably results in the establishment of permanent, institutionalized VA programs.

Use of Failure Analysis in Materials Selection

George F. Vander Voort, Buehler Ltd.

Introduction

MATERIALS SELECTION for parts or components usually occurs under two conditions. The first is when a new part or component is designed, while the second is when an existing part or component needs to be upgraded. Upgrading may be needed due to a variety of reasons. If the part or component is relatively new, upgrading may be needed if part life proves to be marginal or inadequate. Or, a competitor's newly improved part is performing better and sales of your part are dropping. Or, operating conditions may have changed and your part is no longer performing acceptably. Of course, it is possible that parts have failed and the failure study recommended upgrading the material being used, perhaps also with other suggestions regarding the design and manufacturing processes.

George F. Vander Voort, Buehler Ltd.

Relationship between Failure Analysis and Materials Selection

Several failure analysts have categorized the nature of the failures that their organizations have studied over a long period of time (Ref 1, 2, 3, 4). In most such summaries, few, if any, failures are attributed to the wrong material choice. The usual purpose of such surveys is to determine the frequency of failure mechanisms. A survey by Davies (Ref 4) is the exception because it considers mechanisms and causes of failures separately. Table 1 from this survey shows the frequency of failure mechanisms for failed engineering components and aircraft components. As expected, the percentages vary for different types of components. For example, none of the aircraft components failed by brittle fracture, while 16% of the engineering components experienced brittle failure.

Table 1 Frequency of failure mechanisms

Mechanism	Percentage of failures	
	Engineering components	**Aircraft components**
Corrosion	29	3
Fatigue	25	61
Brittle fracture	16	. . .
Overload	11	18
High-temperature corrosion	7	2
SCC/corrosion fatigue/HE	6	8
Creep	3	. . .
Stress rupture	. . .	1
Wear, abrasion/erosion	3	7

SCC, stress-corrosion cracking; HE, hydrogen embrittlement.

Source: Ref 4

While Table 1 is useful and interesting, it tells how components failed but not *why* they failed, which is really of greater importance. Table 2 lists the frequency of the causes of these failures. This information follows from an understanding of

the failure mechanism and is vital for prevention of failures of other identical components in service or to be constructed. As for the failure mechanisms, the causes may be quite different for different types of components. Classification by cause will lead to decisions about the need for materials substitution and will provide guidance as to the characteristics that the substitute material must exhibit.

Table 2 Frequency of causes for failure

Cause	Percentage of failures	
	Engineering components	**Aircraft components**
Improper material selection	38	. . .
Fabrication imperfections	15	17

Design errors	11	16
Unanticipated service conditions	8	10
Uncontrolled environmental conditions	6	. . .
Inadequate inspection/quality control	5	. . .
Material mix	2	. . .
Inadequate maintenance	. . .	44
Defective material	. . .	7
Unknown	. . .	6

Source: Ref 4

Dolan (Ref 5) described a broad-based failure analysis philosophy aimed at preventing future failures through proper materials selection, the basis of the design and reliance on safety factors, careful fabrication and maintenance with input from failure analysis studies, simulated service tests, and prototype evaluations.

Material selection involves more than merely selecting a particular composition or type of metal, alloy, polymer, ceramic, and so forth. For example, suppose that bearings or races used in a certain application are not lasting long enough. A study reveals that failures always initiated at relatively large, hard oxide inclusions. The composition of the steel used was found to be quite common for this application, but the quality of the material was quite ordinary. In this case, fatigue life could be improved dramatically by purchasing a premium quality level of the same steel. For a few of the more common alloy designations, a manufacturer might produce as many as five to ten different variations within the normal composition range, each designed for a certain balance of properties and quality level for specific applications.

When remedies are needed, the use of a better material may not be considered, or may be considered as a last resort. For example, a failure might be attributed to a problem such as stress-corrosion cracking (SCC). The analyst may have recommended steps to remove, or reduce, the chemical species from the environment that caused SCC, or perhaps the residual or applied stress could be reduced or the stress concentrator at the origin of failure could be avoided. It is also possible that the analyst may recommend switching to a different material that is not susceptible to SCC under the particular conditions. However, this solution inevitably raises the unit cost of the component (as will most solutions), but may not be considered even though a better material might, in the long run, be the lowest-cost, most-reliable solution.

A careful study of the reasons for selecting the original material, or quality level of the material (or both), for an existing product may reveal that the existing material was inadequate. In many cases, the manufacturer may realize that part performance could be substantially improved by changing the material being used, but is reluctant to do so. The larger the company, and the greater the number of parts being made, the harder it is to change the material. The willingness to change is influenced by inventory problems, pricing differences, scheduling problems, document modifications, specifications, and so forth. Furthermore, the certainty that the switch will generate the required degree of performance improvement must be very high, and this is often difficult to predict.

Material selection is primarily performed by manufacturers. Not all university engineering programs offer courses in material selection. This is actually a rather difficult course to teach due to the need for extensive knowledge about the design of components and parts, their manufacture, environmental and usage effects, information not readily available to academics (and rarely published because of competitive issues). Indeed, only a few textbooks (e.g., Ref 6) exist on materials selection, and few academics are considered to be, or claim to be, experts on materials selection. Consequently, students generally get limited training in materials selection at universities. Considerable advances have been made in

developing computer software to analyze stress and strain in structures and to predict fatigue life. This information is useful when selecting materials, but it is only part of the overall picture. Materials properties databases are another useful tool in considering alternate materials, although mechanical properties are only part of the overall picture.

The failure analysis methodology generally centers on cause and effect and ignores prevention. Failure studies often do not include recommendations to prevent similar failures in other components in service or to be constructed. In most cases, the analysis concerns only the cause of failure, that is, failure mechanisms, even when the manufacturer's experts perform the analysis. However, after the analysts have determined all of the factors responsible for the failure, they should determine what must be done to prevent similar failures in existing or future components. Prevention should be as important as diagnosis.

Use of Failure Analysis in Materials Selection

George F. Vander Voort, Buehler Ltd.

The Failure Analysis Process

The basic procedure for performing a failure analysis (Ref 7) involves the following general steps:

- Collecting background information on the component and the incident
- Macro- and microfractography (finding the origin when fracture is involved)
- Verification of materials and properties (compare with specifications)
- Microstructural examination
- Stress and life calculations
- Special measurements, for example, residual stress
- Simulations
- Analysis of the data
- Report preparation
- Follow-up on recommendations

A detailed treatment of the failure analysis process is outside the scope of this article, but can be found in *Failure Analysis and Prevention,* Volume 11 of *ASM Handbook* (Ref 8) and in several textbooks (Ref 9, 10, 11, 12 are selected examples).

The failure analysis tends to be influenced strongly by the technical background of the analyst. Mechanical engineers evaluate the design thoroughly and calculate stresses, for example, but tend to ignore the material. On the other hand, metallurgists tend to concentrate heavily on the material and the manufacturing process and do a less thorough study of

the stress situation and design. A balanced approach is necessary; this often requires the collaboration of two or more individuals with the required analytical strengths. The trick is knowing when to call in another person with the required engineering background.

Naturally, the primary focus of the failure analysis is the determination of the cause of failure. Indeed, this may be the sole charge given to the analyst. However, in the larger scheme of things, someone must view the reported failure mechanism, material properties, manufacturing procedure, service conditions, and so forth, and decide what must be done if other similar components could fail in the same way. If the failure was a unique case, the material may be quite adequate. However, if the failure indicates the potential for similar failures in other components, either in service or to be built, or if the percentage of failures is higher than acceptable (depending on the degree of risk or potential consequences), or if the component life span is less than desired or required, changes must be made. In any given situation there may be a number of potential ways in which a component can be improved; each must be evaluated as to its potential to cure the problem, its cost, and its potential to produce other problems (which can happen). One option may be the selection of a different material.

Use of Failure Analysis in Materials Selection

George F. Vander Voort, Buehler Ltd.

Methods for Analyzing Failures to Improve Materials Selection

To evaluate the value of a new, better material, it is necessary to define the required properties of the component. Manufacturing processes can alter the expected properties, as can the environment. Here, the failure study may reveal factors not initially considered, or incorrectly estimated. A host of properties must be considered, as well as their relevance to the part. One must remember that mechanical property tests pertain to idealized situations that have been standardized to reveal comparative information about the material. These data may not be fully relevant to the conditions that exist in the actual component. The uniaxial tension test specimen, toughness tests, such as the Charpy V-notch impact specimen, and hardness tests provide useful comparative data under the test conditions, but the data ranking of materials may not be the same if used in the actual component. Nevertheless, testing by standard procedures is very useful as full-scale testing of components is very difficult and expensive.

Besides these common tests, there are a myriad of other tests and characteristics that can be evaluated for materials under fixed conditions; for example, ductility, fatigue strength, fatigue crack growth rate, notch sensitivity, formability (drawability, stretchability, bendability, etc.), wear resistance (abrasion resistance, adhesion resistance, galling resistance, etc.), machinability, weldability, plus other tests relating to corrosion behavior, thermal expansion/contraction, electrical resistivity, magnetic permeability, and so forth. The failure analysis may show that one or more of these attributes are deficient, and the analyst should be asked to consider these problems, not merely determine the cause of failure.

Once the failure mechanism has been determined, it is important that contributing factors from the design, materials (and quality level), manufacturing and assembly processes, and service conditions be determined. In general, failure analysts tend to do a fairly good job evaluating design and service condition contributions. However, they may overlook the influence of the materials and manufacturing processes unless their assignment includes a specific request to make recommendations for dealing with similar components that may experience the same problems (to prevent failures) or

recommendations on avoiding such problems with components to be manufactured. When recommendations are made, they should be carefully reviewed to ensure that new problems are not created by the recommended changes (as was not done in the precipitator wire problem discussed in Example 2 in this article).

Implementing Changes. Once all of the relevant information is assembled, the analyst is faced with the problem of informing those who can implement the required changes. This can be quite frustrating. Some analysts are hired to simply perform the analysis, and their input is not sought beyond the report generation phase. This is often true for independent laboratories and consultants. Their job is done when the report is written, or perhaps after they testify in court. They may not be requested to comment on corrective actions, and the person who hired them may not be concerned about this either.

If a manufacturer or supplier is performing the analysis, they will be more concerned with the work that follows the analysis than with the analysis itself because of their view of the larger picture. Years ago, there was greater resistance to interdepartmental criticism in organizations, even when totally constructive, and resistance to changes required to fix obvious problems with components. Today, most of these barriers have disappeared as companies try to be competitive and to improve products. "Getting the message out" to the required individuals to implement changes, be they in materials or whatever, used to be one of the most difficult tasks of the analyst, but this has changed dramatically over the past decade because of many factors (of which product liability cannot be ignored).

Use of Failure Analysis in Materials Selection

George F. Vander Voort, Buehler Ltd.

Historical Evolution of Improved Materials

While failures stimulate manufacturers to upgrade their product--through design changes, manufacturing process changes, or materials substitution--they also stimulate research to improve existing alloys and to develop better new alloys. One classic example of this process, the historical evolution of rail steels, is described in the article "Effects of Composition, Processing, and Structure on Properties of Irons and Steels" in this Volume.

Despite some notable historical catastrophes--such as the 15 Jan 1919 failure of a 90 ft diam riveted molasses tank in Boston killing 19 people (Ref 13, 14, 15, 16, 17, 18) and the 14 March 1938 failure of the all-welded Vierendeel truss bridge near Hasselt, Belgium (Ref 19, 20, 21)--it was not until the failures of welded T-2 tankers and Liberty ships during World War II were analyzed that brittle fracture was demonstrated to occur in ordinary mild steels. This research (Ref 22, 23, 24, 25, 26) stimulated not only an understanding of brittle fracture and the measurement of toughness, but also extensive alloy development programs to develop stronger, tougher, weldable carbon- and low-alloy steels in all product forms. These alloys are being continually "tweaked" to further improve properties through advances in steelmaking technology (control of residual elements, gases, inclusion content, segregation, grain size, and microstructure). It is interesting to speculate that, had the RMS Titanic sunk on the night of 14-15 April 1912 in shallow waters so that studies could have discovered the extreme brittleness of the steel used, this failure might have initiated brittle fracture studies three decades earlier.

Use of Failure Analysis in Materials Selection

George F. Vander Voort, Buehler Ltd.

Failure Analysis Examples

Three examples are provided to illustrate the use of failure analysis in materials selection and materials development/refinement.

Example 1: Use of Failure Analysis Results in the Improvement of Line Pipe Steels.

A superb example of continual product refinement, stimulated by product failures, concerns gas transmission line pipe steels. Brittle fracture of some line pipes occurred, and these fast, full-running fractures were spectacular demonstrations of a poor combination of materials, environment, manufacturing and installation problems, and loads (Ref 27, 28). Following previous research on brittle fracture, the initial efforts were to decrease the Charpy ductile-to-brittle transition temperature (DBTT). Other toughness tests, such as full-section drop-weight tests, were used in an effort to make the toughness tests more relevant. Indeed, fracture initiation tests were even performed on actual full lengths of pressurized line pipes (see Ref 29, 30, for example). To illustrate, Fig. 1 shows a full-size section of an X60 grade line pipe that was pressurized internally to 40% of its yield strength and tested at 56 °F (13 °C), 8 °F above its 50% shear-area drop weight transition temperature (DWTT). A 30-grain charge was detonated beneath an 18 in. (45.7 cm) notch cut into the pipe. The crack, moving at 279 ft/s (85 m/s), stopped after a short distance. The fracture was ductile, and the line pipe was tough enough at this temperature to arrest the crack. However, when another pipe was tested in similar fashion at -15 °F (-26 °C), 40 °F below its 50% shear-area DWTT, the crack moved at 2215 ft/s (675 m/s), the fracture was fully brittle, and the line pipe was not ductile enough to stop the crack. Figure 2 shows that the full length of the line pipe opened up in this test.

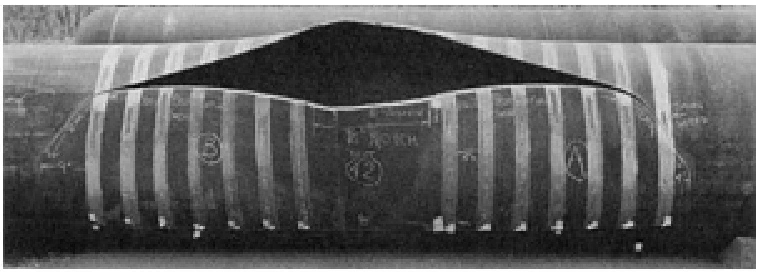

Fig. 1 Ductile fracture of a full section X60 grade line pipe tested at 56 °F (13 °C), which is 8 °F above its 50% shear-area DWTT

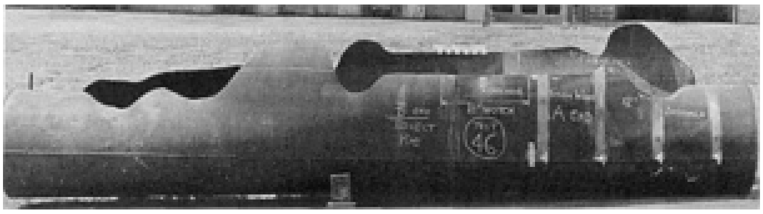

Fig. 2 Brittle fracture of a full-section X60 grade line pipe tested at -15 °F (-26 °C), well below its 50% shear-area DWTT

Despite substantial reductions in the DBTT of line pipe steels, line pipe failures still occurred; this time, however, they occurred under a ductile fracture mode (Ref 31). It was subsequently learned that the absorbed energy on the upper shelf of the Charpy energy-temperature curve was critical for arresting a moving crack. Hence, researchers concentrated on improving the upper-shelf energy. Meanwhile, the strength of these tougher alloys (hot rolled, non-heat treated) was also raised while designers increased the line pipe diameter.

In the 1960s, steelmaking technology was found to be inadequate as pipe sizes increased, stresses increased, and service temperatures decreased. Failure analysis revealed that brittle fracture was the culprit. However, application of the standard approach of reducing the ductile-to-brittle transition temperature of the line pipe steel merely changed the failure mode. Both fracture initiation and fracture propagation had to be controlled. Further studies showed that the upper shelf energy had to be improved in order to stop a crack, once initiated, from propagating. This work led to still further enhancements permitting development of weldable higher-strength, larger-diameter pipe but with satisfactory fracture control. Overall, the changes in steel composition were relatively minor, at least on a total weight percent basis. However, these changes, chiefly in residual gas content, sulfur content, and grain refining additives, required steelmaking technology enhancements. Improved steel processing procedures, chiefly hot-working temperature and deformation control, were also required to optimize microstructure and properties.

Example 2: Failure Analysis Leading to Improved Materials Selection for Precipitator Wires in a Basic Oxygen Furnace.

This example of how a component failure stimulated materials selection concerns the failure of wires used in a wet precipitator for cleaning the gases coming off a basic oxygen furnace (BOF). The system consisted of six precipitators, three separate dual units, each composed of four zones. Each zone contained rows of wires suspended between parallel collector plates. The original 0.109 in. (2.77 mm) diam AISI 1008 (for zones 2 to 4 in each precipitator) carbon steel wire was cold drawn to a tensile strength of 100 ksi (690 MPa). One end was looped around an insulator spool at the top and fastened with a ferrule made from AISI 430 stainless steel. The top end of the wire is attached to the insulator on the framework while the bottom end of the wire was attached to a bottle-shaped weight. A potential was placed between the rows of wires and the interspersed parallel collector plates to remove the particulate matter from the gas.

Wires began failing about one year after start-up of the BOF shop. The frequency of failures varied in the different zones. Figure 3 shows an example of an unwrapped 1008 wire and two views of a failed wire. The maintenance metallurgist determined that the 1008 wires failed because of corrosion fatigue. It was decided to replace all of the wires in the two zones with the highest rates of failure with stainless steel wire. Type 304 austenitic stainless steel wire was chosen, and it was ordered cold drawn (150 ksi, or 1034 MPa, tensile strength), mainly because the 1008 wire was cold drawn.

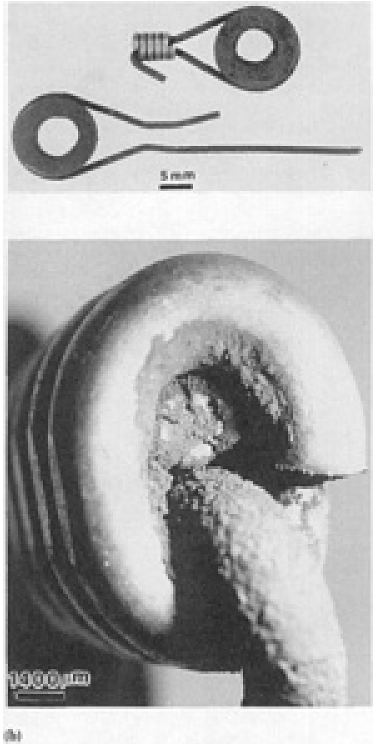

Fig. 3 Precipitator wires from a basic oxygen furnace. (a) Original AISI 1008 carbon steel wire, wrapped around an insulator spool and fastened with a ferrule made from type 430 ferritic stainless steel. One ferrule has been removed. (b) Close-up view showing the fractured wire face inside the ferrule

Seven days after the more expensive type 304 wires were installed, the first failed. Thus, switching from inexpensive 1008 carbon steel wire to a much more expensive type 304 austenitic stainless steel wire changed the time to first failure from one year to one week! As a result, further failure analysis was requested.

For the new type 304 wires, ferrules were not used at the ends. Instead, 18 in. (45.7 cm) long cold-drawn 1010 carbon-steel tubes were used. The type 304 wire was inserted into one end of the tube, and the tube was crimped in two places to fix the wire. The other end of the tube was bent so that it could be looped over the insulator on the frame, as shown in Fig. 4. The wires broke at the apex of the tube or just slightly below it, as shown in Fig. 5.

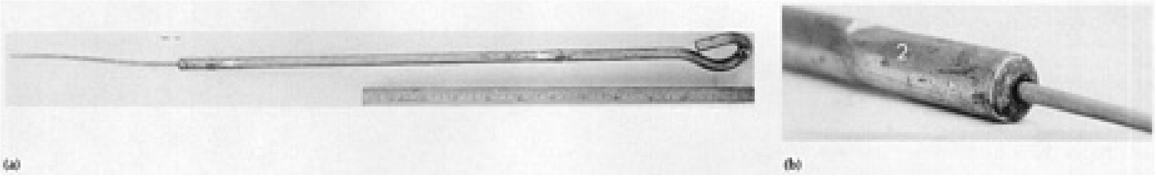

Fig. 4 Replacement precipitator wires. (a) View of a type 304 replacement precipitator wire and the AISI 1010 tube bent at one end to place over the insulators. The arrows point to the two crimps used to fix the wire in the tube. (b) Close-up view of one of the crimps

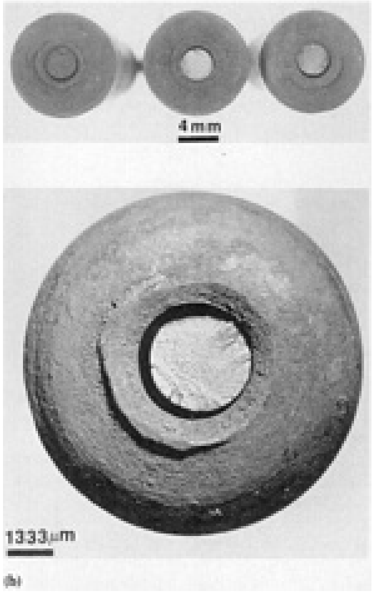

Fig. 5 Fractured replacement precipitator wires. (a) View of fractured type 304 precipitator wires. (b) Close-up view of one of the wires. Note the deformation at the inside diameter of the tube due to the motion of the wire.

The new type 304 stainless steel wires failed by transgranular SCC. The plant metallurgist was either unaware of the potential for SCC or did not realize that the hot gas from the BOF was cooled with river water before entering the precipitators. Because the river water goes through the plant piping system it was treated three times daily with chlorine to prevent algae growth in condensers, pipes, and so forth. The air temperature within the precipitator varied from about 425 to 200 °F (218 to 93 °C). Thus, the new attachment method produced an ideal stress concentrator, the wire had a high level of residual stresses, the gas contained chlorine ions and the temperature was above 200 °F--ideal conditions for chloride ion SCC of type 304.

Furthermore, the framework holding the wires was vibrated periodically at 60 Hz to dislodge particulate matter from the wires. The bottle weight produced a tensile load of slightly less than 2 ksi (14 MPa). During operation, both ends of the wires were constrained so that the force of the wind through the precipitator concentrated stresses at the tube opening. Calculation of the natural frequency of the wire showed that its third harmonic was almost exactly 60 Hz. Consequently, it was felt that this could be another source of stresses.

To prevent future problems, either from corrosion fatigue or SCC, wires were made from annealed type 430 ferritic stainless steel, which is immune from chloride ion SCC. Attachment was made using type 430 ferrules. The wire diameter and bottle weight were changed so that the natural frequency was about 90 Hz. Over the next few years, most of the precipitator zones (2 to 4, zone 1 used barb wire) were restrung with type 430 wires, and they performed for more than twenty years (except for failures due to electrical short circuits) until the BOF shop was closed down recently.

This is a good example of the problems that can occur in practical failure analyses work. The original carbon steel wire was deemed to be inadequate for the application. The metallurgist decided to replace these wires with a more corrosion-resistant alloy, but did not realize that his choice, under the operating conditions, was unwise. The more expensive type 304 stainless steel wire failed catastrophically after only a week of service time. Use of a ferritic stainless steel solved the problem, but other solutions were also possible.

Example 3: Failure of Chipper Knives.

This example describes how a steel research engineer used failure analysis results to identify the need for a better alloy. In this case, a new alloy had to be developed because no suitable composition existed. This example concerns the development of an alloy steel for knives used to chip logs, either hardwoods or softwoods. Traditionally, chipping of logs for making paper, cardboard, or particle board took place in a paper mill using an alloy with a nominal composition of Fe-0.48C-0.30Mn-0.90Si-8.50Cr-1.35Mo-1.20W-0.30V.

This alloy performed well in pulp mill applications where the knives are typically 20 to 30 in. (51 to 76 cm) long, from about 5 to 7 in. (13 to 18 cm) wide, and usually 0.5 to 0.625 in. (13 to 16 mm) thick. One of the long edges is beveled and sharpened.

However, with the development of total tree harvesters, where the chipper is taken out in the field to chip the logs (see Fig. 6), knife failures were frequently encountered due to the less rigid support of the knives and because fewer knives are used (Fig. 7) than in a pulp mill. Typical examples of failed knives are shown in Fig. 8; Fig. 9 shows close-ups of edge damage.

Fig. 6 A 75 in. Morbark total tree harvester

Fig. 7 Chipper knife being installed in a 75 in. Morbark total tree harvester

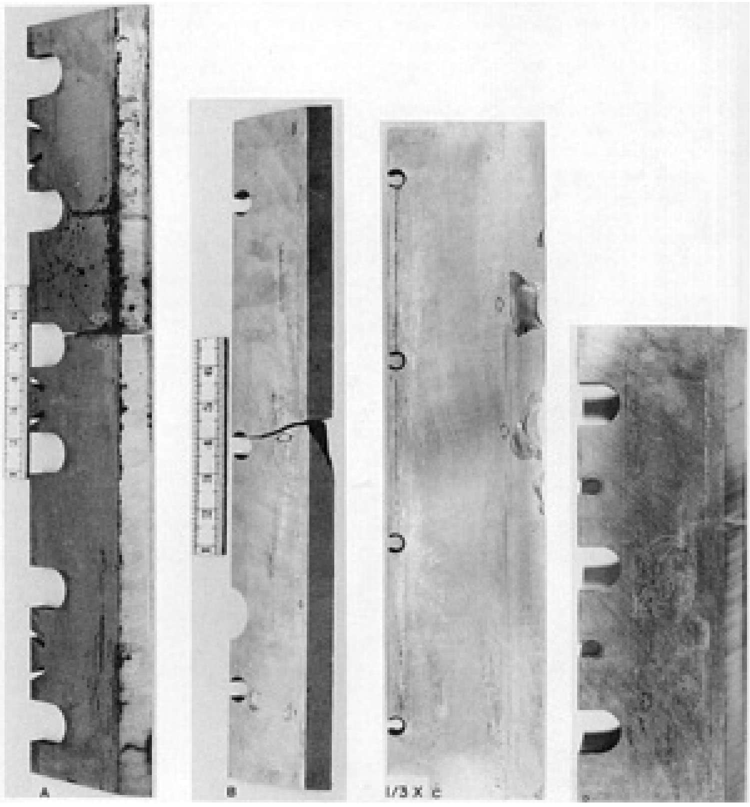

Fig. 8 Examples of a few of the different types of failed chipper knives examined. Arrows point to fractures. (a) Knife from a 75 in. Morbark total tree harvester. (b) Knife from a 66 in. CM&E sawmill chipper. (c) Knife from a Carthage Norman chipper. (d) Knife from a 96 in. Bush chipper

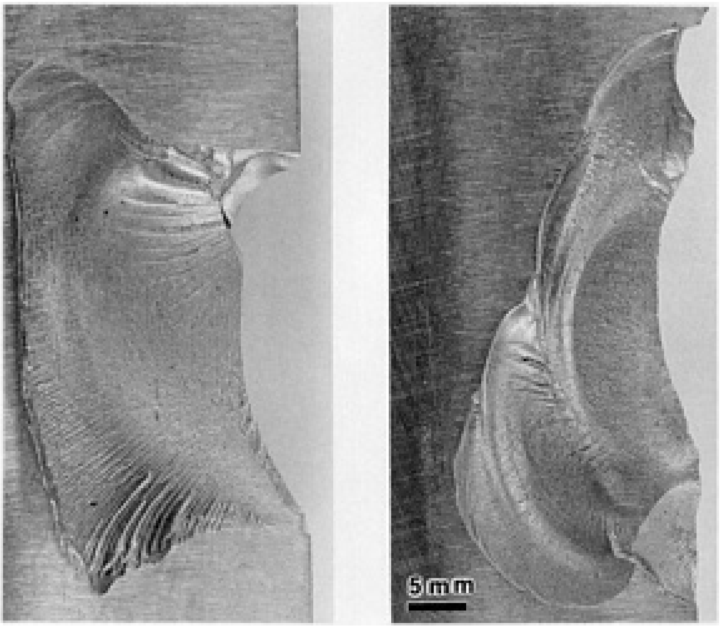

Fig. 9 Close-up of the fracture on the Carthage Norman chipper knife shown in Fig. 8(c)

In this case, a tougher alloy steel was needed that would still exhibit all of the other necessary characteristics of a knife steel, for example, edge retention, resistance to softening under frictional heating, wear resistance, ease of heat treatment, dimensional stability in heat treatment, grindability, low alloy cost, and so forth.

The failure analysis revealed longitudinal Charpy V-notch (room temperature) impact strengths of 3 to 5 ft · lbf (4 to 6.8 J), hardnesses from 56 to 59 HRC, and retained austenite contents varying from a trace to 8% in failed knives. The alloy design program was established to produce a lower-cost composition (based on the cost to add various alloying elements) with significantly higher toughness, which is easily heat treated and yields a hardness of at least 58 HRC with as high a tempering temperature as possible. Furthermore, tempering must produce high dimensional stability.

The program developed the nominal composition of Fe-0.50C-0.30Mn-0.40Si-5.00Cr-2.00Mo (Ref 32, 33), which achieved the goals described above. Optimal austenitizing temperature was 1850 °F (1010 °C), and either air or oil quenching could be used. Many manufacturers oil quench using a press to maintain flatness. The optimal tempering temperature was 980 °F (527 °C), followed by a second temper at 940 °F (504 °C), yielding hardness of 59 HRC and absorbed energy of 6.5 to 7.5 ft · lbf (8.8 to 10.2 J) on longitudinal, room-temperature Charpy V-notch specimens. With this tempering practice, all residual retained austenite was eliminated.

Knives were made from the above composition, and blind trials were conducted using a 75 in. Morbark Chip Harvester (Fig. 6 and 7). Knives were also tested from steel of the old composition using two different sources. Knives (B) of the old composition were made by the same company that made the knives from the new composition, while old knives A were made by a competitive knife manufacturer using the former composition. Table 3 presents the results from field trials conducted by a knife user. It is quite obvious that the new composition outperformed the standard composition (and A and B performed similarly) in all areas. Furthermore, in this and in further usage none of the knives made from the new composition broke in service.

Table 3 Results of chipper knife field trials

See Example 3 in text.

Knife material	Average results per run					Production per in. of knife		
	Run time, min	No. boxes of chips	Resharpening time, min	Stock removal, in.	Stock removal, mm	No. of runs	Run time, min	No. boxes of chips
New	75.0	1.67	29.0	0.036	0.91	27.78	2083.3	46.4
Old A	58.75	1.19	34.4	0.057	1.45	17.54	1030.7	20.9

This example is typical of many such studies conducted by researchers working for steel and specialty alloy manufacturers. A problem was observed through contacts with manufacturers of knife blades. Knives from a variety of pulp mill, portable tree harvesters, and saw mills were studied to characterize the steel and the reason for their failures. These data then served as the basis for an alloy development program where all of the relevant parameters were evaluated to develop an optimal composition. This was followed by trials in which a knife manufacturer made knives from trial compositions and then evaluated their performance in the field. This information was used to refine the final composition, which was evaluated in blind trials by a disinterested party. The key to the development was a careful study of a number of failed knives with different problems, but chiefly gross fracture, used in different types of operations.

Conclusions

When failures occur in existing products or prototypes, study of the failures provides valuable information to guide the materials selection process, at least in those cases where the material used appears to be part of the problem. Many failures, of course, are not caused by the use of inadequate materials, but a significant percentage of failures do result from use of materials that may not be optimal for the application. Published failure analyses generally concentrate on failure modes and mechanisms and do not always consider if the best material is being used. However, by examining the reasons for the failure and the role of the chosen materials, the appropriateness of the chosen materials can be determined. The analyst should always consider what steps must be taken to prevent such failures in other similar components. The materials development engineers need to be sensitive to the deficiencies of materials under certain operating/environmental conditions. Only by recognizing needs can new and better materials be developed. The materials selection engineer needs to be sensitive to deficiencies in product performance in order to make materials substitutions in a timely manner.

Introduction to the Effects of Composition, Processing, and Structure on Materials Properties

Richard W. Heckel, Michigan Technological University

Introduction

MATERIALS are selected and used as a result of a match between their properties and the needs dictated by the intended application. In this sense, the properties should be defined broadly and include fabricability, required maintenance, costs associated with the original materials and maintenance, and the behavioral characteristics associated with the function of the item within the overall design (Ref 1). Materials are classified as metals (alloys), ceramics, polymers (plastics), and composites; they are either naturally occurring (e.g., wood, rock, and leather) or manufactured (e.g., organic fibers, aluminum alloys, industrial diamonds, and graphite-reinforced plastics). The rapid increase in the variety of manufactured materials in the last half century and the ranges of material properties thereby available have played a major role in substantial technological progress. In this Section of the Handbook, emphasis is placed on structural materials, that is, those materials whose applications involve primarily their mechanical behavior (e.g., stiffness, strength, ductility, toughness, and hardness) rather than their physical properties (e.g., electrical, thermal, magnetic, and optical behavior). Degradation behavior of structural materials (e.g., corrosion, oxidation, and radiation effects) is also considered where appropriate for specific materials and service conditions.

Richard W. Heckel, Michigan Technological University

Composition and Structure Determine Properties

The contemporary view of materials holds that properties are determined by composition and internal structure, with the latter being the result of the processing of a given composition. Simplistically, it is not just the types and amounts of various atoms or ions that constitute the material that alone determine its properties. The arrangements of the atoms or ions and the various types of defects (deviations from perfect atomic arrays) that exist within these arrangements contribute in a major way and positively to the properties of the material. It is the processing of the material during the various stages of its manufacture that determines the atom or ion arrangement and defect structures. Thus, processing parameters control the structure of a given assemblage of atoms or ions; this internal microstructure, along with composition, determines the properties of the material.

The importance of the composition of a material in influencing its properties is readily acceptable to everyone. "What's in it" is important to the taste of our food; the same principle should be applicable (and is) to the properties of materials. The properties of aluminum oxide are expected to differ from those of copper, polyethylene, and graphite because it is known that their compositions vary widely. It is less obvious that internal structural features are important in the determination of properties as well. In fact, a half-century ago it was not uncommon to hear from practitioners that metallic alloys failed by "crystallizing," a statement that implicitly assumed that alloys in service were amorphous and lacked crystalline structure. (It is unfortunate that "failure by crystallization" may yet be heard on rare occasions.) However, experience with food shows that material structure is important (Ref 2). Chefs and lesser cooks know that the texture of their raw materials and

the sizes of various components in their recipes must be controlled. Pasta has a wide range of geometric forms, soups contain solids of specific sizes and shapes, bones in broiled fish ruin the entree, and salad dressing can be formulated with two immiscible phases (olive oil and vinegar) to provide two solvents into which a variety of different types of flavorings can be dissolved. Structural features, in addition to composition, are just as important to engineering materials as they are to the preparation of culinary delights even though the raw materials and methods of processing vary substantially.

Most people have experienced examples of the dependence of internal structure on the behavior of materials, but may not have recognized this relationship. A common example is the use of a steel wire coat hanger as the "raw material" in the conversion by hand to another useful form. The bends in the coat hanger that were formed during its factory processing into a coat-hanger shape are difficult to straighten, whereas the already straight sections will readily deform as forces are applied. Clearly, the bent sections are strongest, a fact which indicates that something other than composition controls properties because the coat-hanger wire is of uniform composition (essentially iron with small amounts of carbon, manganese, and silicon). It is now well established that the deformation of the wire during the original production of the coat hanger introduces structural defects (line defects called dislocations) into the otherwise uniform arrangement of the atoms (a body-centered cubic crystalline array for this alloy). These defects increase strength in the regions of the bends, causing the difficulties associated with the straightening of the coat hanger.

A corollary to the above example is the incomplete prediction of properties that usually occurs when composition alone is specified. Chemical analysis of a sample of glass-reinforced plastic composite material (fiberglass) would provide information on the amounts of carbon, hydrogen, oxygen, and silicon plus some additional minor elements in the material. However, a block of material constituted from these elements in the amounts found could behave in a manner entirely apart from glass-reinforced plastic. The keys to the remarkable mechanical behavior of glass-reinforced plastic are the arrangement of the glass fibers in the continuous plastic matrix, the properties of the glass and plastic (due to their individual compositions and structures), and the bond at the interface between the glass and plastic. Thus, the overall composition of the composite, the composition found by the bulk chemical analysis, is determined by the compositions of the individual phases, glass and plastic, and their volume fractions in the composite. The overall composition gives no information on the geometrical features of the glass fibers, their arrangement in the plastic matrix, and the individual compositions of the fiber and matrix phases, all of which contribute to the properties of the composite.

Elements of Structure

Full appreciation of the effects of structure on material properties is impeded by the wide variety of structural elements, their size, and the effects of processing on each of them. In addition, there are a large number of individual properties of interest with each of them being determined typically by more than one structural element. In most instances, more than one property is critical, leading to a large number of critical structural elements to be controlled by processing. Not uncommonly, when several properties are specified, structure/property conflicts occur and the specifications have to be reconsidered because of technological limitations in processing to achieve desired structures and/or the mutual exclusion of specific property combinations.

The common structural elements that are most important in materials include (Ref 3, 4, 5):

- Type of atom-to-atom (or ion-to-ion) bonding (primary metallic, ionic and covalent, and secondary)
- Type of interatomic (or interionic) packing: crystalline (crystal structures), amorphous (dimensionality,

for example, one-dimensional chains, three-dimensional networks), or mixed (nature of crystalline and amorphous regions and fractions of each)

- Alloying atoms (or ions); these are sometimes classified as "point defects." Crystalline structures either replace host atoms on their crystalline lattice sites (substitutional atoms) or fit into the spaces between host atoms (interstitial atoms). Amorphous structures are atom groups or single atoms substituted into the one-dimensional or three-dimensional arrangements or between adjacent one-dimensional chains causing enhanced interchain bonding.
- Defects in crystalline materials. Point defects are vacant atom or ion positions (the local charge imbalance in the case of an ionic vacancy is compensated by an additional defect). Line defects, or dislocations, are disruptions (displacement of atoms) in the lattice that occur along a single dimension and extend about ten or so atom (or ion) diameters from the core (line) of the defect. Surface defects, or interfaces, are two-dimensional defects between two adjacent crystals of different spatial orientation (defects are termed grain boundaries when the crystals have the same crystal structure as in a two-phase material); free surfaces may be added to this category because they are the termination of the crystal lattices of grains at the surface of the material.
- Microstructure is the arrangement in a material of grains (polycrystalline materials) and discrete regions having different atomic and defect structures; regions with different atomic structure are typically called phases (multiphase materials); often multiphase materials have phases with different chemical compositions as well as different atomic structures. The microstructure is classified by its morphology: the size, shape, amount, and distribution of the discrete regions.
- Macrostructure is, typically, the features of a material that can be observed at very low magnification (or none) such as notches, cracks, and large-scale composition variations (e.g., compositional inhomogeneities in large castings, corrosion products on the surface of a material, and weld-fusion zones).

The dimensions of the defects listed above range from atomic through component size or about ten orders of magnitude. The difficulties associated with the simultaneous visualization of such a range of dimensions further complicates the application of structural concepts in understanding the nature and controlling the behavior of engineering materials using processing. For example, "defects" are universally accepted to be flaws when observing merchandise in stores or showrooms; from a materials structure standpoint, such flaws would be considered as "macrostructure." Defects in the structures of materials, on the other hand, because they may approach atomic or ionic dimensions, are many orders of magnitude smaller in size than what are normally referred to as defects in merchandise and can often confer benefits to the properties.

The small size of many of the critical structural elements has greatly impeded the understanding of composition/structure/processing relationships. Figure 1 (Ref 1) provides a comparison of the sizes of various structural elements in materials along with applicable techniques for their observation. Observation and understanding had to await the development of instrumentation with the resolving power necessary for the study of structure and to correlate such studies with composition and processing conditions and parameters.

Introduction to the Effects of Composition, Processing, and Structure on Materials Properties

Richard W. Heckel, Michigan Technological University

Historical Perspective

The Various Materials Ages. Materials have played a dominant role in the continued development of civilization and significant advances have coincided with the development of new materials. Westbrook has provided several useful and detailed reviews (Ref 6, 7, 8) of the evolution of various types of materials and their processing over the period of the last 12,000 years. Clearly, a strong linkage has existed and continues to exist between advances in materials and civilization.

The evolution of materials over the ages has been summarized by Ashby (Ref 9) as depicted in Fig. 2. For about the first 9000 years of recorded history, essentially all structural materials were naturally occurring. Processing was minimal, and some shaping was possible. Even the copper metal used early in this period was "native copper," a material of high purity found at just a few locations on Earth (e.g., the Upper Peninsula of Michigan, Ref 10) as metallic copper and not as a compound such as copper sulfide that would require extensive refining to yield a useful metal. From the beginning of the Iron Age in 1000 B.C. through most of the 19th century, processing and raw materials development resulted in the advances from iron to cast iron to steels (Ref 11). Major effort was directed toward the development of ferrous production capacity (Ref 12). The transition to steels was accelerated by the expansion of railroads and the industrial revolution. Alloy steels followed in the late 19th and early 20th centuries and were joined by nonferrous alloys based on aluminum, copper (now beginning a growing dependence on sulfide ores rather than "native copper"), nickel, and so forth, in the rapidly growing array of structural materials. As the outset of World War II approached, metallic alloys dominated the overall spectrum of available structural materials in terms of importance to industrial and societal requirements.

The twenty-year period beginning with the onset of World War II clearly marked a transition for materials manufacture, availability, and application as shown in Fig. 2. The trends initiated during this period have continued to the present time (Ref 13). Certainly, the wartime economy of the 1940s and subsequent military requirements greatly accelerated the development of elastomers (artificial rubber) and plastic materials, leading to a wide range of useful properties in these types of materials and production capacities that presently exceed that of steel in the U.S. economy. In addition, the wartime economy expanded the ranges of metallic alloys and their properties. Higher strength and toughness, especially with lower-density and/or higher-temperature capability were in demand and soon provided well-defined needs for the composites segment of the materials field. Ceramic materials were developed in part because of composite materials needs and subsequently have become important in coatings and monolithic components.

More recent societal interests and problems have continued the development and application of materials having increased technological sophistication (traditional materials with improved reliability and new materials with enhanced performance). The new imperatives of increased fuel efficiency, decreased environmental damage, and increased recycling have placed increased emphasis on higher strength-to-weight ratios, higher engine operating temperatures, increased component lifetime, and systems allowing efficient recycling of materials. Furthermore, these advances, to be effective, have carried minimal cost penalties. Thus, thrusts in the development of metals, plastics, composites, and ceramics that began during the 1940 to 1960 transition continue today, driven by expanded sets of societal and industrial goals.

It is meaningful to reflect on the underlying basis for the 12,000 years of materials development depicted by Ashby (Ref 9) in Fig. 2. Following the first 9000 years where practically all materials were naturally occurring (with a minimum amount of shaping), new structural materials became the products of artisans who refined them and then formed them into useful shapes. These growing numbers of artificial materials required carefully selected raw materials and carefully followed recipes for processing because production quality control of chemical composition awaited the 19th century and the understanding of metallic alloy structure was in only rudimentary form in the early 20th century. Arguably, it was (1) the appreciation of the effects of structure, as well as composition, that began to unfold for metals and their alloys in the early 20th century and (2) the recognition in the mid-20th century that processing/structure/property relationships would be important in other types of materials that have been the underlying support for the materials developments to meet industrial and societal needs of the past half-century.

Historians have recognized the importance of materials through the naming of the Stone (prehistoric; prior to 10,000 B.C.), Bronze (4000 to 1000 B.C.), and Iron (1000 B.C. to A.D. 1620) Ages. Another perspective comes from observing the various stages of materials development over the 12,000 years covered by Fig. 2:

- Up to 1000 B.C.: Materials typically used in the "as-found" condition.
- 1000 B.C. to A.D. 1800: Development of new materials where processing altered the composition of the raw material, size was limited, lack of composition and structure analysis limited understanding, quality control based on constant sources of raw materials, and empirically determined processing procedures.
- 1800 to 1880: Development of process mechanization and production quantities (especially in the ferrous industry) and improved compositional control.
- 1880 to 1950: Continuation of mechanization, production capacity development, compositional control; development of new metallic alloys; importance of the structural elements of materials (primarily for metals) began to unfold; and interest in nonmetallic structural materials developed.
- 1950 to present: Emphasis placed on low-cost production of high-quality materials, unified view of materials emerged, importance of structural elements in all classes of materials recognized, new instrumentation providing high-resolution observation of structure developed, detailed understanding of structure/property relationships resulted, and the design *of* materials evolves in partnership with design *with* materials.

Structure and Structure Analysis. Materials science and engineering is certainly an old field and a new one simultaneously. The recognition of the importance of structure in determination of properties is the hallmark of the modern developments in the field. The speculations about the relationships between properties and possible structure changes brought on by processing variations have given way to direct observations of structures developed through controlled processing. A brief history of the development of microstructure analysis techniques is in order. Those interested in detailed treatments should read the presentations of Mehl (Ref 14, 15) and a more recent symposium proceedings that covers advanced microstructural analysis techniques (Ref 16).

Interest in the mechanical behavior of materials preceded an understanding of the causes underlying the variations in material properties. Hooke's law and nonelastic behavior were studied in the 17th century. The mechanics of materials received concentrated attention in the early 1800s by Young, Navier, Cauchy, and Poisson. Mechanical property studies began at this time, and tension test machines were used as early as 1837. Fatigue behavior (*S-N* curves) was studied in the 1860s and mechanical hysteresis (Bauschinger effect) was studied in the 1880s. All of this work on the mechanical behavior of materials predated analysis of the internal structure of materials. Readers desiring detailed information on the subject of mechanical testing may consult Ref 17 and 18.

The modern era of structure analysis had its beginnings in the work of H.C. Sorby (Ref 19, 20), a petrographer at the University of Sheffield, who became interested in the microstructures of metals in the early 1860s. His work necessitated the development of a microscope using reflected light because the transmitted light techniques used for mineral specimens (thin sections) were not appropriate for metals. Sorby studied a piece of steel produced by the now-abandoned Bessemer process and a piece of cast steel. He developed polishing and acid-etching techniques, the latter to provide surface roughening due to preferential attack of certain microstructural features, allowing them to be observed using reflected light at magnifications of 650×. His interest in these microstructures stemmed from his prior interest in metallic meteorites wherein the microstructure was observable (after polishing and etching) with the unaided eye because the microstructural features were coarse. Sorby observed the "pearly" microconstituent in steel (later named pearlite) and correctly concluded it was composed of two phases, essentially pure iron and a hard compound of iron and carbon (later

named cementite or iron carbide, Fe_3C). He went on to study quenched steel where he made the seemingly contradictory, but technologically important, observation of the absence of a hard compound phase in spite of the hard condition of the steel. He also studied annealing following cold working and intragranular and transgranular fracture.

Metallography, the subject launched by Sorby's work, is currently the most widely used investigative technique for revealing the microstructures of materials. It is, therefore, remarkable that he spent only about two years in the early 1860s and three months in the mid-1880s studying metals. In fact, the brief work in the 1880s was in preparation for the two presentations to the Iron and Steel Institute in London in 1885, about two decades after his original work (Ref 21). Without these presentations, his subsequent publications (Ref 19, 20), crucial to the subsequent development of a fundamental understanding of materials, may have never been written.

Interest in structural studies using a variety of techniques immediately followed the metallographic work of Sorby. Much of the early work on structure analysis was carried out in Europe; U.S. interests in materials throughout the late 19th and early 20th centuries were directed mainly toward increased steelmaking capacity. From 1890 through 1910, alloy phase equilibrium (phase diagram determination and use) received much attention due, no doubt, as much to the need for practical information on commercial alloys as to the fundamental work of Sorby (Ref 19, 20) and Gibbs (Ref 22). The demonstration by Laue, Friedrich, and Knipping (Ref 23) in 1912 that x-rays would diffract from crystals led to the development and application of a variety of x-ray techniques for crystal structure analysis. The body-centered and face-centered cubic allotropes of iron and the body-centered tetragonal hard phase formed by quenching steel (phase now known as martensite) were determined during the 1920s and elegant studies of crystal structure and lattice parameter variations were undertaken in the 1930s.

Research in the 1930s in the United States provided a new and comprehensive view of steel heat treatment. The understanding of the kinetics of microstructural change benefited significantly (both scientifically and technologically) from the isothermal transformation studies of steels by Davenport and Bain (Ref 24). The presentation of data in the form of isothermal transformation diagrams and the relationships between their findings and the hardenability of steels have scarcely changed since their work. Steel heat treatment, long practiced and seldom understood, had at last been provided with a rational foundation.

Research in the late 1930s contributed insight to the phenomenon of age hardening, which was originally uncovered by Wilm in 1906 in an aluminum alloy. Age hardening could be achieved, even though not understood for several decades. The mystery of the hardening associated with precipitation began to unravel as a result of x-ray diffraction studies; the importance of the nonequilibrium microstructural features was established. Age-hardening alloys began to be exploited in other alloy systems.

The field of materials entered the era of World War II with great anticipation for the unlocking of the potential for property improvement by structure control through processing. The importance of structure was established even if not universally accepted. The missing link in the structure/processing/properties relationship for structural materials was the structure/properties connection. It had been postulated in the mid-1930s and afterward by Orowan (Ref 25), Polanyi (Ref 26), and Taylor (Ref 27) that line defects called dislocations could explain the low strengths of materials relative to their theoretical strengths. The dislocation behavior was suggested as the necessary structural concept to control mechanical properties. Lack of experimental support limited early acceptance of the dislocation hypothesis. Better resolution and higher magnification than available with light microscopy was needed for observation of dislocations and their interactions, both with themselves and with other microstructural features.

Even in the early 1950s, textbooks hardly made mention of dislocations and usually did so in the form of a one-page afterthought. The use of dislocations to understand structure/property relationships in crystalline materials was not found in textbooks until the middle of the 1950s.

The 1950s witnessed the unification of metals, polymers (plastics), ceramics, and composites into a single discipline--materials. The common thread was structure. Not surprisingly, the 1950s also was a period of development and application of instrumentation having resolution high enough to allow structure observation several orders of magnitude above light microscopy. The missing piece of the structure/processing/properties puzzle was at hand. Scanning electron microscopy improved metallographic resolution by an order of magnitude and together with x-ray compositional microanalysis provided information about compositional variations within microstructures. Transmission electron microscopy permitted the direct observation of dislocations and their interactions with each other and other structural elements. As a plethora of other high-resolution instruments continued to evolve, the long-sought-after documentation of processing/structure/property relationships gushed forth. The new, high-resolution techniques were generally applicable to all types of materials. The crystalline material concepts useful in metals were tested on crystalline ceramics; the

amorphous material concepts of plastics and glassy ceramics were applied to metallic alloys that previously had been considered to be crystalline if solid. Composite materials took advantage of the understanding developed for metals, plastics, and ceramics. Structure could be characterized, processing could be controlled, material property variations could be understood, and materials could be designed.

Fundamental Structure-Property Relationships in Engineering Materials

Thomas H. Courtney, Michigan Technological University

Introduction

THIS ARTICLE deals with the relationships among material properties (primarily mechanical properties) and material structure. The term *structure* is defined broadly; it relates to factors such as the arrangement of atoms (or ions or molecules) in the solid state. Structure also involves considerations of "defects"--abnormalities--in the idealized atomic arrangements. And structure, too, relates to the collective arrangement of these atoms on a scale much greater than that of an individual atom. In the jargon of the materials engineer, this collective arrangement is called the *microstructure* of the material.

This article considers the several material classes: *metals, ceramics,* and *polymers.* All of them are technologically important. Some basic material characteristics (density, elastic modulus, and, to a lesser extent, thermal and electrical conductivity) are determined almost exclusively by material composition. These properties are referred to as *microstructure insensitive.* In contrast, microstructure-sensitive properties depend (sometimes profoundly) on microstructural features. From the standpoint of mechanical behavior, the yield strength and fracture toughness of a material are the most important of the structure-sensitive properties. The yield strength is the applied stress required to initiate material permanent deformation. The fracture toughness is a measure of the resistance to crack propagation (i.e., to fracture). Thus both parameters relate to material "failure," although they represent different kinds of "failure." The yield strength is used in design to prevent (or sometimes, as in metal working, to ensure) plastic deformation; the fracture toughness is utilized to design against material fracture.

Thomas H. Courtney, Michigan Technological University

Fundamental Characteristics of Metals, Ceramics, and Polymers

Before describing structure-property relationships, it is worthwhile to summarize the essential features of the materials classes.

Metals comprise the vast majority of the elements. Metals more or less occupy the left side of the periodic table and nonmetals the right, although the "dividing line" is not a vertical one. Instead, this line skews from left to right as one looks downward in the table. Metals have few valence electrons. These are collectively shared by the atoms of the solid, giving rise to what is referred to as *metallic bonding.* As a consequence of this bonding, metals are "friendly" at the atomic level. That is, they have a large number (typically 8 to 12) of neighboring atoms in their solid form, and this accounts for the relatively high density of metals. Metallic bonding is also responsible for the high elastic stiffness of metals. Finally, the collective electronic nature of metals explains their high electrical and thermal conductivities.

Metals are distinguished from nonmetals in other ways. In particular, many metals dissolve in each other to form an atomic solution or *alloy.* In the liquid state, this solubility is often complete; that is, the elements dissolve in all proportions just as alcohol and water do. The solubility in the solid state is usually more restricted. Nonetheless, this feature of solid solubility allows materials engineers to manipulate properties of many metals and alloys.

Ceramics. Chemical bonding in ceramics is different than in metals. When elements from the left side of the periodic table (i.e., electropositive elements such as sodium) combine with elements from the right side of the table (electronegative elements such as chlorine), an ionic bond results. Common table salt, NaCl, is a prototypical ionic-bonded ceramic. The coordination number (CN) is the number of cation (positive ion)/anion (negative ion) near neighbors

in ionic solids and depends principally upon the relative ionic radii. CNs of ionic solids are, on the average, slightly less than those in metals, and this partially accounts for their slightly lower densities. Ionic-bonded materials have much lower electrical conductivities and, in most cases, much lower thermal conductivities than metals. This is because ions, rather than atoms, are their fundamental units. For example in NaCl, a sodium atom gives up its sole valence electron, and the chlorine ion captures it, to produce ions having full electron orbitals or suborbitals. As a consequence there are no "free" electrons available to conduct electricity. In the liquid state, however, ionic materials often demonstrate respectable electrical conductivities. Flow of electric current in them takes place by ionic motion and is facilitated by the high ionic liquid mobility, which is much greater than the corresponding solid mobility.

Ionic compounds usually form only in stoichiometric proportions (e.g., NaCl, $CaCl_2$, and Al_2O_3). Thus their tolerance for "alloying" is much reduced compared to that of metals, although there are exceptions (some of them notable). "Alloying" that does take place can alter properties considerably. For example, substitution of divalent calcium ions (in amounts on the order of parts per million) for monovalent sodium ions in NaCl increases the electrical conductivity by orders of magnitude, although the resulting conductivity remains much less than that of a typical metal.

Some ceramics are *covalent* solids. Covalent bonding, like metallic bonding, involves electron sharing. However, the sharing is localized in covalent solids. This results in low electrical conductivities; that is, electrons are effectively incapable of detaching themselves from their "parent" atom and moving through the solid in response to an electric field. Another characteristic of the localized electron sharing is a reduced CN. For example, diamond--an elemental covalent solid--has a CN of 4. The relatively low densities of covalent solids are partly a consequence of their low CNs. There are also covalent compounds, such as Si_3N_4, which because of its strength is a potential high-temperature structural material. Both elemental and compound covalent solids are restricted to narrow composition ranges (e.g., pure silicon and stoichiometric Si_3N_4). However, small quantities of "dopants" may be added to, for example, pure silicon, as they are in the semiconductor industry. Such additions--on the order of parts per million--render silicon an effective engineering *semiconductor.* While the electrical conductivities of doped semiconductors are orders of magnitude below those of metals, their conductivities are much greater, also by orders of magnitude, than those of the elements on which they are based.

Although this discussion has apparently categorized ionic and covalent bonding as distinctly different, the categorization is somewhat arbitrary. Many "ionic" solids, even NaCl, manifest a degree of covalent bonding, and the converse holds for "covalent" compounds. Silica (SiO_2), which exists in a number of structural forms, is an example of a material that manifests mixed ionic and covalent bonding. Materials of this nature are called *polar covalent solids.* Polar covalent solids often demonstrate high melting points and elastic moduli because of this "mixed," strong bonding.

Polymers. Covalent bonding is also dominant in polymers. The resulting low polymeric CNs partly account for their low densities. However, polymers are light primarily because they consist of light atoms (e.g., carbon and hydrogen). As expected, the localized nature of electrons in polymers renders them electrical insulators. They are not good thermal conductors, either.

The molecular architecture of *thermoplastics,* one type of polymer, differs significantly from that of metals and ceramics. The basic atomic or ionic "building blocks" of metals and ceramics usually arrange themselves in a regular three-dimensional pattern, but this is not so with thermoplastics. The basic "molecular unit" in them is a long chain containing many (thousands in some cases) atoms along the chain backbone. Abutting from the chain are "side groups." These range from a single hydrogen atom (as in polyethylene) to a fairly complicated group containing a number of atoms. Bonding between the chains is weak (van der Waals or a variant thereof), in contrast to the strong intrachain covalent bonding. Because of the size and complexity of the individual chains, thermoplastics display a reluctance to assume the long-range atomic ordering that characterizes most ceramics and metals.

Processing Characteristics. The different "chemistries" of the material classes influence the ways in which they are manufactured. Some metals and alloys are melted and then poured directly into a finished shape, as in *castings.* This is possible because liquid metals have high fluidities (conversely, low viscosities), which is a consequence of their small atomic structural units. Other metals are first melted and poured into a large *ingot, strand cast billet,* or *slab.* One or more ingot dimensions are then reduced by *deformation processing,* as in rod or wire drawing, plate rolling, forging, or extrusion. The extensive material shape changes accomplished during deformation processing are possible because of the inherent *malleability* of metals. Final shape is imparted to these *wrought* products by a finishing operation, such as machining or stamping.

Although the basic unit of ceramics is a small ion (or group of ions), ceramics are not processed in the ways that metals are. The high melting temperatures of ceramics and/or the tendency of them to react chemically with containers, make it

difficult to cast them. Furthermore, ceramics are not malleable. Quite the contrary, they are usually quite brittle and are seldom capable of being extensively deformed. Ceramics are frequently produced by powder processing. Appropriate particulates (made by one of a number of suitable processes) are pressed together, and the resulting compact is heat treated at a high temperature where the powder particles *sinter* together, resulting in partial or complete densification of the powder compact. Ceramics containing residual porosity cannot be used in demanding structural applications, because ceramic fracture resistance is very sensitive to pores. Application of an external pressure during sintering can yield ceramics having minimal porosity. As might be expected, materials made this way cost more. Some metals are also produced by powder processing. For metals, this processing route may be economically viable when the part made is relatively small or has an intricate shape (the near-net-shape powder processing operation is a plus) or when the resulting properties warrant the additional cost.

Thermoplastics are often fabricated in ways similar to those used to fabricate metals. Precursor polymer powders are heated to a temperature at which they flow viscously. Owing to their complex molecular architecture, polymer viscosities are high compared to those of metals. Because of this the polymer can be subjected to mechanical forming while heated. Enclosing dies permit the polymer to be formed directly into a finished shape, such as a soft drink container. It should be noted that the low softening and/or melting temperatures of thermoplastics allow them to be processed at moderate temperatures. Production costs are modest because of this and because the tools used to form polymers have a long life in comparison to tools used to form metals.

This background provides a basis for discussing in more detail the atomic arrangements within the materials classes. The important property differences among the classes are summarized in Table 1, where the classes are roughly categorized in terms of densities, conductivities, malleabilities, and so on.

Table 1 Characteristics of the several classes of engineering materials

Material class	Stiffness	Strength	Malleability	Electrical conductivity	Thermal conductivity	Density
Ceramics	High	Very high	Nil	Very low	Low	Medium
Metals	High	High	High	High	High	High
Polymers	Low	Low	High	Very low	Very low	Low

Fundamental Structure-Property Relationships in Engineering Materials

Thomas H. Courtney, Michigan Technological University

Crystal Structure and Atomic Coordination

Basic Concepts. The arrangement of atoms (or molecules or ions) in most solid metals, many solid ceramics, and a few solid polymerics demonstrates a long-range pattern. That is, the atomic packing is repetitive over distances that are large in comparison to the atomic size. Such an arrangement is called *crystalline,* and the repetitive pattern can be described by a fundamental repeating unit or *unit cell.*

Almost all metals crystallize in one of three patterns: face-centered cubic (fcc), hexagonal close-packed (hcp), or body-centered cubic (bcc). The atomic arrangements in these cells are depicted in Fig. 1. The positions of atom centers are noted on the left, and the atoms are represented by spheres (or partial spheres when an atom is shared by adjacent unit cells) on the right. All the arrangements are characterized by efficient atomic packing. Indeed, the fcc array (Fig. 1a) represents the most efficient possible atomic packing, as manifested by the high CN (12) of this structure. Viewing a face of an fcc cell, we see that an atom in a face center is coordinated by four other atoms at cell corners. The distance separating the atom centers is the *atomic diameter,* equal to $a/(2)^{1/2}$ where a is the edge length or *lattice parameter* of the

unit cell. However, the atom at the face center is this same distance from four other atoms on the centers of the four adjoining cell faces. The reference atom is likewise coordinated to four atoms in the centers of adjacent faces in the unit cell directly in front of the unit cell of Fig. 1(a) (not shown). Thus CN = 12 for the fcc structure.

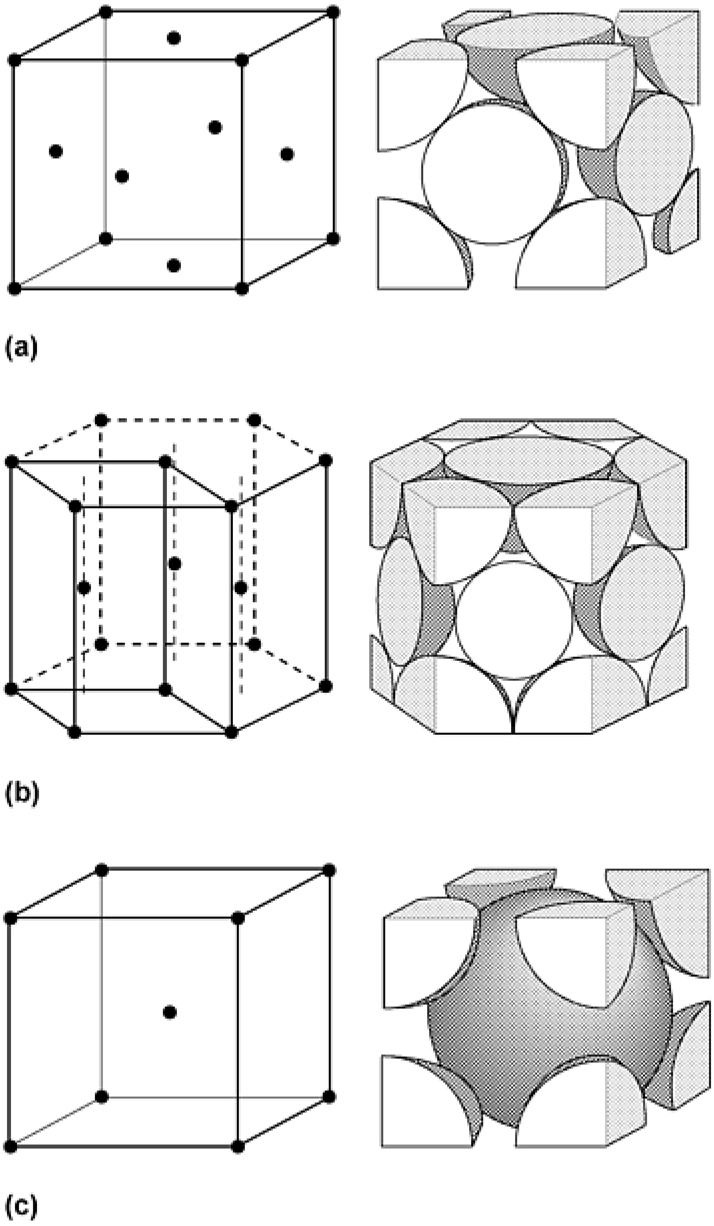

Fig. 1 Representation of several simple unit cells. Points represent positions of atom centers (left), and atoms are represented by spheres or portions of spheres (right). (a) Face-centered cubic unit cell. (b) Hexagonal close-packed unit cell. (c) Body-centered cubic unit cell. Source: Ref 1

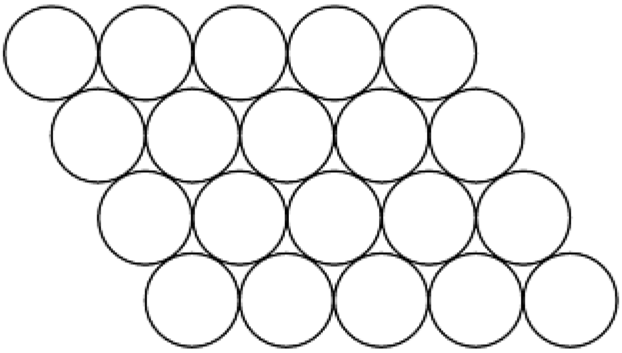
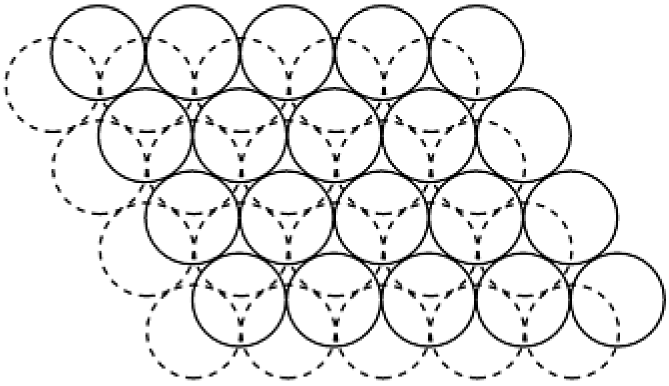
An alternative view of fcc packing permits another way of seeing that it is efficiently packed. Figure 2(a) is a view of a close-packed plane in the fcc structure. A plane is defined by two nonparallel directions; in Fig. 2(a), these are taken as two face diagonals. The atoms in this plane are arranged as billiard balls are in a cue rack. When these atomic planes are stacked vertically and in a direction parallel to the cube diagonal, atoms of one plane lie in the vertices of atoms in the plane beneath (Fig. 2b). Such a stacking pattern generates a close-packed structure. In the fcc pattern, the positions of atom centers repeat every fourth of these planes. That is, atom centers in the fourth plane lie directly above atom centers in the first, atom centers in the fifth plane are directly above those in the second, etc. The stacking is thus described as ABCABC.



(a)



(b)

Fig. 2 (a) Plan view of a close-packed plane in the fcc structure. The directions along which atoms touch are face diagonals. (b) Plan view of two close-packed planes of spheres, with spheres in the top plane (solid circles) situated in interstices in the bottom plane (broken circles). Source: Ref 1

The ideal hcp structure (Fig. 1b) is packed as efficiently as the fcc one. Atoms in the close-packed (basal) plane have an atomic arrangement identical to that in a close-packed fcc plane. However in the hcp structure, these planes repeat every other layer (i.e., atom centers in the third layer lie directly above atom centers in the first, atom centers in the fourth layer are directly above atom centers in the second, etc.). This stacking is therefore described as ABAB.

Two lattice parameters (c and a; Fig. 1b) are needed to define the hcp unit cell. An hcp cell has the maximum atomic packing efficiency only when a definite relationship between c and a exists (c/a = 1.63). Few hcp metals exhibit this ratio (most have c/a < 1.63). In these situations, the hcp structure can no longer be viewed as being as efficiently packed as the fcc one.

The CN for the bcc structure (Fig. 1c) is 8. This can be deduced with reference to the atom in the center of the bcc unit cell; it is equidistant from eight atoms at the cell corners. Because the atomic packing is less efficient in bcc, the closest-packed plane in this structure is also less densely packed than in the corresponding fcc plane. A view (Fig. 3) of the closest-packed bcc plane (which is defined by a cell edge and a face diagonal) shows that atoms within this plane touch along the cube diagonals. There are two nonparallel *close-packed directions* of this kind in this plane; the corresponding number for the fcc close-packed plane is 3.

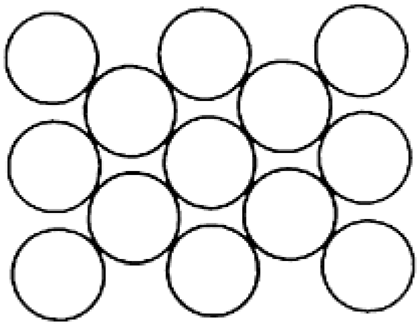


Fig. 3 Plan view of atomic packing in closest-packed bcc plane. Atoms touch along two nonparallel close-packed directions (the cube diagonals). Source: Ref 1

Many metals exist in more than one crystalline form, depending on pressure and temperature. At one atmosphere, for example, iron is bcc at temperatures below 912 °C, is fcc between 912 and 1394 °C, and reverts to the bcc form above 1394 °C until melting at 1538 °C. Titanium, zirconium, and hafnium all exhibit a transition from an hcp structure to bcc on heating. Many other metals (as well as some nonmetals, such as SiO_2) also exhibit such *allotropic* transformations.

The unit cells of three simple ionic solids are depicted in Fig. 4. Chloride ions assume an fcc array in NaCl (Fig. 4a); for each chloride ion there is a sodium ion displaced by half a lattice parameter from the chloride ion along a unit cell edge. In CsCl (Fig. 4b), the chloride ions assume a *simple cubic* array (i.e., they are situated at unit cell corners), and a cesium ion is at the cell center. A more complicated arrangement is found in zirconia, ZrO_2 (Fig. 4c). The structure is not as complex as it might appear at first glance. It is only a variant of simpler structures. The zirconium ions assume an fcc array, with oxygen ions occupying internal cell sites. As indicated in Fig. 4(c), the oxygen ions take on a simple cubic array.

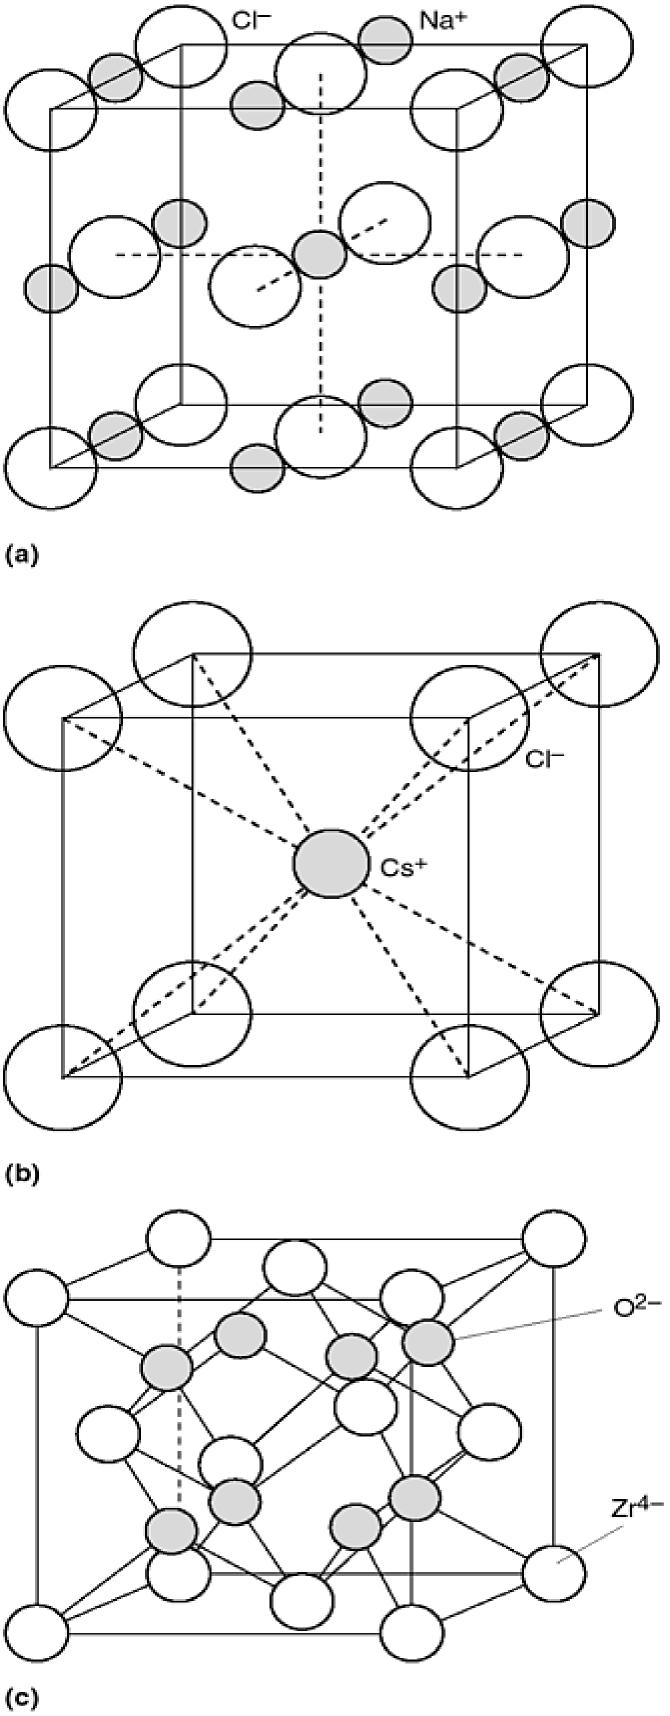

Fig. 4 Unit cells of several crystalline ceramics. (a) The unit cell of NaCl. Chloride ions assume an fcc array with one sodium ion (displaced by half a lattice parameter along a cube edge) for every chloride ion. Source: Ref 1. (b) The CsCl structure. Chloride ions assume a simple cubic array with a cesium ion in the center of each cell. Source: Ref 1. (c) The structure of ZrO_2. Zirconium ions have an fcc array. The oxygen ions, which take on a simple cubic array, are located within the unit cell. Source: Ref 2

Formal description of ceramic crystalline arrangements often appears cumbersome. However, in many cases the arrangements are only variations of much simpler ones.

Some important ceramics, *glasses*, are noncrystalline. Atomic arrangements in glasses do not repeat over distances that are large in comparison to the atomic size, although there is a definite short-range order to them. Most common glasses are based on polar-covalent-bonded silica. The basic structural unit here (as well as in crystalline silica) is the silicate tetrahedron. As shown in Fig. 5, silicon atoms (ions) are located at tetrahedral centers, and oxygen atoms (ions) are located at their tips. Tetrahedra are then joined tip-to-tip, thereby generating a three-dimensional solid. When the arrangement manifests a long-range order, a crystalline form of SiO_2 results; when not, a glassy form is the consequence. The two situations are schematically illustrated in a two-dimensional version in Fig. 6. Liquid SiO_2 has an atomic arrangement essentially the same as that of the more rigid solid glass. Viscosities of silicate glasses are usually much greater than those of metals, even though the basic structural unit (the tetrahedron) is not large. Viscous flow in silicates requires displacement of tetrahedra with respect to each other, and this is difficult because of the strong polar-covalent bonds linking the tetrahedra. Addition of certain impurity ions to silicate glasses reduces their viscosities by orders of magnitude, and this tactic is employed in the economic production of most commercial glassware.

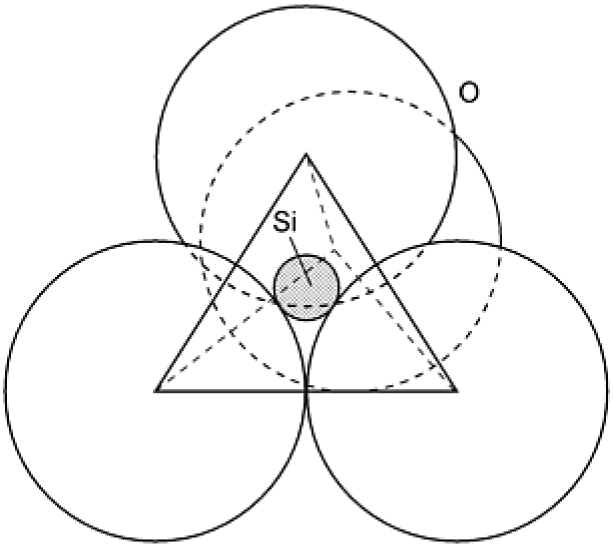

Fig. 5 The basic structural unit in SiO_2 is a tetrahedron in which silicon is located at the center and oxygen at the corners of the tetrahedron. Source: Ref 1

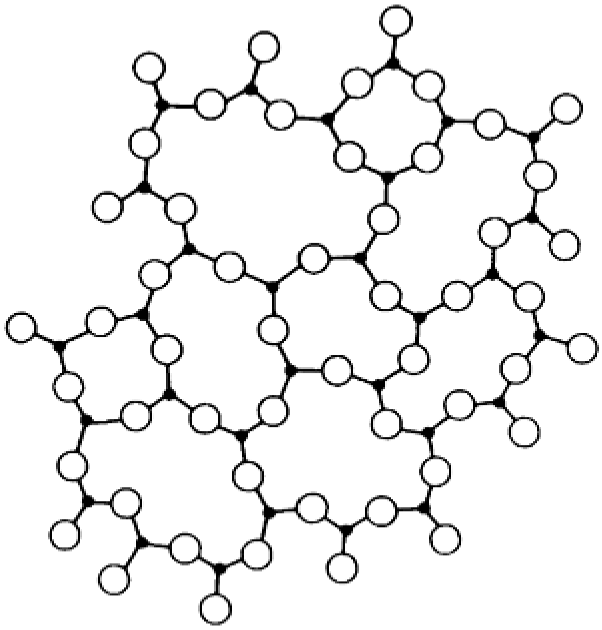
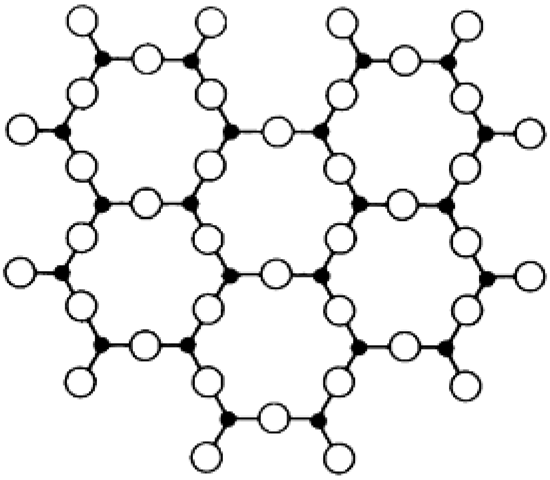


(a)



(b)

Fig. 6 Schematic two-dimensional representation of (a) a SiO_2 glass structure and (b) a SiO_2 crystalline structure. Tetrahedra are joined tip to tip in both situations, but in crystalline SiO_2 a long-range pattern to the tetrahedra exists; this is not the case for glassy SiO_2. Source: Ref 1

Thermoplastics are seldom crystalline. Polyethylene is an exception, but noncrystalline regions persist in even the most crystalline form of this substance. The structure of most thermoplastics is schematized in Fig. 7, which indicates that the polymeric chains are arranged randomly in three dimensions. As with silicate glasses, the atomic arrangements in "glassy" solid and liquid thermoplastics are similar.

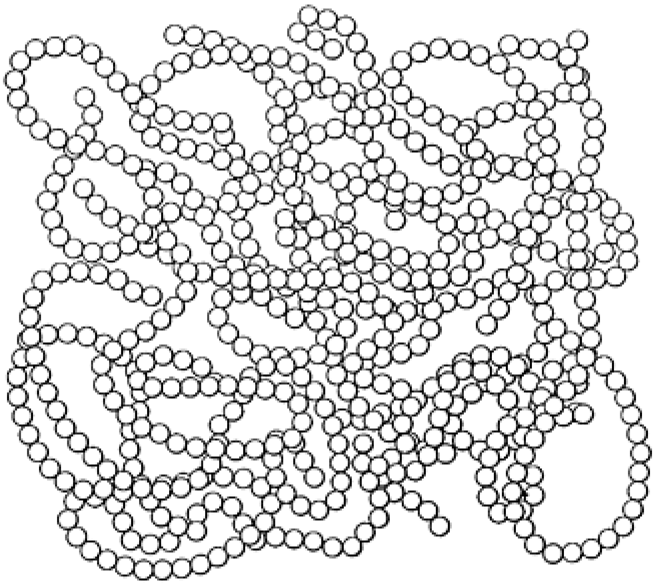


Fig. 7 A schematic representation of a long-chain polymer. The spheres represent repeating units in the polymer chain, not individual atoms. Source: Ref 3

Some Crystallographic Details. Further details of atomic arrangements are described here, because they are relevant to plastic deformation of crystalline materials. As shown in Fig. 2, the close-packed plane in the fcc structure is defined by two face diagonals, and within such a plane there are three nonparallel close-packed directions. In addition, there are four nonparallel planes of this nature in the fcc crystal structure (Fig. 8). (To better illustrate the point, the planes in Fig. 8 are taken from adjacent cells.) There are thus 12 combinations of nonparallel planes and directions (four planes times three directions per plane) in the fcc lattice.

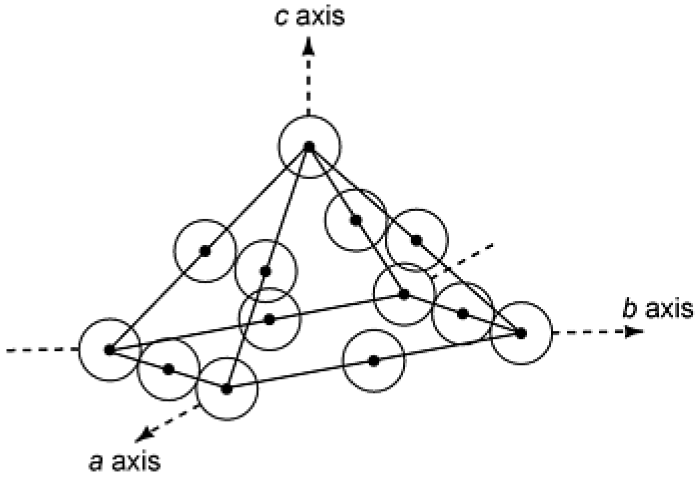

Fig. 8 Four nonparallel close-packed planes characterize the fcc structure. There are three nonparallel close-packed directions within each plane, giving rise to 12 slip systems. Source: Ref 4

The above is germane because plastic deformation takes place by *slip* (sliding) of close-packed planes over one another. A reason for this slip plane preference is that the separation between close-packed planes is greater than for other crystal planes, and this makes their relative displacement easier. Furthermore, the slip transit direction (or *slip direction*) is a close-packed direction. The combination of planes and directions on which slip takes place (12 for the fcc structure) constitutes the *slip systems* of the material. In polycrystalline materials (defined in the next section), a certain number of

slip systems must be available in order for the material to be capable of plastic deformation. Other things being equal, the greater the number of slip systems, the greater the capacity for this deformation. Face-centered cubic metals have a large number of slip systems, and indeed, all of them except two (iridium and rhodium) are capable of moderate to extensive plastic deformation even at temperatures approaching 0 K.

Materials having the bcc structure also often display 12 slip systems, although this number comes about differently than it does for the fcc lattice. A closest-packed bcc plane is defined by a unit cell edge and face diagonal (Fig. 3). There are only two close-packed directions (the cube diagonals) in the closest-packed bcc plane, but there are six nonparallel planes of this type. Over certain temperature ranges, some bcc metals display slip on other than close-packed planes, although the slip direction remains a close-packed one. Thus bcc metals have the requisite number of slip systems to allow for their plastic deformation. That some of them become "brittle" at low temperatures is a result of the strong temperature sensitivity of their yield strength, which causes them to fracture prior to undergoing significant plastic deformation.

Depending on the c/a ratio, polycrystalline hcp metals may or may not have the necessary number of slip systems to allow for appreciable plastic deformation. The ideal hcp structure has only three slip systems, as there is only one nonparallel close-packed plane in it (the basal plane, which contains three nonparallel close-packed directions). Three slip systems are insufficient to permit polycrystalline plastic deformation, and so hcp polycrystals for which slip is restricted to the basal plane are not malleable. When c/a is less than the ideal ratio, basal planes become less widely separated, and other planes compete with them for slip activity. In these instances, the number of slip systems increases, and material ductility is beneficially affected.

The limited ductility of polycrystalline ceramics is often tied to their lack of slip systems. When slip does take place in polycrystalline ionic-bonded ceramics, it does so on planes and in directions that ensure maintenance of local charge neutrality. The number of these slip systems is insufficient to allow significant plastic deformation. At higher temperatures, though, additional slip activity permits some ceramics to demonstrate appreciable ductility.

Fundamental Structure-Property Relationships in Engineering Materials

Thomas H. Courtney, Michigan Technological University

Crystalline Defects

Atomic arrangements in crystals deviate slightly from the ideal ones described above. Such deviations are called *crystalline defects* (or *imperfections*), although these "defects" often lead to improved material performance. Defects can be classified by their scale or size. The smallest deviation in the ideal crystal arrangement has a volume comparable to that of an atom; such a defect is termed a *point* defect.

Point defects are of two types, *impurity atoms* and *vacancies.* A vacancy is schematically illustrated in Fig. 9; here, rather than having all lattice sites occupied, one site is vacant. Vacancies arise as a result of entropic effects, and the fraction of vacant lattice sites increases with temperature. This fraction is zero at 0 K and is on the order of 10^{-3} for many metals at or close to their melting point. A somewhat different type of "vacancy" found in ionic solids is illustrated in Fig. 10. Here, to maintain electrical neutrality, there must be an equal number of cation and anion vacancies; thus "double" vacancies (*Schottky defects*) are formed.

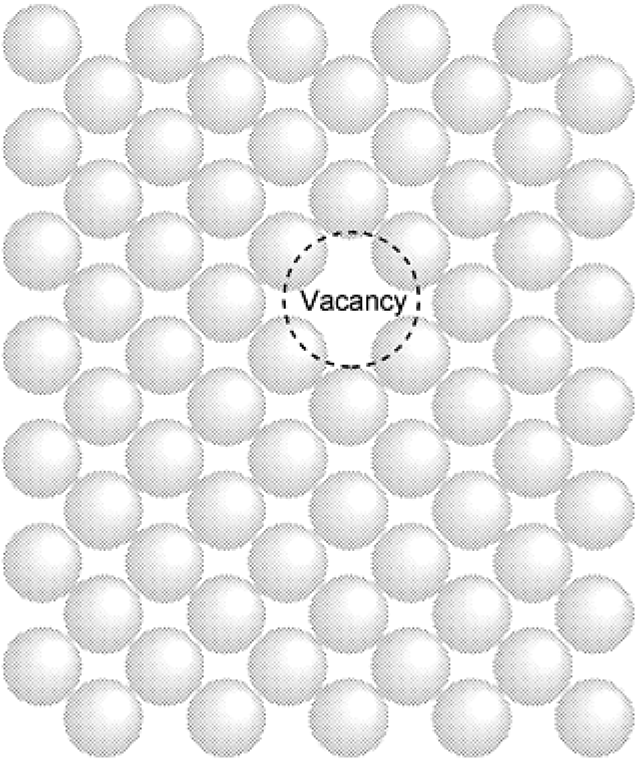

Fig. 9 Two-dimensional representation of a crystal illustrating a vacant lattice site. Source: Ref 3

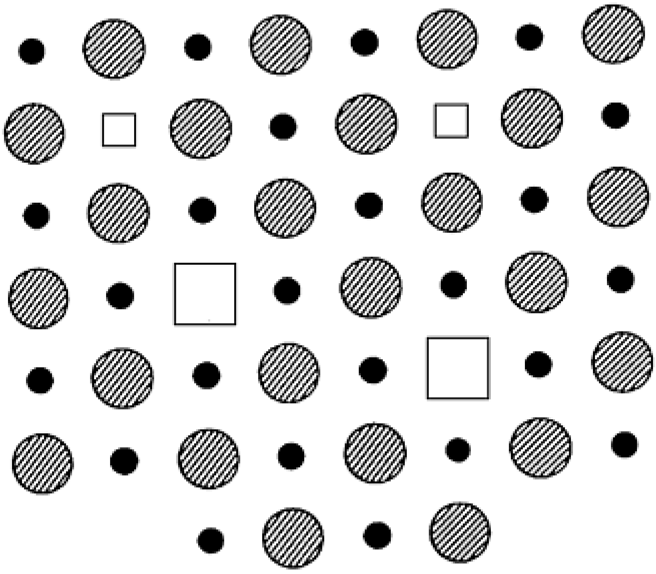

Fig. 10 Schottky defects in an ionic crystal. Cations are represented by solid circles and anions by shaded ones. Equal numbers of cation and anion sites are vacant so as to preserve charge neutrality. Source: Ref 5

Vacancies alter properties. Density is (very slightly) decreased by them. Material strength is slightly increased by vacancies (which seems counter-intuitive). Vacancies increase the electrical resistivities of metals, but Schottky defects have an opposite effect in ionic solids. The reason is that conduction in ionic solids results from the motion of ions, and ionic migration is facilitated by vacancies. Vacancies also enhance *atomic diffusion,* the macroscopic atomic mixing that takes place as a result of the motion of many individual atoms. If a layer of copper is placed on one of nickel, for

example, and then held at an elevated temperature for a long time, the resultant solid displays a uniform composition as a result of the interdiffusion of copper and nickel atoms.

Impurity atoms are also termed point defects. For example, an fcc unit cell of an alloy of composition 75at.%Cu-25at.%Ni contains, on average, three times as many copper atoms as nickel ones. The substituted nickel atoms are considered defects, since their size differs from that of the host copper atom, and this causes a local distortion of the unit cell. Impurity atoms affect properties, too. Electrical and thermal conductivities in metals are reduced by them. However, metallic strengths are increased by impurities. This *solid solution hardening* is used to strengthen a number of metals. Adding zinc to copper, as in brasses, is a technologically important example.

Small impurity atoms do not substitute for the host atoms, but rather enter into *interstitial* spaces among them and are referred to as interstitials. Typical interstitials in metals are nitrogen, carbon, and oxygen. The sites they occupy in the fcc lattice are the same as those that the smaller sodium ions occupy in the NaCl structure (Fig. 4). Interstitials generally strengthen a metal more than substitutional atoms do, since the interstitials cause more distortion. Carbon atoms in the bcc form of iron are particularly potent hardeners in this respect. The effect is used beneficially in strengthening of *quenched and tempered* steels (see the section "Strengthening of Steels" in this article).

Ionic materials also can have substitutional ions. Potassium, for example, can substitute for sodium in NaCl. When the substituted ion has a different valence than the host, charge balance requirements complicate things. If a calcium ion, with a valence of 2, substitutes for a sodium ion in NaCl, the substitution is accompanied by the formation of a vacant site in the sodium anion array. This satisfies the charge neutrality requirement (two monovalent sodium ions are replaced by a divalent calcium ion and a neutral vacancy). In such situations, the solubility of the replacement ion (i.e., the maximum concentration of impurity that can be dissolved in the host material) is quite restricted. Impurity ions strengthen ionic solids just as impurity atoms do metals. In addition, the generation of excess vacancies, as accompanies the solution of calcium in NaCl, substantially increases electrical conductivity and diffusivity.

Some ionic solids can be viewed as interstitial compounds. Indeed, as alluded to earlier, NaCl can be considered an fcc array of chloride ions, with sodium ions occupying interstitial sites in the lattice.

A *line* defect has two dimensions comparable to an atomic diameter and one dimension that is much greater. An example of a particular line defect, an *edge dislocation,* is shown in Fig. 11. The upper half of the crystal shown contains one more atom column than the lower half of it. The resultant atomic disregistry is centered about a small region. As suggested by Fig. 11, the disregistry is accommodated in an approximately cylindrical volume having a radius comparable to that of an atom and extending along the termination of the atomic column for distances much greater than this. Dislocations are found in all crystalline solids, but the extent to which they exist varies among the material classes. The quantity of dislocations (the *dislocation density*) can be expressed in terms of their number per unit area. With reference to Fig. 11, for example, the dislocation density would be the number of dislocations emerging from a surface divided by the area of the depicted crystal plane. Dislocation densities in metals range from about $10^{10}/m^2$ to $10^{15}/m^2$; in ionic compounds they are usually several orders of magnitude less. Covalent solids have lower dislocation densities still.

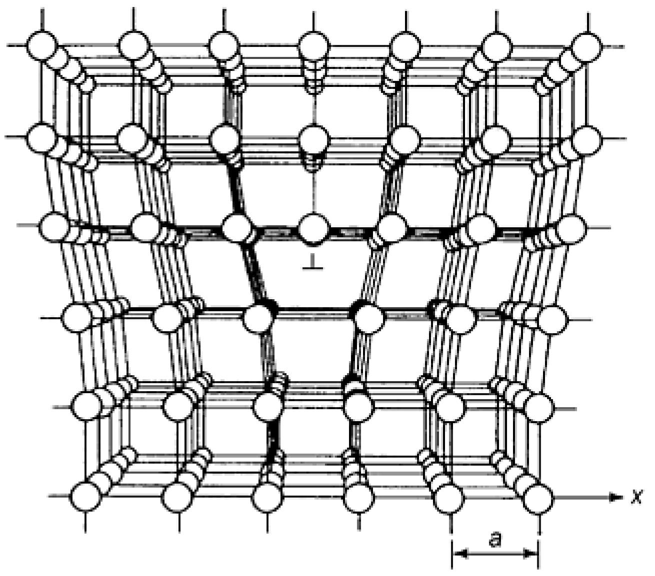

Fig. 11 A schematic of an edge dislocation, represented by a partial atomic plane, in a crystal. The "core" of the dislocation is localized at the partial plane termination. Atomic positions are distorted in region of this core, making slip easier in the vicinity of the dislocation. Source: Ref 6

Dislocations are important because their motion in response to an applied stress is responsible for plastic deformation in most crystalline solids. As mentioned above, plastic deformation takes place by the relative displacement of atomic planes. This is easier to accomplish when dislocations are present. The atomic disruption in the dislocation vicinity is responsible for the easier slippage of planes on which dislocations are situated. In fact, the stress required to cause dislocations to move is orders of magnitude less than the stress needed to cause slip plane displacement in a "perfect" crystal.

The role of dislocations in plastic flow is verified by the exceptionally high strengths of metal crystals not containing (or containing very few) dislocations. It might be thought that the greater the dislocation density, the lesser the stress required for plastic deformation. This is true for materials containing relatively few dislocations (e.g., about less than $10^8/m^2$). Paradoxically, though, when the dislocation density becomes high enough, the stress required to cause plastic flow increases with dislocation density. This is so because dislocations mutually impede each other's motion. Dislocations in metals also multiply, sometimes substantially, when they are plastically deformed. This is accompanied by an increase in the stress required to continue deformation. This phenomenon of *work hardening* is used to manipulate strengths of a number of metallic materials, including conventional stainless steels and copper and its alloys. The lesser dislocation densities found in ionic and covalent solids is one (but only one) reason that these materials are less malleable than metals.

Crystalline solids also contain internal surface defects. A surface defect has one dimension comparable to the atomic size and two dimensions that are much larger. The most important surface defect is a *grain boundary.* As indicated in Fig. 12, such boundaries separate differently spatially oriented crystals, and the collective aggregate is termed a *polycrystal* (or polycrystalline solid). The average diameter of the individual grains within a polycrystal defines the material *grain size.* Grain sizes in engineered materials vary by quite a bit. They are usually less in nonmetals than in metals, and they can be as fine as 0.1 μm in some ceramics. Metallic grain sizes typically range from several micrometers to, in the case of slowly cooled castings, several centimeters. Some recently developed processes (e.g., *rapid solidification* and *mechanical alloying*) produce materials having grain sizes on the order of nanometers. To put this in perspective, the diameter of a "typical" atom is about 0.25 nm. Thus, grains having a diameter of several nanometers are about ten atoms across.

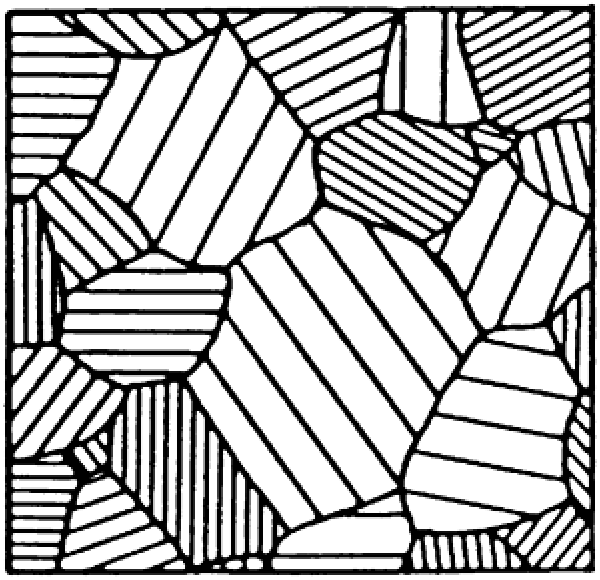

Fig. 12 Schematic representation of the orientations of individual grains in a polycrystal. Within individual grains, a set of atomic planes has the same orientation in space. At a grain boundary, the orientation changes abruptly. Source: Ref 1

Grain size affects mechanical properties. The yield strength increases with decreases in grain size, because the distance over which dislocations can move freely is limited to the grain diameter. (Dislocations are restricted from crossing grain boundaries.) Fracture resistance also generally improves with reductions in grain size. This is particularly beneficial, because as discussed below, the general situation is that structural changes that increase yield strength diminish fracture toughness. Fracture resistance improves because the cracks formed during deformation, which are the precursors to those causing fracture, are limited in size to the grain diameter.

Stacking faults and *twin boundaries* are other internal surface defects. While found in all crystal structures, they are most easily described with reference to the fcc one. A stacking fault in a fcc lattice corresponds to a "mistake" made in the close-packed plane stacking sequence. Instead of the usual ABCABCABC sequence, an ABC**ABAB**CAB one is found. The placing of a plane in the A, rather than C, position results in a thin layer of hcp-like material (denoted by **ABAB**). The thickness of this defect is only several atomic diameters in the direction normal to the close-packed planes. Stacking faults in fcc materials generally occur as ribbons (Fig. 13). The fault extends normal to the plane of this figure over distances that are large compared to an atomic size. The ribbon width (the distance between points A and C or B and D in Fig. 13) is highly variable, ranging in size from the order of one to many atomic diameters. Generally, if the energy of the hcp and fcc allotropic forms of the solid are comparable, the width is large, and vice-versa. The boundaries at the edges of the faults (lines AB and CD, Fig. 13) are defined by a special type of dislocation that accommodates the disregistry between the hcp and fcc stacking at the boundaries. Stacking faults play an important role in the work hardening behavior of some fcc metals and alloys. If their width is large, the material work hardens more than if it is small.

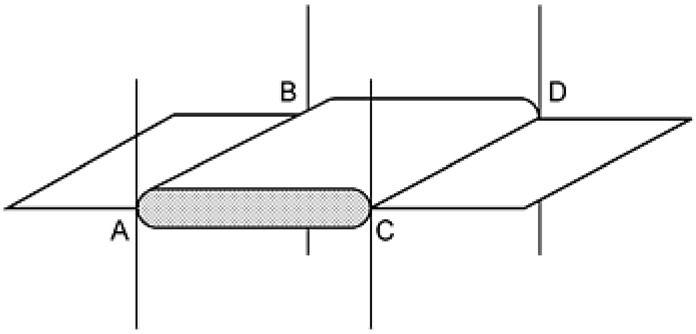

Fig. 13 A three-dimensional sketch of a stacking fault in a fcc crystal. The fault is narrow ribbon several atomic diameters in thickness. It is bonded by partial dislocations (the lines AB and CD). Source: Ref 4

The stacking sequence across a twin boundary is ABCA**B**ACBA; the position of the boundary is denoted by **B.** Note that to either side of this boundary the stacking sequence is typical of fcc. (ACBACB represents the same stacking as does ABCABC, in that close-packed layers repeat every fourth layer.) At the twin boundary, a layer of ABA (hcp stacking) exists, so twin boundaries are somewhat akin to stacking faults. However, there are differences between these types of defects. The differences arise from the different positioning of the atoms in the atomic plane twice removed from the respective boundaries. Twins also typically have a width much greater than that of stacking faults. Examples of twins in a copper alloy are shown in Fig. 14. These twins developed in response to heat treatment, and for this reason they are called *annealing twins.* Twins do not affect mechanical behavior to the same degree that stacking faults do (an important exception is low-temperature deformation of bcc metals). Thus, of the several surface defects discussed, grain boundaries play an important role in plastic deformation, stacking faults affect the work hardening behavior of fcc metals, but twins generally play only a minor role in plastic flow.

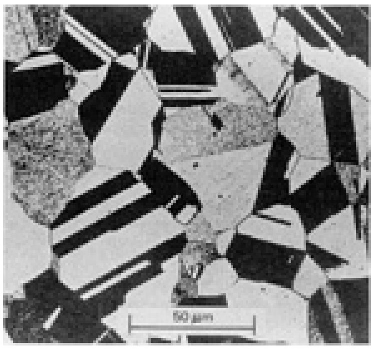

Fig. 14 The microstructure of annealed cartridge brass (70Cu-30Zn), illustrating both grain boundaries and annealing twins. The twins are the regions with parallel sides within the grains. Source: Ref 1

Volume defects--pores and microcracks--are often present in engineering solids. Volume defects have all three of their dimensions much larger than the atomic size, although the characteristic dimension may still be small (e.g., on the order of 10^{-7} m). Volume defects almost invariably reduce strength and fracture resistance. (An exception is for spherical pores having a radius on the order of nanometers. Such voids are sometimes found in materials exposed to high energy radiation, and a modest increase in strength attends their presence.) The reductions in strength and fracture resistance can be quite substantial, even when the defects constitute only several percentage by volume of the material. In metals, pores are much more likely to be found in cast than in wrought products. The shrinkage accompanying solidification in almost all metals is manifested in microporosity (i.e., pores having diameters on the order of micrometers). The extensive deformation accompanying the production of wrought metals is usually sufficient to "heal" or close this microporosity. Powdered materials, be they metals or ceramics, frequently contain pores. As mentioned, powder products are typically fabricated by a pressing operation followed by a high-temperature heat treatment (sintering) that results in material densification. Full density is difficult to achieve through a "press and sinter" cycle, and thus residual porosity is usually found in the sintered product. Full density is more likely to be obtained when a stress is applied during sintering (as in hot

pressing, in which a uniaxial compressive stress is applied, or hot isostatic pressing, in which the stress state is hydrostatic compression). Pore removal is facilitated by pressure for much the same reason that deformation processing removes pores in the original ingot structure in wrought products.

Evaluation of Mechanical Properties

Since this article is primarily concerned with the relationships among microstructure and mechanical properties, the most common means by which such properties are determined are reviewed here. The relevance of the properties to design is also emphasized.

Tensile Properties. A tensile test (Fig. 15) determines a number of important mechanical properties. The material to be tested, in the form of a cylinder or sheet, is gripped at its ends. A standard length l_0, the sample initial or gage length, is marked on the sample. The initial cross-sectional area (A_0) normal to the sample long axis is also measured. The cross-head of the machine moves downward at a specified rate, thereby elongating the sample. A length measuring device (e.g., an extensometer) measures the instantaneous sample length (l); the change in sample length (the extension, $\delta l = l - l_0$) is then calculated. The load cell simultaneously records the force (F) needed to produce this extension.

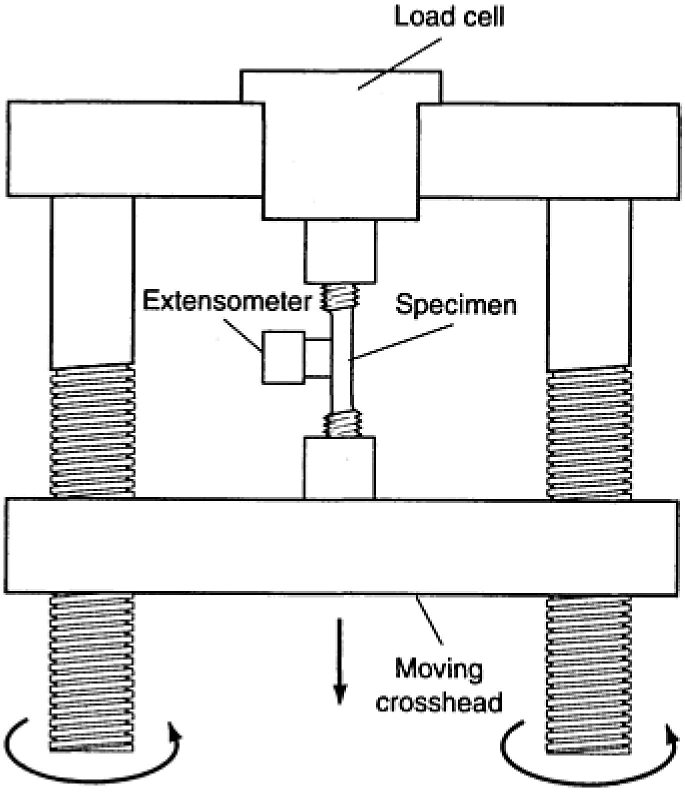

Fig. 15 A schematic of a tensile test. The sample is elongated at a specified rate, and the force required to produce a given elongation is measured by the load cell. Elongation is measured by an extensometer or similar device. Source: Ref 4

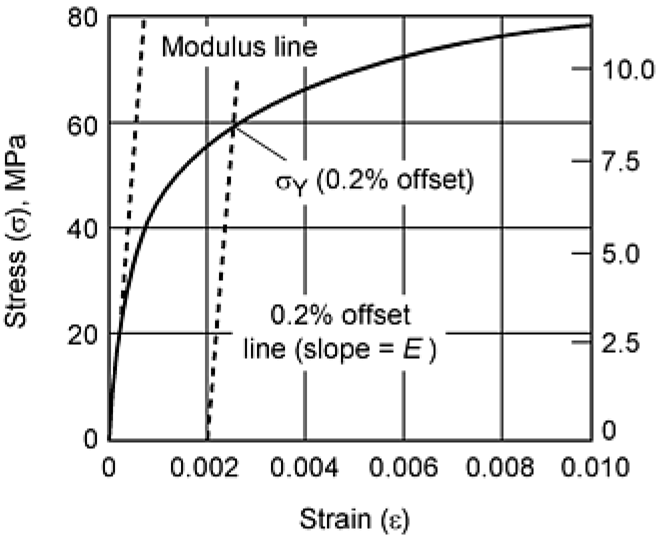
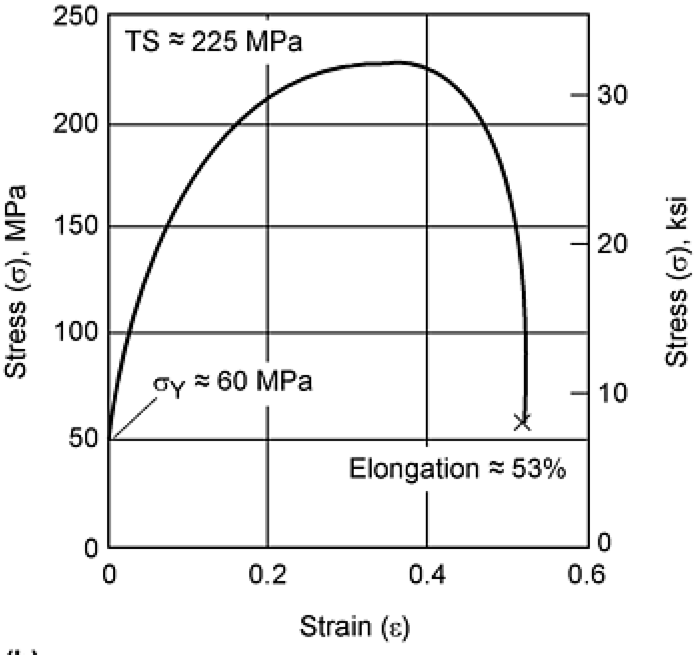
Thus, the "raw" data obtained from a tensile test are F and δl. The force depends on the sample cross-sectional area as well as the material. The geometrical dependence is eliminated by dividing F by A_0, and the resulting parameter is termed the engineering stress: $\sigma_E = F/A_0$. The extension is similarly normalized to eliminate sample length effects on test results. This is done by dividing δl by l_0, and the ratio is called the engineering strain: $\varepsilon_E = \delta l/l_0$. Test results, now no longer dependent on sample geometry for the most part, are displayed as a graph of σ_E versus ε_E.

The results of a tensile test on a simple metal, copper, are shown in Fig. 16. Figure 16(a) illustrates the low-strain region of the test, whereas Fig. 16(b) displays the complete test results.



(a)



(b)

Fig. 16 The engineering stress-strain diagram for soft polycrystalline copper. (a) The low strain region, indicating the initial linear elastic behavior of cooper, followed by plastic yielding. The slope of the dotted line defines the elastic modulus (*E*) and the offset line, with this same slope, is used to determine σ_y. (b) The complete stress-strain curve, indicating the yield strength, the tensile strength (TS), and the percent elongation to fracture. Source: Ref 4

At very low strains (less than about 0.05%), stress and strain are related linearly. This corresponds to *linear elastic deformation,* for which the deformation is elastic or recoverable. That is, when the force is removed the material length returns to its initial length. The proportionality constant relating stress and strain in the elastic region is the *elastic modulus, E:*

$$\sigma = E\varepsilon \qquad \textbf{(Eq 1)}$$

Values of elastic moduli reflect atomic bond strengths. Moduli are highest in materials with strong bonding (e.g., covalent solids) and are lowest in polymers. The elastic modulus is used in design to limit or control elastic deflection. For a specified stress, a high modulus material deflects less than a low-modulus one.

At a certain stress, the stress and strain no longer relate linearly. This corresponds to the onset of permanent (plastic) deformation. It is difficult to determine the critical stress precisely, because it varies among testing devices and is sensitive to machine "stiffness." An alternative way of defining the approximate onset of plastic deformation is therefore used (Fig. 16a). A specified offset of 0.2% (ε = 0.002) is made on the strain axis. A line parallel to the elastic loading line (of slope *E*) is then drawn. The intersection of this line with the stress-strain curve defines the 0.2% offset yield strength, σ_y. The procedure ensures that reported yield strengths do not vary from laboratory to laboratory or machine to machine. The physical significance of σ_y is that it is the applied tensile stress producing a permanent strain of 0.2%. The yield strength of a material, unlike its modulus, is structure-sensitive. Some relationships between microstructure and σ_y are discussed in the section "Microstructure and Low-Temperature Strength" in this article. The yield strength is also a design parameter. It is the stress (adjusted by an appropriate safety factor) that engineers use to ensure that plastic deformation does not occur in a structure. It is also the stress that designers of metal-processing equipment consider when developing deformation processing schemes.

For a material like copper, continued plastic deformation beyond yielding is accompanied by an increase in σ_E (Fig. 16b). This phenomenon, work hardening, is a result of dislocation multiplication and a concomitant reduction in dislocation mobility, as discussed above. At a certain critical (material-specific) strain, σ_E reaches a maximum value, called the material tensile strength (TS; in Fig. 16b, TS = 225 MPa, or 33 ksi). For strains beyond the tensile strain (0.36 in Fig. 16b), the engineering stress decreases until the material fractures (noted by an X in Fig. 16b).

It might appear that copper "work softens" beyond the tensile strain, but the maximum in σ_E is an artifact. Specifically, the TS corresponds to the onset of *necking* (Fig. 17), wherein a geometrical instability (localized deformation at a specific cross section along the gage length) initiates. Before necking, plastic deformation occurs uniformly along the gage length. That is, the material extends uniformly at all positions along the length, and because material volume remains essentially constant, material diametrical (or thickness for sheet samples) contractions are likewise uniform. However, at necking deformation becomes localized and is restricted to a specific cross-sectional area. Continued straining leads to a further reduction in this area, and the load decreases due to this effect. Since σ_E is calculated on the basis of a constant (initial) cross-sectional area, it also decreases. In other words, although the material continues to work harden, this effect is more than compensated for by the reduction in cross-section in the necked region.

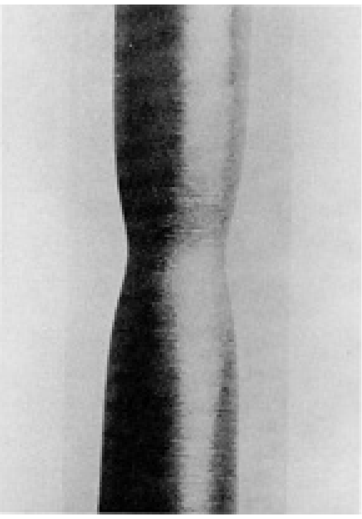


Fig. 17 A neck in a round tensile bar. The neck starts to develop when the tensile strength is reached and becomes more pronounced as the test is continued. Source: Ref 4

A more precise way of calculating stress following necking is to base the calculation on the cross-sectional area of the neck. In fact, given that the sample cross-sectional area decreases (albeit uniformly) prior to necking, such a procedure is preferable even before necking. To do this a *true stress* is defined ($\sigma_T = F/A_i$, where A_i is the instantaneous sample cross-sectional area). As the gage length increases during deformation, a better way of defining strain is with the *true strain* ($\varepsilon_T = \ln (l_i/l_0)$, where l_i is the instantaneous sample length). Before necking, there are well-defined relations among the respective engineering and true stresses and strains. These come about because material volume remains constant and the initial and instantaneous sample lengths and cross-sectional areas are related by $A_0l_0 = A_il_i$. The following relations then apply:

$$\sigma_T = \sigma_E (1 + \varepsilon_E) \quad \textbf{(Eq 2a)}$$

$$\varepsilon_T = \ln (1 + \varepsilon_E) \quad \textbf{(Eq 2b)}$$

It is important to reiterate that Eq 2a and 2b hold only for strains prior to necking. The equations show that, for tensile loading, $\sigma_T > \sigma_E$ and $\varepsilon_T < \varepsilon_E$. Thus for strains less than the necking strain, a tensile true stress-strain curve is displaced upward and to the left relative to the tensile engineering stress-strain curve.

To determine the corresponding true stress and strain for strains beyond necking, the neck area (A_{neck}) must be measured. Then σ_T is calculated as $\sigma_T = F/A_{neck}$, and ε_T is determined by $\varepsilon_T = \ln (A_0/A_{neck})$. A schematic comparison of the true stress-strain and engineering stress-strain diagrams is made in Fig. 18. It is clear that the material work hardens throughout plastic deformation (i.e., the slope of the true stress-strain curve is always positive). Furthermore, the necking point cannot be discerned on the true stress-strain curve.

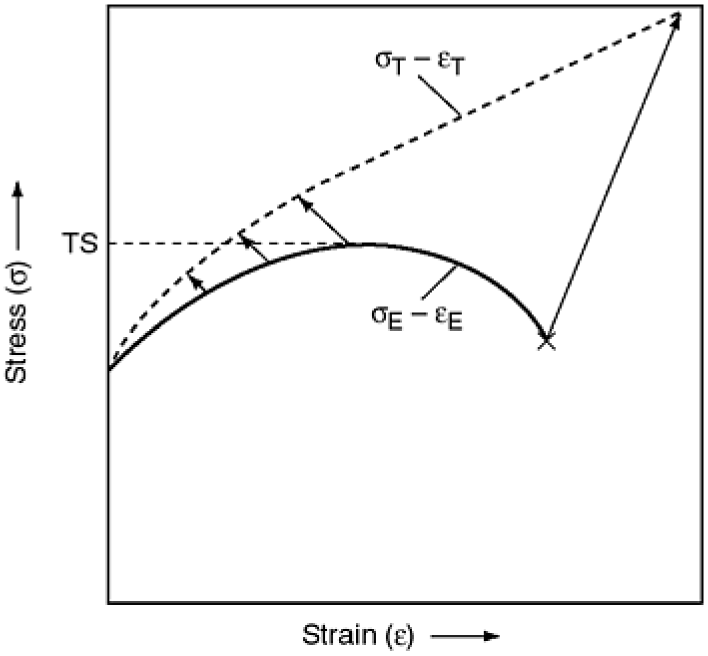

Fig. 18 Schematic illustrating the relationship between the tensile true stress/true strain (dotted line) and engineering stress/engineering strain (solid line). For engineering strains less than the necking strain, the true stress-strain curve is displaced vertically and to the left relative to the engineering stress-strain curve. At some strain beyond the necking strain, the true strain becomes greater than the engineering strain, while the true stress remains greater than the engineering stress. Source: Ref 4

Another useful, but seldom reported, feature that can be obtained from a true stress/true strain curve is the area under this curve. It represents the plastic work per unit volume done on the material through fracture. (Since strain is dimensionless, the units of this area are stress in Pa, or J/m^3.) This area can be considered a measure of the material fracture work. As discussed below, however, there are better measures of resistance to fracture.

To summarize, the important design parameters obtained from a tensile test are E (used in design involving elastic deflection) and σ_y (used in design concerned with plastic flow). The TS is routinely relayed when tensile test results are reported, but TS has no direct bearing in design, although it is a good qualitative measure of the overall strength level of the material. In addition, the percent *elongation to fracture* (53% for the copper of Fig. 16b) is reported. To a degree, this parameter is a measure of material malleability or ductility. However, percent elongation depends on the choice of initial gage length (it is greater the shorter the length). A better parameter to assess ductility is percent *reduction in area,* which is the reduction in sample cross-sectional area of the neck at fracture. An additional parameter useful in metal-forming operations is the work hardening behavior of the material. There are several ways to assess this. All of them relate to the slope of the true stress-strain curve following the onset of plastic deformation; the higher this slope, the greater the work hardening.

Figure 16 illustrates the tensile behavior of a typical ductile metal. Other materials exhibit different behavior, as illustrated in Fig. 19. Brittle ceramics, such as silica glass and alumina (Al_2O_3) at room temperature (Fig. 19a), exhibit linear elastic behavior and undergo no permanent deformation before fracture. The thermoplastic polyethylene displays an extraordinary degree of permanent deformation at room temperature (Fig. 19b), whereas Bakelite (phenol-formaldehyde, a thermosetting polymer incapable of permanent deformation) and Lucite (polymethyl methacrylate, a thermoplastic) exhibit low room-temperature tensile fracture strains (Fig. 19c). Were Lucite tested at a somewhat higher temperature, its stress-strain curve would resemble that of room-temperature polyethylene. Conversely, were polyethylene tested at a low temperature, its tensile behavior would qualitatively resemble that of room-temperature Lucite. Thus material stress-strain behavior is temperature sensitive. For thermoplastic polymers, there is a transition between malleable and "brittle" behavior at a critical temperature close to what polymer chemists call the *glass transition temperature.* Many metals, particularly the bcc transition ones, also exhibit a similar temperature sensitivity of their ductilities.

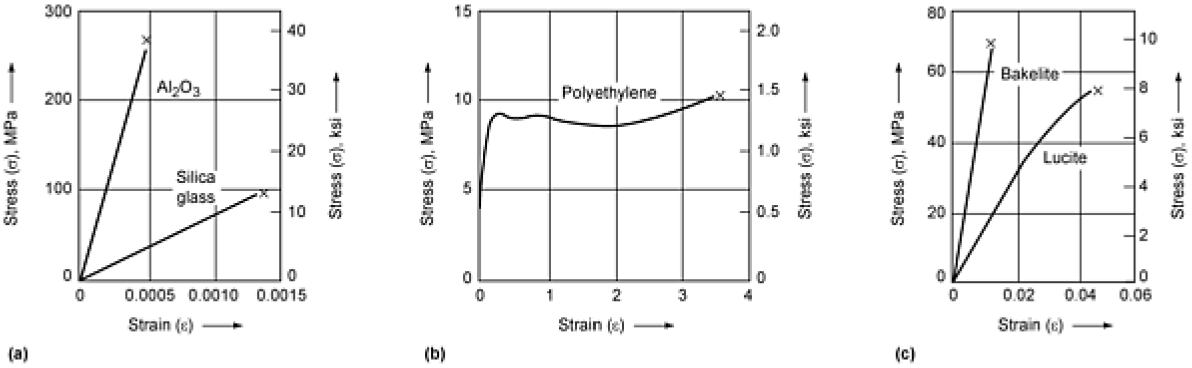

Fig. 19 Room-temperature tensile engineering stress-strain curves for selected materials. (a) The curves for polycrystalline Al_2O_3 and SiO_2 glass are characteristic of brittle solids that only elastically deform prior to fracture. (b) Polyethylene at room temperature demonstrates extensive malleability, coupled with a relatively low strength. (c) Bakelite (a thermosetting polymer) and Lucite (a thermoplastic) are not as "brittle" as Al_2O_3 and silica glass, but they are not malleable materials at room temperature. (Bakelite is never so, but Lucite becomes ductile at a temperature above room temperature.) Source: Ref 4

It is difficult to tensile test ceramics. They are brittle, and gripping them in such a test often leads to their fracturing prematurely. Thus, other tests are often employed to evaluate ceramic mechanical properties. A compression test is one. In such a test a rectangular or circular cross-sectioned sample is placed between two platens, which are displaced so as to reduce sample length, rather than increase it as in a tensile test. For the most part, the platens eliminate the "grip" problem. A compression test can be used to determine the material modulus, yield strength (if it deforms permanently), and compressive fracture stress (if it is brittle). Ceramic compressive fracture stresses are about ten times greater than their tensile fracture stresses. This is so because preexisting flaws, commonplace in ceramics, tend not to extend and grow when subjected to compressive loading, whereas a tensile stress facilitates their growth.

A bend test (Fig. 20) measures something like a tensile fracture stress. During bending, one side of the sample is subjected to tensile loading and the other half to compressive loading. The maximum tensile stress is obtained at the sample surface and, for the configuration of Fig. 20, is given as:

$$\sigma = 6M/bd^2 \quad \textbf{(Eq 3)}$$

where M is the applied bending moment (=Fl), b is the sample dimension (width) into the plane of the drawing, and d is the thickness of the sample. The *modulus of rupture,* σ_r, is the stress of Eq 3 evaluated at fracture. Ceramic moduli of rupture are somewhat higher than tensile fracture stresses (although much less than compressive fracture stresses). The reason is that only one-half of a modulus-of-rupture sample experiences a tensile stress, and it is only on the surface of this half that the maximum such stress acts. Since ceramic fracture almost invariably initiates from microscopic flaws, the fraction of the sample experiencing a substantial tensile stress is less in a modulus-of-rupture test than in a tensile test where the material is uniformly loaded. A corollary to this "probability" effect is that fracture stresses of ceramics (whether tensile, compressive or modulus of rupture) are size dependent. Smaller samples display, on the average, higher fracture stresses because the probability of finding large preexisting flaws in them is less. Suitable procedures exist for

converting average fracture stresses from one sample size to another. Finally, a fairly large variation in measured fracture stresses of similarly sized samples is also observed in ceramics. This is due to the variations in finding different-sized flaws in a given material volume. Thus, design against ceramic fracture is a "calculated gamble," and this partly accounts for the reluctance to use ceramics in critical applications. Only by processing these materials in a way so as to minimize the presence of microscopic flaws can ceramics be considered for such use. This distinguishes them from metals, which are remarkably flaw tolerant in comparison.

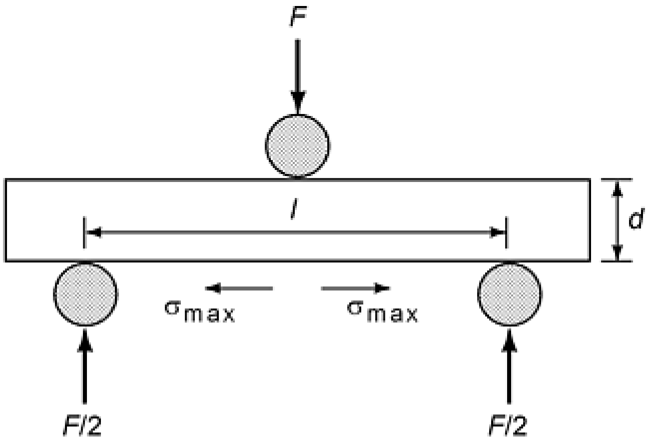

Fig. 20 A bend test eliminates the grip problem in tensile testing ceramics and can be used to measure the material modulus of rupture (Eq 3). Source: Ref 4

Hardness. A *hardness* test is easy to execute and provides information on the yield strength of a material. In brief, a hard material (the indentor) is placed above the sample surface. A load is then placed on the indentor that penetrates this surface. The size of the resulting indentation, a measure of the permanent deformation the material undergoes in the test, relates to the material hardness; a small indentation indicates high hardness and vice-versa. When the load is divided by the indentation area (sometimes the projected area of the indentation), a hardness number, *H,* is defined. Hardness has units of stress and, since it relates to permanent deformation, *H* correlates with σ_y. The stress state arising during a hardness test differs from that in a tensile test, however. This results in *H* being greater than σ_y. To a good approximation, $H \sim (2.5 \text{ to } 3.0)\sigma_y$; the approximation $H = 3\sigma_y$ is often used.

Strain-Rate Sensitivity. Low-temperature (usually room-temperature) properties of metals and ceramics are not *strain-rate sensitive.* (Polymers are considered later.) That is, σ_y and flow stress depend not at all, or only slightly, on how fast the material is strained. This is not so at elevated temperatures, where materials manifest a higher flow stress the more rapidly they are strained. ("Elevated" here means temperatures typically greater than about 40% of the material's absolute melting temperature.) *Strain rate* is defined as:

$$\dot{\varepsilon} = (1/l)\,(dl/dt) \qquad \textbf{(Eq 4)}$$

where *l* is the instantaneous gage length and *dl*/*dt* is the rate at which the sample is extended or compressed. At elevated temperatures, the flow stress (at a particular strain) varies with $\dot{\varepsilon}$ according to the empirical equation

$$\sigma = K(\dot{\varepsilon})^m \qquad \textbf{(Eq 5)}$$

where *K* is a "strength coefficient" and *m* is the *strain-rate sensitivity.* Strain-rate sensitivities can be as high as unity, as they are for viscous glasses at high temperature. More typically, high-temperature *m* values range from about 0.2 to 0.5 for inorganic solids, with *m* monotonically increasing with temperature.

Creep. A corollary to the above is that at high temperature, materials may permanently deform under a constant stress, contrary to their low-temperature behavior. The phenomenon is called *creep,* and creep deformation, eventually culminating in fracture, is an important high-temperature design consideration. Creep tests assess material suitability for such applications. In these tests the material is subjected to a constant stress (sometimes a constant load) and the

extension is measured. A schematic of the results of a creep test is shown in Fig. 21. As indicated, both the strain level and the strain rate increase with stress and/or temperature. Following an initial transient (Stage I), the strain rate attains a minimum, constant value: the steady-state or Stage II creep rate. This creep rate is often a high-temperature design parameter. For a potential application, for example, it might be required that the steady-state creep rate of a material be less than a specified value. Following Stage II creep, the creep rate increases. This Stage III creep is the precursor to material fracture (denoted by X in Fig. 21).

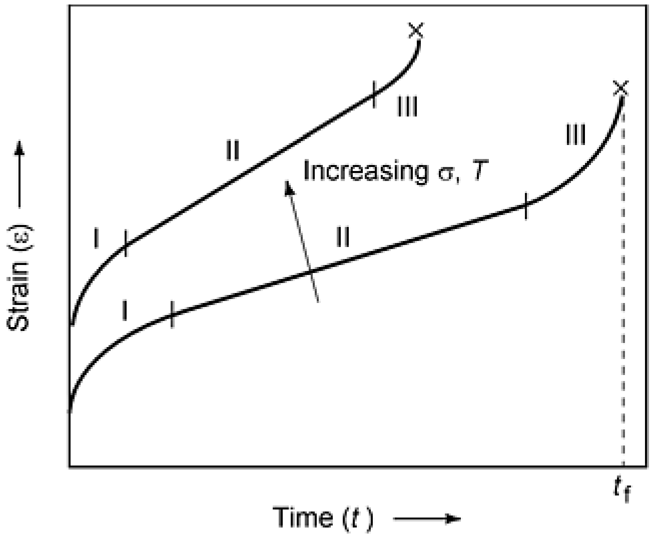

Fig. 21 Schematic results of an elevated-temperature creep test in which a material permanently deforms at a constant stress. As indicated, increasing stress and/or temperature increases the creep strain and the creep rate (*dε/dt*). Source: Ref 4

A slightly different test, a stress-rupture test, is also used to assess creep resistance. In this test, the sample is subjected to a constant load, and the time to fracture (also called time to rupture) is measured as it varies with stress and temperature. Stress versus time-to-fracture diagrams are then constructed and used in design. (Extrapolation is required, because anticipated high-temperature material lives can be decades. Such durations exceed by far the times available for laboratory testing.) Further information on creep deformation and creep fracture is provided in the article "Design for High-Temperature Applications" in this Volume.

Fatigue and Corrosion. Materials subjected to cyclical loading often fail even when the maximum stresses to which they are subjected are less than their yield strengths. The phenomenon is called *fatigue.* Materials can be assessed for fatigue resistance by subjecting them to cyclical stresses and measuring the number of cycles they sustain before fracturing. One common test applies alternating tensile-compressive stresses of equal magnitude. More specialized tests vary the maximum and minimum stresses, and some tests tensile-compressive stresses) are summarized by plotting the maximum stress versus the logarithm of the number of cycles to failure (Fig. 22). As expected, higher applied stresses result in a lesser number of cycles to failure; the effect is most pronounced at short material lives. At longer lifetimes, material life is not as sensitive to stress. In fact, for the steel whose behavior is illustrated in Fig. 22, there exists a stress level, the *fatigue limit,* below which the material may be assumed not to fail by fatigue, regardless of how many stress cycles it experiences. Such behavior is observed in many ferrous materials, and for them the fatigue limit becomes a design parameter. Other materials do not manifest a fatigue limit (e.g., the aluminum alloy of Fig. 22). For such materials, the stress that causes failure in a very large number of cycles (e.g., 10^8 to 10^9) is the corresponding fatigue design parameter.

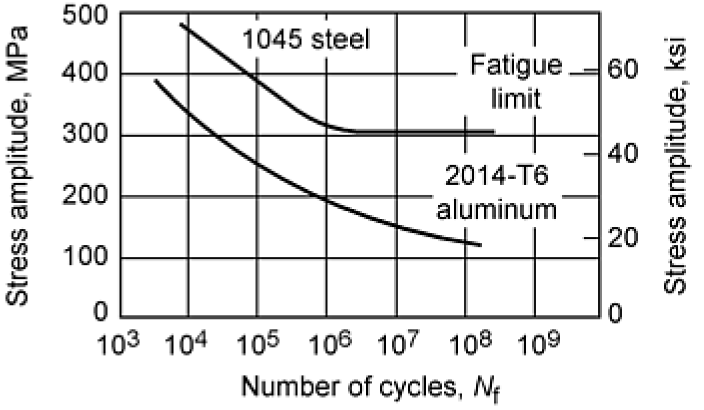

Fig. 22 Maximum stress versus number of fatigue cycles to failure for a plain carbon steel and an age-hardenable aluminum alloy. The steel manifests a fatigue limit, whereas the aluminum alloy does not. Source: Ref 7

Polymers display fatigue behavior somewhat similar to that of metals. However, repeated cycling of polymers leads to their heating (thus test frequency is an important parameter), and this must be taken into account in design. Ceramics, too, are prone to fatigue, but the flaws they contain generally result in short fatigue lives if the applied stress is any appreciable fraction of their fracture strengths.

Corrosive environments often accelerate material failure. The detrimental effect of corrosion and stress acting concurrently can lead to *stress corrosion* fracture. Likewise, gaseous environments may accelerate high-temperature material failure. Creep and fatigue can interact, often deleteriously. Factors like these play an ever more important role as materials are called on to perform in ever more demanding situations. Further information may be found in the articles "Design for Corrosion Resistance," "Design for Fatigue Resistance," and "Design for High-Temperature Applications" in this Volume.

Discussion to this point has focused on failure involving permanent deformation (i.e., by low-temperature yielding, high-temperature creep, or fatigue). We now turn our attention to material fracture.

Fracture Properties. *Fracture mechanics* is the engineering science underlying design against material fracture. Although a relatively new discipline (less than half a century old), fracture mechanics has had a profound impact on design. A fundamental assumption of fracture mechanics is that all structures contain surface and/or interior flaws. It is further assumed that quality control and/or material inspection permit a reasonable estimate of the largest flaw that a material might contain when put into service. These flaws are considered to have a crack-like shape, a shape conducive to producing a high stress concentration in the flaw vicinity. It is the propagation of these flaws, at a stress level that depends upon the flaw size and material, that results in material fracture.

Formal fracture analysis uses mechanics concepts. The stress (σ_{tip}) at the tip of a crack varies with the crack length (c) as:

$$\sigma_{tip} = A\,\sigma_{nom}\,(c)^{1/2} \quad \textbf{(Eq 6)}$$

where σ_{nom} is the nominal applied stress. The proportionality factor A includes terms such as the radius of curvature of the crack tip. If the material is very brittle (e.g., glass at room temperature) when the stress in front of the crack attains the value required to rupture atomic bonds (the theoretical fracture stress), the crack spontaneously propagates, causing fracture. The nominal stress at which fracture takes place, σ_F, is thus

$$\sigma_F = K/(c)^{1/2} \quad \textbf{(Eq 7)}$$

where K is a material property (proportional to the theoretical fracture strength in the case of a very brittle material).

Most materials are not as brittle as glass. For them the stress concentration in front of the crack may induce localized plastic deformation there prior to crack propagation. These complexities are taken into account by rewriting Eq 7 as:

$$\sigma_F = K_{Ic}/(\alpha \pi c)^{1/2} \quad \textbf{(Eq 8)}$$

where K_{Ic} is the *fracture toughness,* a material property. (The π term in Eq 8 is a convention, whereas the α term takes into account details of the crack shape. That is, α is crack-shape dependent, although values of α are always of the order of unity.)

Fracture toughness is straightforwardly measured by any of a number of standard tests. A material containing an intentionally introduced sharp crack (the length of which is measured before testing) is subjected to a tensile stress, σ_F is measured, and Eq 8 permits K_{Ic} to be calculated. For example, a beam with an initial crack on its tensile side can be bent until it breaks, or a plate containing a surface crack can be stressed in tension until the crack propagates.

A hardness test can be used to determine fracture toughnesses of brittle materials. Thus, a hardness test can assess the resistance of a brittle material to both fracture and permanent deformation. To be useful for measuring K_{Ic}, cracks must extend outward from the hardness indentation. K_{Ic} is high when the lengths of these cracks are short, and vice-versa.

As noted, the stress concentration in front of a crack is often sufficient to initiate yielding there. This plastic deformation then accounts for most of the fracture work (the irreversible work accompanying crack propagation). Even very brittle materials (e.g., room-temperature glass) have a work (energy) associated with crack propagation. In the case of glass, this is the energy associated with formation of the fracture surfaces accompanying crack propagation. When a material is capable of plastic deformation, surface energy also accounts for a (very small) portion of the fracture work, but most of this work is taken up in crack-tip plastic deformation. The parameter G_{Ic}, the *toughness,* is a measure of the work of fracture. The dimensions of G_{Ic} are energy/area, and G_{Ic} can thus be thought of as the fracture work per unit area of fracture surface. Toughnesses vary widely. They range from about 1 J/m^2 for brittle materials, such as glass, to something on the order of 10^7 J/m^2 for "tough" steels.

It might be expected that G_{Ic} is related to K_{Ic}; after all, both properties relate to crack propagation and fracture. This is the case, and the relationship is:

$$K_{Ic}^2 = EG_{Ic}(1 + \nu) \quad \textbf{(Eq 9)}$$

where E is the modulus and ν (about equal to $\frac{1}{3}$ for most metals) is Poisson's ratio.

Impact Properties. While fracture toughness is the most useful material property in design against fracture, there are other tests that provide a measure of fracture resistance. An *impact test,* widely used in the ferrous metals and plastics industries, is one such test (Fig. 23). A notched bar is broken by a falling pendulum whose kinetic energy is partially absorbed in fracturing the bar. The absorbed energy is measured, and the temperature of the sample can also be varied. Graphs of this impact energy versus test temperature for several steels are shown in Fig. 24. Most ferrous metals show an energy absorption/temperature variation similar to that displayed in the figure. The temperature at which the energy decreases rapidly with decreasing temperature relates to the *ductile-to-brittle transition temperature* of the material. Use of the material below this temperature requires some care in preventing fracture. Above this temperature, material "failure" is likely to occur through plastic deformation rather than fracture.

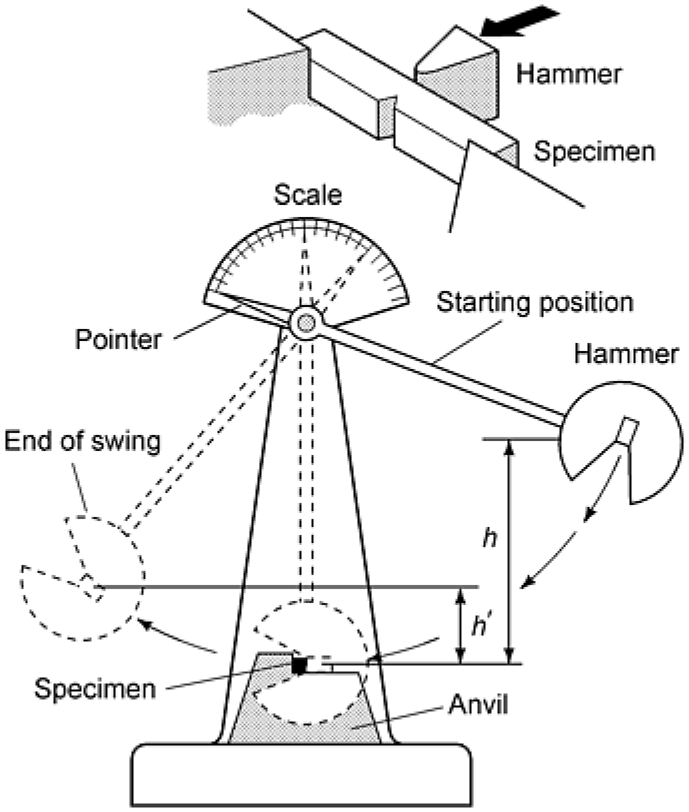

Fig. 23 A Charpy V-notch impact testing apparatus. The hammer is released from a fixed height, strikes the sample, and fractures it. The energy absorbed in fracturing the sample is equal to the loss in potential energy of the hammer. Source: Ref 7

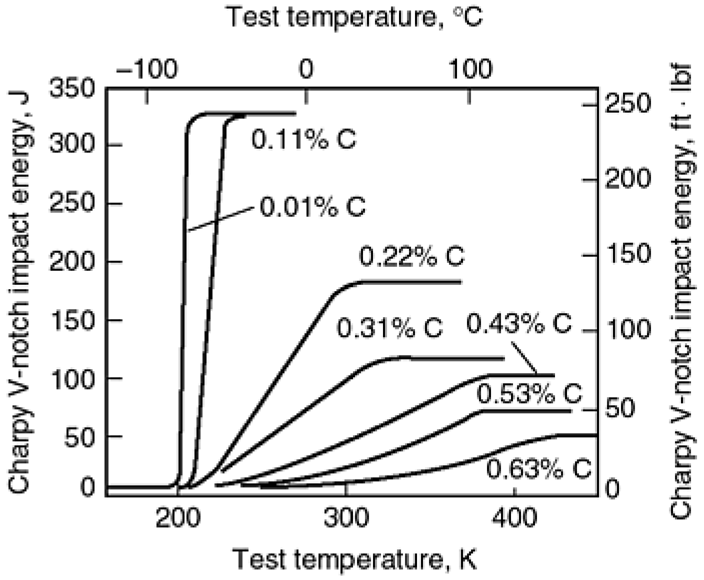

Fig. 24 The temperature variation of impact energy for steels of varying carbon content. For steels with low carbon content, the ductile-to-brittle transition is sharp and clearly identifiable. This transition is more diffuse with higher-carbon content steels. Note that the low-carbon steels are "tougher" at temperatures above the transition temperature. (They are also not as strong as the higher-carbon steels.) Source: Ref 8

Empirical guides concerning safe low-temperature use of ferrous metals and alloys have been established. For example, the impact energy might be required to be above a specified value, found from experience not to result in unanticipated

material fracture. While the results from impact tests are useful, it is worth repeating that fracture mechanics is the preferred tool for design against fracture.

Key Mechanical Properties for Design against Failure. Although a number of mechanical tests have been described above, it is important to recall that the two key material mechanical properties are fracture toughness (K_{Ic}) and yield strength (σ_y). K_{Ic} is used to design against fracture; σ_y is used to design against plastic deformation. In practice, design considers both deformation and fracture, but one factor is often more important. Thus modern design can be simply (but realistically) summarized as shown in Fig. 25.

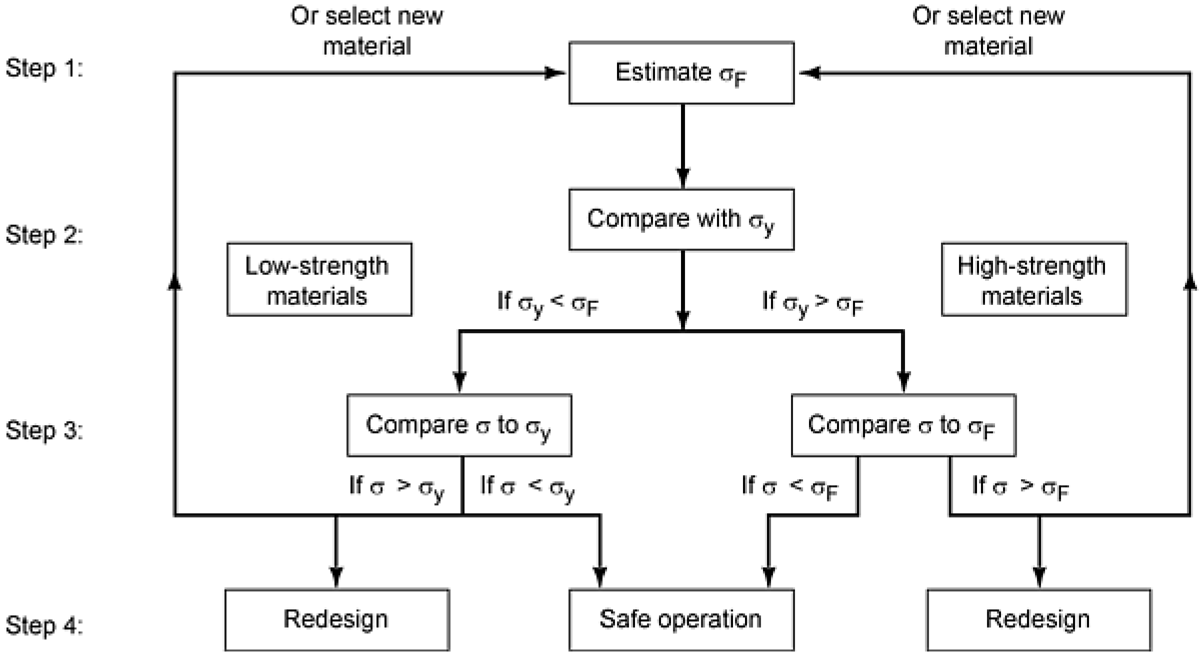

Fig. 25 Schematic of logic employed in design against "failure". Failure can take place by either material permanent deformation or fracture. Thus design entails comparing the 2% offset yield strength (σ_y) to the nominal stress at which fracture occurs (σ_F), and then using the lower of these strengths in design. Source: Ref 4

There is a simple logic to the design process of Fig. 25. After incorporating important safety factors so as to design conservatively, σ_F is compared to σ_y. If σ_y is less than σ_F (generally the situation for low-strength materials), design is conducted to prevent permanent deformation. For high-strength materials (for which σ_F is generally less than σ_y), design is dictated by material fracture. The process requires knowing the appropriate material properties. These are being currently compiled in computer-ready sources, which now complement existing handbooks. Further information is supplied in the article "Sources of Materials Properties Data and Information" in this Volume.

Microstructure and Low-Temperature Strength

The common means for increasing low-temperature strength are described in this section, and brief explanations for their effectiveness are provided. While the various strengthening mechanisms are discussed separately, it is important to realize that often more than one strengthening mechanism is utilized in engineering materials. Practical examples are also provided here. To treat adequately the topics of this section, some "excursions" must be made. In particular, it is difficult to discuss material strengthening without discussing phase diagrams. The phase diagram of a specific system often dictates the means by which it may be strengthened. Space limitations prevent extensive discussion of phase equilibria, so an attempt is made to keep things simple.

Low-Temperature Strengthening of Crystalline Solids

Since dislocations are responsible for crystalline plastic flow, any factor that reduces dislocation mobility increases strength. A number of microstructural features can be used to decrease this mobility. Collectively, they are referred to as *strengthening mechanisms.* This section discusses the most common and important of these: work hardening, solid-solution hardening, grain-size hardening, and particle hardening.

Work Hardening. As noted above, while dislocations are responsible for crystalline plastic flow, there can be "too much of a good thing." If the dislocation density is high, dislocation motion is impeded by the presence of other dislocations. Almost all engineering metals and alloys have relatively high dislocation densities. Furthermore, since the number of dislocations is known to increase during plastic deformation, a material becomes stronger the more it is plastically deformed; the phenomenon is called *work hardening.*

Yield strength is related to dislocation density, ρ, by:

$$\sigma_y = \sigma_0 + \alpha G b (\rho)^{1/2} \quad \textbf{(Eq 10)}$$

where G is the material shear modulus, b is the atomic diameter, σ_0 is the yield strength absent work hardening, and α is a material-specific constant. α has a value of about 0.4 for fcc metals and is somewhat higher, about 1.0, for bcc metals.

If dislocation density were to increase linearly with strain, Eq 10 predicts parabolic work hardening (i.e., the flow stress should vary with the square root of the strain). Some metals, notably copper and several of its alloys, exhibit such work hardening characteristics. On the other hand, dislocations are also removed during cold work, albeit not at the same rate they are created. This leads to a less than parabolic work hardening rate. (Under certain conditions some bcc metals linearly harden.) Since it is difficult to theoretically estimate dislocation multiplication and annihilation rates, recourse is made to empirical *constitutive equations* to describe work hardening. One such common expression is:

$$\sigma_y = \sigma_0 + K\varepsilon^n \quad \textbf{(Eq 11)}$$

where K is a "strength coefficient" and n is the work hardening coefficient. As implied above, n for metals at room temperature is usually less than about 0.5.

Work hardening coefficients can be influenced by other factors affecting strength. These include material composition and whether or not second-phase particles are present in the material. Work hardening is an important consideration in metal forming operations. A high n value indicates a high resistance to neck development, so materials are more formable the more they work harden. Examples of high work hardening materials that are extensively deformed prior to use include brass cartridge shells and aluminum beverage containers. Though most aluminum alloys do not work harden extensively, aluminum beverage container alloys do.

Varying degrees of cold work are used to manipulate the strengths of some alloys. For example, pure, soft copper has a TS of 210 MPa (30 ksi), whereas the TS of extensively cold-worked copper is 390 MPa (57 ksi) (Table 2). The high strength of stainless steel hypodermic needles (required so that they puncture skin with a minimum of pain) derives from their extended drawing during manufacturing. The high yield strength of piano wire (4140 MPa, or 600 ksi) comes primarily from the extensive wire drawing to which it is subjected. To put this strength in perspective, were a 1 $in.^2$ section of piano wire available, it could support 300 one-ton automobiles without yielding plastically!

Table 2 Tensile strengths of copper-zinc alloys

Alloy composition (wt%)	Tensile strength			
	Soft alloys		**Hard alloys**	
	MPa	**ksi**	**MPa**	**ksi**
Cu	210	30	390	57
Cu-10Zn	250	36	505	73
Cu-20Zn	285	41	610	88
Cu-30Zn	305	44	625	91

Note: Not to be used for design purposes. "Soft" alloys refer to commercially available annealed alloys; "hard" to commercially

Solid Solution Strengthening. Impurity (solute) atoms strengthen metals and ceramics, sometimes substantially. The impurity atoms have a different size than the host atom and also a different atomic "stiffness" (i.e., atomic bonding is not the same in the solute and solvent). Both effects alter the crystal lattice in the vicinity of a solute atom. As a result, a moving dislocation is either attracted to, or repelled by, the impurity. Either situation results in a strength increase. When the dislocation is attracted to the impurity, the additional force required to pull the dislocation away from it is the cause of the added strength. If the dislocation is repelled by the impurity, an additional force is required to push the dislocation past the solute atom.

Treatments of solid-solution hardening indicate that the hardening depends on the differences in elastic stiffness and atomic size between the solvent and solute. Quantification of the effects is difficult, however, and has only been done in a few cases. Nonetheless, Eq 12 adequately represents the increase in yield strength, $\Delta\sigma_y$, due to solute atoms:

$$\Delta\sigma_y = A(c)^{1/2} \qquad \textbf{(Eq 12)}$$

where A is a constant that depends upon the solute-solvent combination and c is the solute concentration (in atomic fraction). Equation 12 has been confirmed for a number of materials, with the constant A considered an empirical parameter.

Equation 12 suggests that the maximum strength increase due to solid-solution strengthening depends on the extent to which the solute dissolves in the solvent. Solid solubilities are generally limited. Thus it is seldom that one element dissolves in another to the degree (c = 0.5) that the maximum possible strengthening results.

Phase diagrams are useful for indicating solid solubilities; two binary phase diagrams are provided in Fig. 26. A phase diagram is a map in which the "states" of the material are delineated as they vary with temperature and composition. Any combination of temperature and composition that lies within the region designated as "Liquid" in the copper-nickel phase

diagram (Fig. 26a) corresponds to a fully liquid state. Likewise, any composition-temperature combination lying within the region marked (Cu, Ni) implies a fully solid state. There is only one solid region in Fig. 26(a), and this indicates that copper and nickel dissolve in all proportions in the solid, as well as the liquid, state. This is unusual; most elemental combinations do not display complete solid solubility. It is possible in the copper-nickel system because the two elements have similar atomic sizes and "chemistry." (They lie beside each other in the periodic table.) The region in the diagram separating the single-phase solid and liquid regions represents temperature-composition combinations for which the state of the material is a mixture of liquid and solid phases. This indicates that copper-nickel alloys do not melt at a specific temperature (as do the pure elements) but rather over a range of temperature. For example, a 50at.%Cu-50at.%Ni alloy begins to melt at about 1240 °C, but it does not become fully liquid until about 1315 °C.

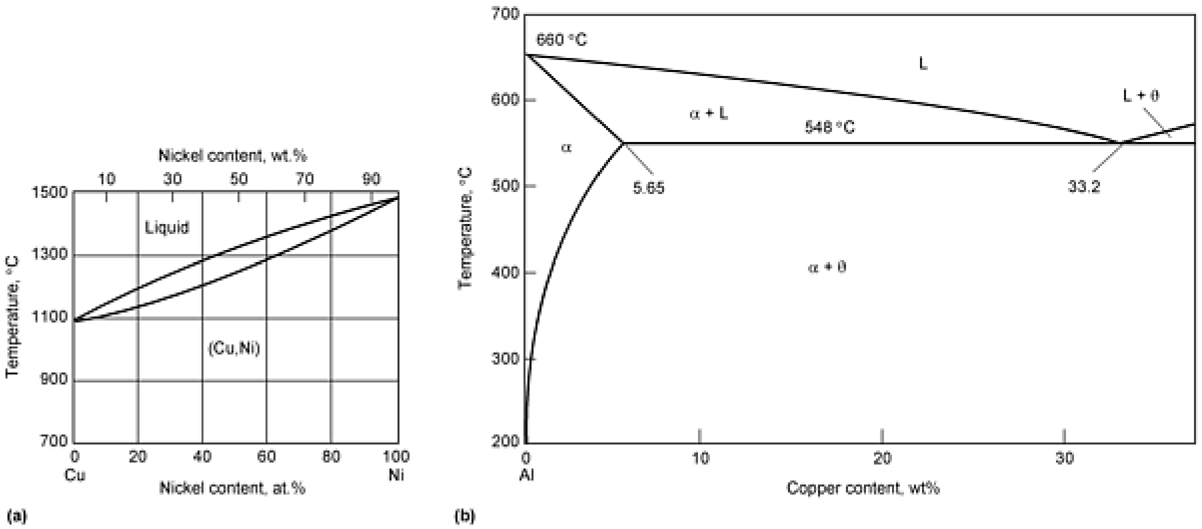

Fig. 26 Two metallic phase diagrams. (a) The copper-nickel diagram. Copper and nickel are completely soluble in both the solid and the liquid states. Source: Ref 9. (b) The aluminum-rich portion of the aluminum-copper diagram. The solubility of copper in solid aluminum is restricted, being a maximum of 5.65 wt% at 548 °C. Source: Ref 4

Aluminum is commonly used in applications requiring good strength combined with low density. (The density of aluminum is 2.7 g/cm^3.) Solid aluminum seldom dissolves other elements in large amounts. An example of such limited solid solubility is provided by the aluminum-rich portion of the aluminum-copper phase diagram (Fig. 26b). Here, as in the copper-nickel diagram, there is a single-phase liquid region (abbreviated L in Fig. 26b) and a two-phase (α + L) region. (α refers to a solid phase based on pure aluminum. Greek letters are commonly used in phase diagrams to signify solid phases.) However, there is also a solid two-phase ($\alpha + \theta$) region. The lines separating the single-phase α region and the two-phase regions represent the amount of copper that can dissolve in solid aluminum at different temperatures. The maximum solubility (5.65 wt% Cu) is found at 548 °C, where the boundaries between the lines separating the α region and the different two-phase regions intersect. The solubility of copper in aluminum at room temperature is essentially nil. Figure 26(b) is more or less typical of aluminum phase diagrams in that solid solubilities of most elements in aluminum are limited. As a consequence aluminum is not often strengthened by solid-solution hardening. Rather, the feature of limited solubility allows for hardening by second-phase particles, as discussed below.

The extent of solid-solution strengthening depends on the system-specific value of the constant *A* in Eq 12 as well as the solubility effect. In many cases, the two factors work against each other. That is, high solubility is favored when the atomic sizes and moduli of the solute and solvent do not differ much, yet small differences in these parameters usually correlate with low *A* values. Nonetheless, solid-solution strengthening is utilized for hardening many commercial metals, such as nickel-base superalloys, stainless steels, and brasses. Zinc (the major solute in brass) can dissolve in amounts up to 35 at.% in solid copper. The resulting increases in strength are impressive, as shown in Table 2, which also indicates how solid-solution strengthening and work hardening can be used in tandem. More extended discussion of structure-property-processing relationships in nonferrous alloys can be found in the article "Effects of Composition, Processing, and Structure on Properties of Nonferrous Alloys" in this Volume.

The most technologically important use of solid-solution strengthening is found in iron-carbon *martensites.* As discussed later, carbon does not appreciably dissolve in the low-temperature bcc form of iron. However, appropriate thermal manipulation permits carbon in excess of the equilibrium solubility to be "trapped" in it. The amount of trapped carbon remains low (less than several atomic percent), but significant hardening is provided nonetheless. The reason that carbon is such a potent hardener of iron is that it dissolves interstitially in the bcc lattice, producing a (tetragonal) distortion. The resulting internal stress interacts strongly with moving dislocations, substantially reducing their mobility. More extended discussion of martensite is given in the section "Strengthening of Steels" in this article.

Grain Boundary Strengthening. Dislocations cannot cross grain boundaries, so grain boundaries strengthen a material. A corollary is that the finer the grain size, the higher the yield strength.

Yield strength is found to vary with grain size according to the Hall-Petch relationship:

$$\sigma_y = \sigma_0 + k_y d^{-1/2} \qquad \textbf{(Eq 13)}$$

where k_y (the Hall-Petch coefficient) is a material constant, d is the grain diameter, and σ_0 is the yield strength of an (imaginary) polycrystal having infinite grain size. Hall-Petch coefficient values vary widely; some for metals are given in Table 3, where it is seen that k_y values for fcc metals are usually less than for bcc metals. The values listed in Table 3 can be used to assess how much grain size reductions increase strength. Aluminum, for example, cannot be substantially strengthened by grain size refinements. A reduction in grain size from 100 μm to 1 μm in an aluminum alloy yields a modest increase in σ_y of 61 MPa (9 ksi). On the other hand, an equivalent reduction in grain size in a low-carbon steel increases σ_y by 275 MPa (40 ksi). Thus, grain size reduction can be used to effectively harden iron, but not aluminum, alloys.

Table 3 Values of Hall-Petch coefficients for several metals

Material	Material class	k_y	
		MPa $\sqrt{\text{m}}$	**ksi** $\sqrt{\text{in.}}$
Low-carbon steel	bcc metal	0.307	1.24
Molybdenum	bcc metal	1.768	7.14
Magnesium	hcp metal	0.279	1.13
Titanium	hcp metal	0.403	1.63
Copper	fcc metal	0.112	0.45
Aluminum	fcc metal	0.068	0.27

As noted, ceramic grain sizes are usually less than metal ones. Moreover, Hall-Petch coefficients are generally greater for ceramics. Thus, grain size effects are important to ceramic strength. And, as noted above, grain size is the one structural feature that both strengthens a material and improves its fracture resistance.

Particle Strengthening. When fine particles are dispersed in a material, strength increases, sometimes appreciably. There are several ways to produce such a dispersion. One involves powder processing, in which small particles of an

essentially insoluble solid are mixed with powders of the base material. The mixture is then consolidated and, provided that the dispersoid size is sufficiently fine, effective strengthening can result. Another way to achieve such a dispersion involves selective (internal) oxidation. Aluminum, for example, oxidizes more readily than does copper. If a copper-aluminum solid solution is heat treated in an atmosphere with a suitable oxygen partial pressure, oxygen diffuses into the solid, where it preferentially reacts with aluminum to form minute Al_2O_3 particles that serve as the hardening agent.

Particles can be dispersed in a matrix by other processing routes, as they are for particle-hardened aluminum alloys. Consider again Fig. 26(b). If a 4 wt.% Cu alloy is heated into the single-phase α region (requiring a heat treatment temperature greater than the *solvus* temperature, 500 °C), the structure consists of an aluminum-rich fcc phase containing all the copper in solid solution. On cooling this alloy to a temperature below the *solvus,* the solubility of copper in aluminum is exceeded and θ phase precipitates. (This symbol indicates a phase having the approximate composition $CuAl_2$.) If the θ particles that precipitate are sufficiently fine, appreciable particle hardening is expected.

Precipitation in solids is complex. To form $CuAl_2$ from an aluminum solid solution requires the following events. Copper-rich regions must first form, and this requires diffusion of copper atoms. Then, since the crystal structure of $CuAl_2$ is different from that of aluminum, a cluster, or nucleus, of $CuAl_2$ phase must form. This *nucleation* is not spontaneous, for the nucleus-matrix interface has an associated surface energy (analogous to a grain boundary energy) that impedes nucleation. Following nucleation, the $CuAl_2$ particles grow, and this also requires atomic diffusion, which is temperature sensitive (the higher the temperature, the more capable the atoms are of moving about). Thus, precipitation involves both nucleation and growth of the new phase. Precipitation stops when a certain (equilibrium) amount of precipitate forms, the amount depending on the transformation temperature. The lower it is, the greater the precipitate fraction (the solubility of copper in aluminum decreases with decreasing temperature) and (almost always) the finer the precipitate size. Finally, because of the importance of diffusion, precipitation takes place sluggishly at temperatures below about half of the absolute melting temperature of the material.

Following the above events, the average precipitate particle size increases. Since the precipitate amount remains constant, this particle *coarsening* reduces the precipitate number and increases the spacing between precipitate particles.

While the above describes isothermal precipitation of $CuAl_2$ from supersaturated aluminum, the thermal processing employed to harden commercial aluminum alloys takes a different route. Slow cooling these alloys to room temperature leads to precipitates having too large a size to be effective in hardening. It is feasible to cool the alloy to an intermediate temperature and hold it there for a time that yields an effectively hardening particle dispersion, but there are more convenient ways to achieve the same thing: *quenching* and *aging.* The alloy is first heated into the single-phase α region to *solutionize* it. The alloy is then cooled sufficiently rapidly (quenched) to room temperature so that no precipitation occurs during the operation. Thus, the structure at room temperature is the same (i.e., the solid solution) that it was at the solutionizing temperature.

Following quenching, the alloy is "aged." This involves heating the alloy to a (relatively low) temperature for a specified period. During aging, precipitation takes place and, provided that the proper aging time and temperature are chosen, substantial particle hardening results. Figure 27 shows a graph of room-temperature yield strength versus aging time for an Al-4.5wt%Cu alloy aged at different temperatures. Due to precipitation, σ_y initially increases. However, a strength maximum is found at a temperature-dependent aging time; the lower the aging temperature, the longer this optimum time. Moreover, the strength maximum is greater at lower aging temperatures, because a greater precipitate fraction forms at lower temperatures.

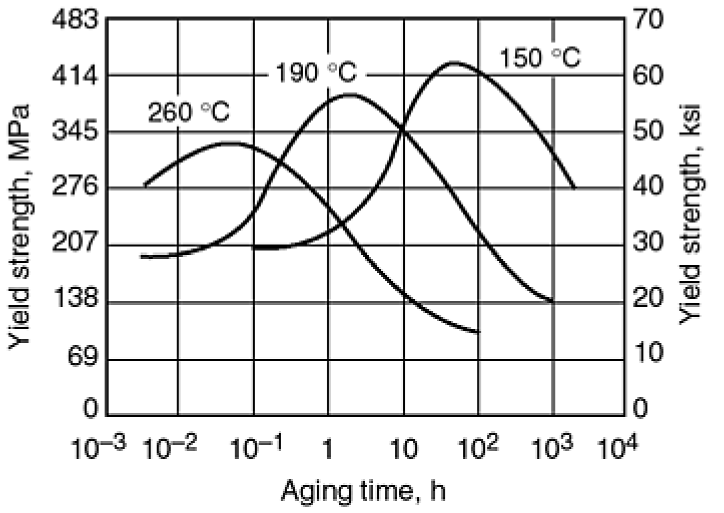

Fig. 27 Room-temperature yield strength vs. aging time at several temperatures for an initially solutionized and quenched Al-4.5wt%Cu alloy. Maximum strength is obtained at lower aging temperatures, but the time required to yield this strength is correspondingly greater.

Aluminum alloys may be "overaged." That is, if the alloy is heated too long, a strength less than the maximum is obtained. This often results from precipitate coarsening, which generates particles having too large a size for effective hardening.

The above discussion has not specified the hardening precipitate, although it has been implied that it is $CuAl_2$. While this phase does form on aging of aluminum-copper alloys, nonequilibrium (transition) precipitates are precursors to $CuAl_2$, and these are the phases associated with maximum hardening. Although this is so, it does not alter the general description of precipitation given here.

Some factors responsible for particle strengthening can now be considered. The discussion is a little complicated, since several effects can be responsible for the hardening. Some description of the nature of particle-matrix interfaces is first necessary. Precipitation often yields "ordered" particle-matrix interfaces (i.e., atoms to either side of the interface "match up" across the boundary). Due to the different average atomic sizes in the matrix and the precipitate, the crystal lattice is "strained" in the interface vicinity. Yet it is important that atomic continuity persists across the boundary, for it means that dislocations can glide through particles as they wend their way through the material. If the particle-matrix interface is "disordered" (i.e., if atomic matching does not exist across it), dislocations cannot pass through the particle (analogous to the situation pertaining to grain boundaries). Instead, dislocations "bow" around particles with this kind of interface. Disordered particle-matrix interfaces are found, for example, in the powder-processed materials mentioned above.

The "particle hardening" stress depends on whether dislocations pass through or bow around particles. For bowing, it is found that the increase in yield strength due to the presence of the particles is approximately described by the Orowan equation:

$$\sigma_{part} = C[Gb/(\lambda - 2r)] \quad \textbf{(Eq 14)}$$

where C is a constant of order unity, G is the matrix shear modulus, b is the atomic diameter, r is the particle radius, and λ is the mean center-to-center distance between particles; thus, (λ - 2r) is the corresponding mean surface-to-surface distance. (To keep things simple, some liberties have been taken in defining terms. The geometrical distances noted actually apply to the slip plane of the material. The approximations made can be incorporated within the constant C.) Implicit in Eq 14 is that the greater the particle volume fraction (f), the greater the strength. That is, f scales with r/λ and, therefore, for a fixed particle spacing, strength increases with increases in f.

While alloys with disordered particle-matrix interfaces always deform by dislocation bowing, this is also the dominant deformation mechanism in alloys with coarse particle dispersions, regardless of the nature of the particle-matrix interface. This is so because the bowing stress is less than that needed to push dislocations through particles; that is, dislocations

take the "easy way out." In fact, the transition from under- to overaging (i.e., the point of maximum strengthening) often corresponds to a transition in dislocation transit mode. Dislocations pass through particles in underaged alloys and bow around them in overaged ones.

When dislocations pass through (shear) particles (as they do for finely dispersed particles with an ordered interface), several factors may contribute to strength. Some of them bear similarity to those leading to solid-solution strengthening. For example, the different atomic bonding and sizes between the precipitate and matrix cause strengthening for much the same reasons that these features result in solid-solution strengthening. However, other factors may also play a role in particle hardening. When a particle is sheared, additional interface area between it and the matrix is generated. Moreover, if the particle is an ordered compound (i.e., if different atoms preferentially occupy certain lattice sites in it), when dislocations pass through the particle they produce atomic disorder. The attendant increase in system energy in both cases is manifested by an increase in strength. The most important strengthening mechanism (or mechanisms) is system specific. While this is so, irrespective of the most important strengthening mechanism, strengths of alloys that deform by particle shearing increase with increased particle fraction.

Multiple Strengthening Mechanisms. Many alloys utilize more than one strengthening mechanism. Work hardening and solid-solution strengthening together impart high strength to cold-worked brasses (Table 2) and stainless steels. Nickel-base superalloys combine solid-solution and particle strengthening, with different kinds of particles used for different purposes. One type of particle, having an ordered interface with the matrix, is located within grains, whereas the other is situated on grain boundaries. Grain boundary hardening is ubiquitous in polycrystals, so such boundaries always strengthen a material (although not always substantially).

The generally accepted view (although with little justification) is that the different strengthening contributions are additive. Given our current understanding, this idea is a useful engineering approximation.

While the basic "physics" of strengthening are known, they are system specific. In addition, it is difficult to calculate a priori the strength increase expected from a specific mechanism for a given system. And, for particle hardening, the most important hardening mechanism can seldom be identified through first principles. So our understanding of strengthening remains semiquantitative. However, knowledge of the parameters affecting strength has been used fruitfully in alloy development. It is therefore appropriate to end this section with some examples. They are taken from ferrous alloys, a good choice because these materials have long been stalwart structural alloys.

Strengthening of Steels. To a metallurgist, the iron-carbon diagram is the eighth wonder of the world. The low-temperature, iron-rich portion of this diagram is shown in Fig. 28. Steels contain less (usually quite a bit less) than about 1.2 wt% C. Steels also almost invariably contain manganese, but steel mechanical properties can be discussed without considering this element.

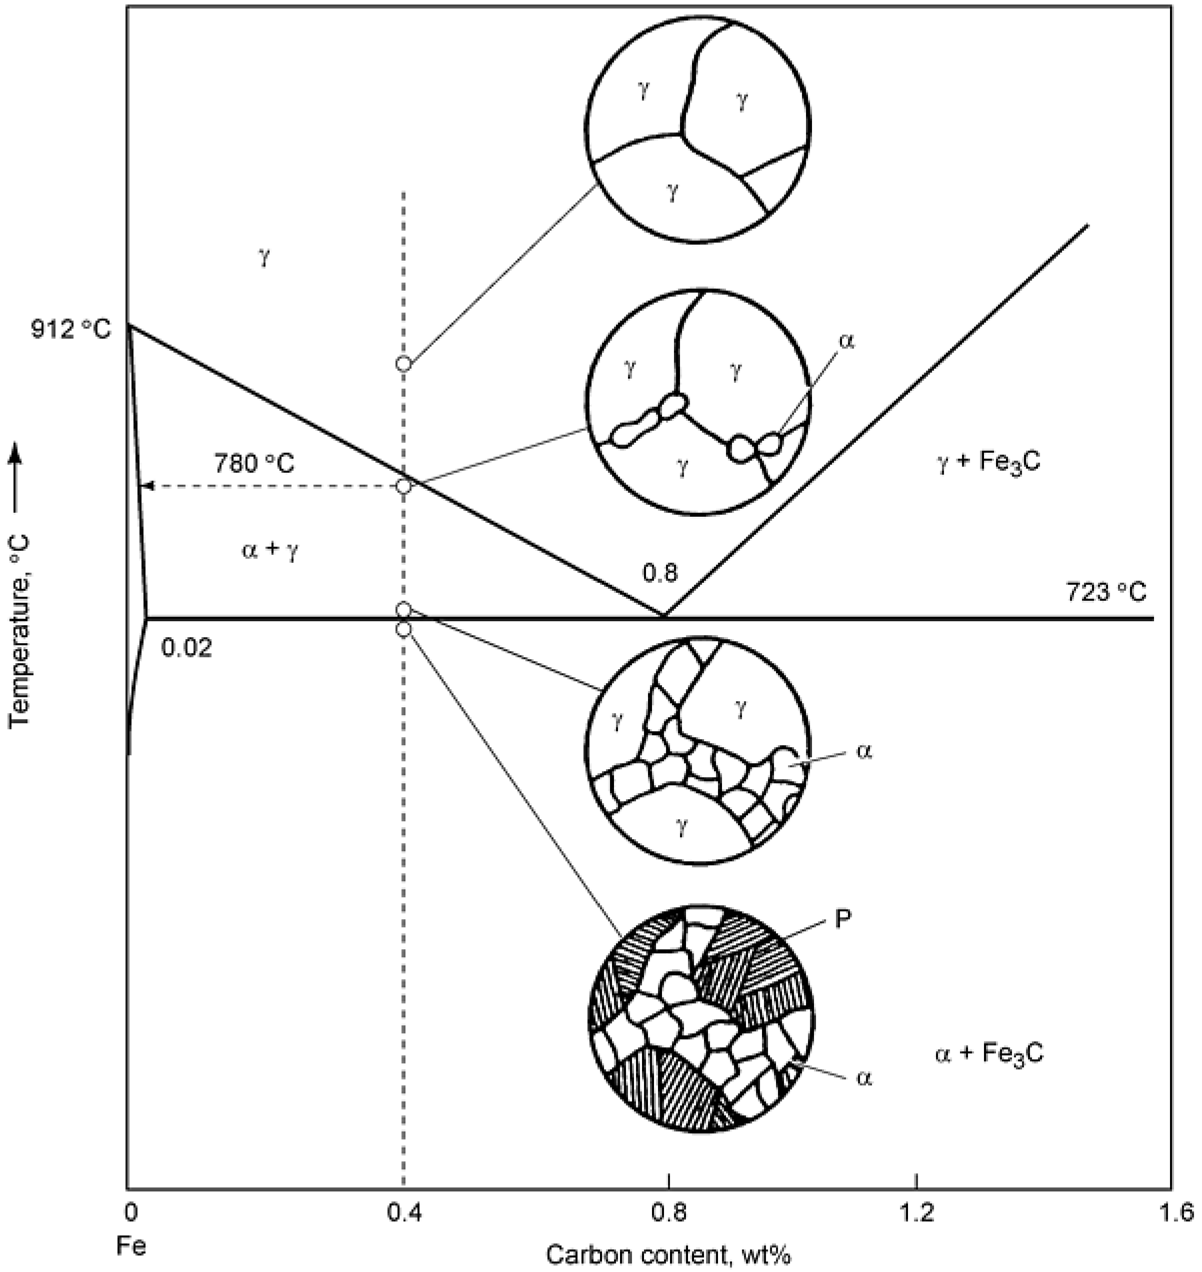

Fig. 28 The low-temperature and iron-rich portion of the iron-carbon phase diagram. The schematic microstructures illustrate the evolution of the structure of a 0.40 wt% C steel upon slowly cooling to room temperature from the γ (austenite) phase field, as described in the text. Source: Ref 3

Thermal treatment is used to vary steel properties. In brief, at some point during processing (which may be concurrent with deformation processing) the steel is heated into the single-phase fcc region (designated γ in Fig. 28; γ is also referred to as austenite, in the jargon of the ferrous industry). We describe the structural changes taking place when a steel is slowly cooled from this region to room temperature; a steel containing 0.4 wt% C is used as an example.

When a steel having this composition is cooled below 780 °C, it enters into a two-phase region of α (also called ferrite, which is bcc) and γ. As it does so, iron-rich α particles precipitate from γ. In many cases, these particles are situated on γ grain boundaries, as indicated in the 780 °C schematic microstructure of Fig. 28. On further cooling, the amount of α increases and, at a temperature slightly above 723 °C, the material is about 50% α and 50% γ. (See the schematic microstructure at this temperature in Fig. 28.) The amount of each phase depends on the steel composition. The 50% ferrite arises here because at a temperature slightly above 723 °C, the composition of a 0.40 wt% C steel lies about

halfway between the two boundaries separating the two-phase and single-phase regions. If the composition were increased to, say, 0.6 wt% C (i.e., to a composition closer to the austenite boundary), the amount of α would be reduced to about 25%. Conversely, if the composition were 0.2 wt% C, the amount of ferrite would be about 75%.

Further reference to Fig. 28 indicates that something happens on cooling below 723 °C. Specifically, the phases now present are α and Fe_3C (the latter is called cementite). We note that the γ present above 723 °C is not present below this temperature. What has happened is that it has transformed into a mixture of ferrite and Fe_3C; the mixture is called *pearlite.* A schematic of the steel microstructure at a temperature slightly below 723 °C is also provided in Fig. 28. Such a microstructure is representative of "garden variety" or *ferritic-pearlitic* steels.

Properties of ferritic-pearlitic steels depend on composition (i.e., they depend upon how much pearlite the steels contain). The pearlite *microconstituent* of the steels is harder than ferrite, so the strengths of ferritic-pearlitic steels increase with carbon content. A hot-rolled ferritic-pearlitic steel containing about 0.10 wt% C contains about 10% pearlite, and its yield strength is on the order of 275 MPa (25 ksi). By contrast, a 0.80 wt% C hot-rolled steel, which is fully pearlitic, has a yield strength in the range of 450 MPa (65 ksi). Piano wire is a fully pearlitic steel, although its high strength derives primarily from the extensive cold work accompanying its production.

Microalloyed steels are a fairly recent development. They are quite a bit stronger than conventional ferritic-pearlitic steels. Microalloyed steels contain small amounts (about 0.1% by weight) of strong carbide forming elements (e.g., niobium or vanadium). These elements form carbides more readily than iron does; the alloy carbide particles serve to refine ferrite grain size. When processed optimally, a considerable grain size reduction is obtained in microalloyed steels, and since iron can be substantially hardened by grain size reductions, yield strengths of microalloyed steels are high. For example, σ_y of a 0.10 wt% C microalloyed steel is on the order of 550 MPa (80 ksi). This is much higher than the yield strength of a conventional ferritic-pearlitic steel of the same carbon content.

Quenched and tempered steels are very strong. To understand their behavior, we refer to the iron-carbon phase diagram, with a 0.40 wt% C steel again serving as an example. This alloy is heated into the single-phase γ region, as before. However, rather than being slowly cooled, the steel is rapidly *quenched* to room temperature. The quenching prevents the precipitation of α and Fe_3C; the situation is analogous to quenching of solutionized aluminum age-hardenable alloys. There is a fundamental difference with iron-carbon alloys, though. Iron undergoes an allotropic transformation, from fcc to bcc, on cooling. Iron-carbon alloys also can undergo such a transformation. Indeed, when a 0.40 wt% C alloy is quenched rapidly enough to suppress the equilibrium reactions, at a critical undercooling (the temperature of which decreases with increasing carbon content), the fcc structure spontaneously transforms into an essentially bcc one. The transformation takes place by shear absent diffusion. Because of this feature, the transformation is termed a *martensitic* transformation.

Steel martensites are not truly cubic; they are a slightly distorted (tetragonal) form of this structure. However, this alteration is not what causes ferrous martensites to be so strong. One factor is that the carbon content of the martensite is the same as that of its parent austenite, and well in excess of the equilibrium solubility of carbon in bcc iron. This produces substantial solid-solution hardening; the large effect is due to the carbon atoms residing in interstitial sites (this causes the tetragonal distortion), and these atoms interfere markedly with dislocation motion. In addition, a slight volume increase accompanies martensite formation. The accompanying deformation generates a high dislocation density in as-quenched martensite, similar to what is found in cold-worked metals. Finally, twins are present in some quenched martensites. They strengthen the material in a manner similar to (but not as effectively as) grain boundaries. Thus, quenched martensite is strengthened by a combination of solid-solution, dislocation, and twin boundary hardening.

While yield strengths of quenched martensites are high, these materials cannot be effectively used, because they are quite brittle and prone to fracture. Quenched martensites can be rendered more useful by *tempering* them. During tempering, the steel is heat treated in much the same way that aluminum alloys are aged, and somewhat comparable microstructural changes take place during tempering. For example, carbide particles precipitate, and the dislocation density is also reduced. There is an important distinction between aging aluminum alloys and tempering martensite, though. Tempering results in a strength reduction. That is, the strength decrease accompanying the lessened carbon solid-solution hardening is greater than the strength increase arising from carbide precipitation. This is opposite to the effect found on aging aluminum alloys.

Tempering occurs gradually. The matrix composition gradually approaches equilibrium as the carbide particles precipitate, grow, and coarsen. Tempering is usually interrupted before equilibrium is reached, and *tempered martensite* results, which combines high strength (often on the order of 1380 MPa, or 200 ksi, or higher) and reasonable fracture

toughness. Tempered martensites find application in highly stressed components, such as automobile drive shafts and aircraft landing gears. Extended tempering of quenched martensite yields a structure called *spheroidite.* The phases present in spheroidite (α and Fe_3C) are the same as in ferritic-pearlitic steels. However, the shape of Fe_3C is spherical in spheroidite. This feature renders spheroidites tougher than ferrite-pearlite mixtures of the same carbon content, but spheroidite is not nearly as strong as tempered martensite.

Quenched martensite is a necessary precursor to tempered martensite. Thus the steel must be rapidly cooled from the γ region if martensite is to form. Martensitic surfaces are almost always obtained by quenching. However, the structure that forms in the interior of the material is another question. Large-diameter sections experience a moderate cooling rate in their interiors, regardless of how rapidly their surfaces might be cooled, and the section interior is thus likely to have a ferritic-pearlitic structure. In fact, with plain carbon steels (i.e., those containing only carbon and manganese as alloying additions), the centers of even fairly thin pieces are ferritic-pearlitic. Alloying elements are added to steels to improve their *hardenability* (i.e., the propensity for forming martensite during cooling). Elements such as chromium, molybdenum, and nickel reduce the rate at which the diffusional transformations from γ to α and/or pearlite take place, but the added elements have minimal effect on the tendency to form martensite. Thus, these elements permit martensite to be formed in sections having respectable diameters, and such alloy steels are the ones used when strength is required throughout large sections. More extended discussion of structure-processing-property relationships in ferrous materials can be found in the article "Effects of Composition, Processing, and Structure on Properties of Irons and Steels" in this Volume.

Low-Temperature Strengthening of Polymers

Long-chain molecules are the basic units in thermoplastics. Intrachain bonding in them is covalent, but interchain bonding is of the weak van der Waals type. As a consequence, thermoplastic permanent deformation takes place by chain sliding. Strengthening of thermoplastics, therefore, comes about by making chain sliding more difficult.

A simple way of strengthening thermoplastics is to make the side groups more "bulky." This produces a "steric" (geometric) hindrance to chain sliding. Thus, in the polymeric series based on the monomer C_2H_3R (where R is a radical), strength increases almost directly with side-group size. Polyethylene (R = H) is the weakest of this series, polypropylene (R = CH_3) is stronger than polyethylene, and polystyrene (R = C_6H_6) is stronger still. Another thermoplastic series, based on monomers with composition $C_2H_2R_1R_2$, is generally stronger than the series having R_1 = H. For example, polyvinylediene chloride ($R_1 = R_2$ = Cl) is stronger than polyvinyl chloride (based on C_2H_3Cl).

Crystalline polymers are stronger than noncrystalline ones. The higher density of the crystalline form signifies that the polymer chains are closer together, and this makes relative chain displacement more difficult. This is put to advantage in strengthening polyethylene by increasing the percentage of crystalline material within it. However, polyethylene is atypical in this respect. Most thermoplastics are difficult to crystallize because of their bulkier side groups and greater viscosities.

Some techniques used to strengthen metals also strengthen thermoplastics. When extensively drawn, thermoplastics are strong, remarkably so when taking into account their low densities. Table 4 compares some properties of both organic and inorganic filaments. Unfortunately, such strengths are realized only in filament form; such filaments are the backbone of the carpet and fabric industry. It is an oversimplification to consider polymer filaments as having been "work hardened." During drawing, the long axes of the polymer chains align along the draw direction. Thus when the final filament size is attained, filament strengths reflect the strength of the intrachain covalent bonds and are not a measure of resistance to interchain sliding.

Table 4 Strengths of selected filaments and fibers

Material class	Material	Density (ρ), Mg/m^3	Tensile strength (TS)		TS/ρ, MNm/kg
			GPa	**ksi**	
Metals	Pearlitic steel (piano wire)	7.9	4.2	610	0.53

	Be	1.8	1.3	190	0.72
	W	19.3	3.9	570	0.20
Ceramics	Al_2O_3	3.96	2.0	290	0.51
	Graphite (Kevlar)	1.5	2.8	410	1.87
	S Glass	2.5	6.0	870	2.4
	SiC	2.7	2.8	410	1.04
Polymers	Nylon 66	1.1	1.05	150	0.95
	Polyamide-hydrazide	1.47	2.4	350	1.63
	Copolyhydrazide	1.47	2.7	390	1.84
	Poly (p-phenylene) terephthalamide	1.44	2.8	410	1.94

Source: Ref 4

There is minimal polymer analog to solid-solution strengthening, for solid solubilities between polymers are almost always quite limited. (That is one reason polymer recycling is a problem.) An exception occurs when polymers are strengthened by "rigid rod molecules." These molecules, having a stiff "backbone," reinforce the polymer when dispersed in it, in much the same way that fibers reinforce composite materials. In fact, most engineered polymers are one class of composite or another. Metals and ceramics also can be reinforced in composite form.

Composite Materials

Composites are mixtures (blends) of two or more materials having significantly different characteristics. The resulting composite properties are a suitable "average" of the component properties.

Most commercially important composites are polymer-based. The polymer matrix is typically a thermoset, rather than the thermoplastics discussed to this point. Thermosets and thermoplastics differ molecularly. Specifically, thermosets form by a reaction between different chemical species. (The reader may be familiar with setting of epoxy resins, which are thermosets.) The resulting molecular architecture displays a "skeleton-like" array of primary bonds that join the chemical species of the thermoset. Unlike thermoplastics, thermosets are incapable of permanent deformation. Bakelite is probably the most well-known thermosetting plastic.

Thermoset composites are made by adding a reinforcement to the thermoset during or prior to its setting. Strong glass fibers (Table 4) are a common reinforcement. The thermoset serves as a matrix "glue," bonding the fibers together. Glass is also prone to react with water vapor in air. This induces corrosive surface flaws that act much like surface cracks in reducing the glass fracture strength. The polymer matrix also protects the glass-fiber surfaces from this degradation.

Other fibers, even stronger and stiffer, can also reinforce polymers. Various forms of graphite fibers (Table 4) display impressive strengths. Among other uses, graphite-reinforced polymers have application as sporting goods, such as tennis rackets, squash rackets, and golf club shafts. Because of their low densities, polymeric composites have also made inroads in the aerospace industry, where weight considerations are paramount.

As mentioned above, composite properties are some "average" of component properties. Often the average is a volume-weighted one. For example, the volume-fraction rule for the tensile strength of a fiber-reinforced composite is often approximated by:

$$(TS)_c = v_f\,(TS)_f + (1 - v_f)\,(TS)_m \qquad \textbf{(Eq 15)}$$

where $(TS)_c$ is the tensile strength of the composite, $(TS)_f$ and $(TS)_m$ are the corresponding fiber and matrix tensile strengths, and v_f and $(1 - v_f)$ are the respective fiber and matrix volume fractions in the composite. Equation 15 applies when the long axes of the fibers are aligned with the stress axis. When the fibers are randomly dispersed, composite strength is less than that given by Eq 15. A lesser strength is also found when the reinforcement shape is particulate, rather than fibrous.

Expressions similar to Eq 15 are used to estimate other composite properties, such as the elastic modulus. However, not all composite properties lend themselves to such a simple formulation. Fracture toughnesses, for example, are not expressed by a volume-fraction rule, although the formulations for toughness do incorporate component toughnesses.

Composites with metal and ceramic matrices are also available, but they are far more expensive than polymeric composite. Metals can be reinforced by ceramic particles or fibers. Examples include aluminum reinforced with SiC particles or graphite fibers. Metal strengths are increased by such reinforcement, but at the expense of fracture toughnesses.

When metals reinforce ceramics, toughness is increased, but usually at the expense of strength. The increased toughness arises because the imbedded metal blunts and/or arrests matrix cracks. Reinforcement shape plays a role in toughening. Fiber- and plate-shaped metal reinforcements generally improve toughness more than equiaxed particles. When cracks approach fibers or plates, especially when the long axis of the fiber or plate is parallel to the stress axis, cracks often deflect along the reinforcement-matrix interface. This provides additional fracture work and a concurrent increase in fracture toughness.

Because of their cost, metal and ceramic composites have not yet made substantial commercial inroads. This especially pertains to composites intended for room-temperature use. However, since polymers have limited high-temperature capacity, metal and ceramic composites might find high-temperature application.

Additional information on structure-property relationships for composite materials is provided in the article "Effects of Composition, Processing, and Structure on Properties of Composites" in this Volume.

Microstructure and High-Temperature Strength

Materials are made stronger at high temperature by increasing their resistance to both time-dependent plastic deformation (creep) and time-independent plastic deformation. For most high-temperature design, preventing or minimizing creep deformation is paramount.

Equation 5, the relation between material flow stress and strain rate, can be rearranged as:

$$\dot{\varepsilon} = K' \sigma^{m'} \qquad \textbf{(Eq 16)}$$

where m' is equal to $1/m$ of Eq 5, and K' is related to K of Eq 5 by $K' = K^{-1/m}$. Equation 16 can be written in a different form, one providing clarity in later discussion:

$$\varepsilon' = AD\,[\sigma/G]^{m''}\,[\sigma\Omega/kT]\,[b/d]^{n'} \qquad \textbf{(Eq 17)}$$

where Ω is the atomic volume (on the order of b^3, where b is the atomic diameter), k is Boltzmann's constant, T is the absolute temperature, A is a material constant, G is the shear modulus, D is a diffusion constant, d is the grain diameter, and n' is an exponent reflecting the effect of grain diameter on creep rate.

Equation 17 represents the creep rate due to a particular creep mechanism. As discussed below, there are several independent creep mechanisms, and the net creep rate is the sum of the creep rates of all of them. However, at a specific stress-temperature combination, one mechanism usually displays a creep rate much greater than the others, and the total creep rate is then well approximated by this maximum rate. However, a different mechanism might dominate at a different stress-temperature combination. The result is that m'' and n' in Eq 17 can change with changes in stress and temperature.

Equation 17 appears complicated at first glance. Application of it can be illustrated with a simple example, viscous flow of glasses. Since glasses are noncrystalline, $n' = 0$. Moreover, $\dot{\varepsilon}$ varies linearly with stress for a viscous glass, so m'' is also zero. The strain rate/stress relationship for a viscous glass is conventionally written as:

$$\dot{\varepsilon} = \sigma/3\eta \qquad \textbf{(Eq 18)}$$

where η is the glass viscosity. Equating Eq 17 and 18, we have:

$$\eta = kT/3AD\Omega \qquad \textbf{(Eq 19)}$$

The relation between viscosity and diffusivity of Eq 19 is consistent with theories of viscosity derived from chemical reaction rate principles.

The appearance of diffusivity in a creep rate equation indicates that high-temperature deformation involves atomic motion. Indeed, for the viscous flow just discussed, deformation comes about solely by diffusion, although to be sure the flow is prompted by an applied stress. Crystalline materials can also diffusionally creep. The situation is illustrated in Fig. 29. The applied stress locally increases the atomic volume in the vicinity of the crystal faces so stressed, resulting in a higher vacancy concentration in the region. The excess vacancies diffuse to the sides of the crystal not stressed, and this is accompanied by diffusion of mass in the opposite direction. Thus mass is transferred from the sides of the crystal grain to the top and bottom crystal faces; the result is that the material extends (creeps) in the direction of the applied stress. While Fig. 29 indicates that diffusion takes place within the crystal volume, the mass flow can also occur along the crystal faces (or the crystal grain boundaries in a polycrystal).

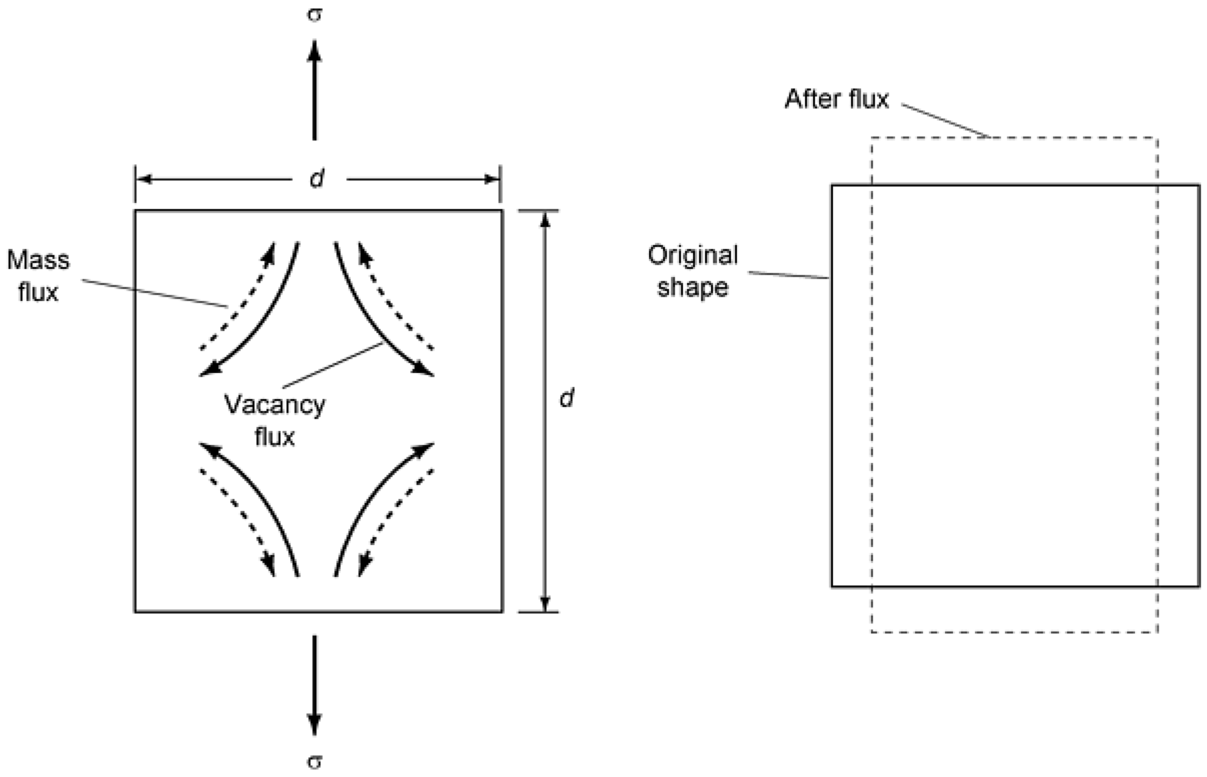

Fig. 29 Diffusional creep results from a higher vacancy concentration in regions of a material that experience a tensile stress compared to regions that do not. This results in a vacancy flux from the former to the latter areas, and a mass flux in the opposite direction. This extends the material, as indicated on the right of this figure. Mass can flow through the grain interior (as indicated here) or along grain boundaries. Source: Ref 4

Grain size plays a role in creep of crystalline solids, at least under stress-temperature combinations at which creep takes place by a mechanism of the kind just discussed. The finer the grain size, the more rapid the mass transport causing permanent deformation. Thus under conditions where creep is solely due to diffusional flow, creep resistance is improved by increasing the grain size of a material. Note that this is different from low-temperature behavior, where a fine grain size is beneficial to strength.

The grain size dependence of diffusional creep depends on whether mass is transported through the crystal volume or along grain boundaries. For the latter (*Coble creep*), n' in Eq 17 is 3. When mass transport is through the crystal volume (*Nabarro-Herring creep*), n' is 2. The different grain size dependencies indicate that, other things being equal, Coble creep should dominate creep in fine-grain materials. The Coble and Nabarro-Herring creep diffusion coefficients also are different, because of the different diffusion paths of the atoms. This results in Nabarro-Herring creep dominating at higher temperatures, and Coble creep dominating at lower temperatures. The temperature at which the transition between the mechanisms takes place is grain size dependent; it is higher the finer the grain size.

Diffusional (Coble and/or Nabarro-Herring) creep dominates creep at relatively low stresses, low enough so that dislocation motion plays no role in creep. At higher stresses, dislocation motion in conjunction with diffusion causes creep. Figure 30 simply portrays the idea. Here dislocations encounter, and pile up against, a slip-plane obstacle. The applied stress is insufficient to enable the dislocations to bow around, or glide through, the obstacle. However, a dislocation may climb by diffusion to a parallel slip plane. Having climbed, the dislocation proceeds along the new slip plane until it encounters another resistant obstacle, whereupon it climbs (or descends) to another parallel plane and the process repeats. Since dislocation motion depends on both dislocation glide and climb, *climb-glide* creep is used to describe this form of creep. Climb-glide creep depends more strongly on stress than does diffusional creep; m'' ranges from 2 to about 5 in many cases, but sometimes it is substantially more. (The variation arises from the different paths that dislocations take in bypassing obstacles, as well as other microstructural features.) Because of the manner in which the creep rate depends on stress, *power law creep* is another term used to describe this form of creep.

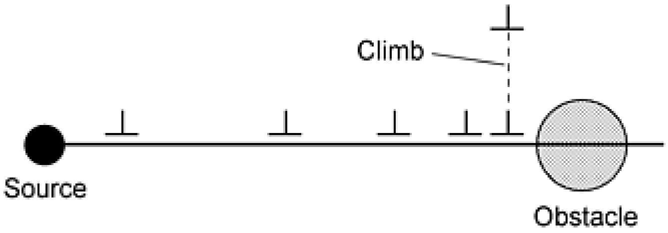

Fig. 30 Schematic representation of the climb of a dislocation that has encountered an obstacle in its slip plane. The "source" noted on the left of the figure represents a region in the material in which dislocations are generated. Source: Ref 10

The dominant creep mechanism at a specific stress-temperature combination is found by calculating the creep rate for the several mechanisms and determining the maximum such rate. Although the net creep rate is the sum of the several rates, the maximum one is usually much greater than the others. Deformation mechanism diagrams having axes of stress and temperature can be used to display the results of such calculations. Regions in the diagram delineate stress-temperature combinations for which a given creep mechanism dominates. Of course, to construct the diagrams the appropriate ancillary data (diffusion coefficients, grain size, etc.) must be available.

Design against creep can take several approaches. It makes sense to use a material with a high melting temperature in high-temperature applications, since to a good approximation, diffusion coefficients (on which $\dot{\varepsilon}$ depends) scale with homologous temperature (T/T_m, where T is temperature and T_m is the melting temperature of the material, both in K). There are exceptions to this generality, though. Face-centered cubic metals generally have superior creep resistance to bcc metals at equivalent homologous temperatures, because the slightly more open bcc structure results in slightly greater diffusivities.

Design against creep may also involve first determining the dominant creep mechanism. If diffusional creep dominates, then increasing material grain size is a beneficial structural alteration. If, on the other hand, power law creep dominates, no improvement in material performance is likely to result from such a change. Further, for diffusional creep, improved creep resistance can sometimes be had by placing inert particles on grain boundaries. This increases the effective grain boundary "viscosity," leading to improved creep behavior.

Example: Structure-Property Relationships in Nickel-Base Superalloys for High-Temperature Applications.

Nickel-base superalloys find application as turbine blades in engines operating at temperatures as high as 1300 °C (T/T_m = 0.9). The microstructure consists of fine Ni_3Al particles dispersed in an fcc nickel-rich solid solution. These alloys are remarkably resistant to particle coarsening, a big plus, owing to a low matrix-particle surface energy. Solid-solution hardening is also used to strengthen the matrix, and when used in polycrystalline form, inert particles (e.g., carbides) may be dispersed on the material grain boundaries. Increases in engine operating temperatures over the last 50 years have been gradual but significant; from about 400 °C to the above-noted 1300 °C. This increase in operating temperature, of course, translates into improved engine efficiency. Improved high-temperature material properties are largely responsible for the increase in the engine operating temperature. Some improved material performance has come about from minor alterations in alloy chemistry. Some has resulted from processing changes. For example, the major stress axis in a turbine blade is parallel to the blade axis. In a polycrystalline blade, this stress is normal to some grain boundaries, and this causes voids, precursors to fracture, to initiate on the boundaries. Directional solidification (i.e., solidifying the material sequentially from the blade bottom to its top) results in columnar grains having boundaries aligned along the blade axis. This significantly reduces the cavitation problem. Further improvements came with the casting of single-crystal blades. Increasing the superalloy grain size from 100 μm to 1 cm (the order of the thickness of a turbine blade) reduces the creep rate by about six orders of magnitude when Coble creep is the creep mechanism, as it often is under typical blade operating conditions. Such a reduction in creep rate then permits operation at a higher temperature and/or stress.

Microstructure and Low-Temperature Fracture

As described in the section "Evaluation of Mechanical Properties" in this article, design against fracture uses the fracture toughness (K_{Ic}) to determine a safe operating stress. Since K_{Ic} is related to toughness (G_{Ic}), as shown in Eq 9, the features that make a material resistant to crack growth culminating in fracture can be elucidated by discussion of G_{Ic}.

Figure 31 is a sketch of "what happens" in front of a crack. The situation pertains to a material with reasonable capacity for plastic deformation. The stress concentration in front of the crack causes plastic yielding there. In turn this causes crack tip "blunting," such that an initially sharp crack with crack-tip radius of curvature on the order of the atomic size assumes a much greater radius of curvature.

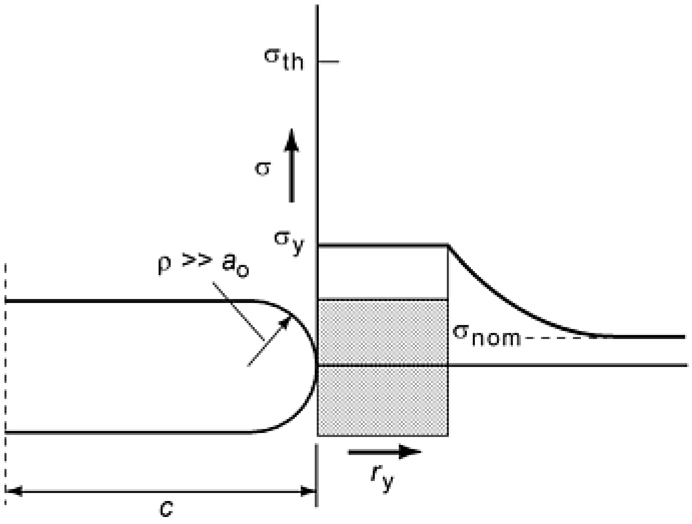

Fig. 31 Schematic of the situation in front of a crack tip in a moderately ductile material. Because of the stress concentration, the material yields plastically in front of the crack tip. Concurrent with yielding, the crack tip is blunted. Source: Ref 4

How much work (G_{Ic}) is done during crack propagation? First, there is the work associated with the formation of the fracture surfaces. But in other than very brittle materials, this is much less than that coming from crack-tip plastic deformation. The tensile work to fracture (per unit volume) is given by the integral of the true stress/true strain curve. Thus, we surmise that the corresponding crack-tip work is also likely related to the product of a strength and a fracture strain which, for convenience, we take as the yield strength (σ_y) and the true fracture strain (ε_f). The units for the product of stress and strain are J/m^3. If this product is multiplied by a length, the units are J/m^2, the same as those of G_{Ic}. If ρ is taken as the effective length of the material undergoing crack tip plasticity, we can sensibly write:

$$G_{Ic} = C\,\sigma_y \varepsilon_f\,\rho \qquad \textbf{(Eq 20)}$$

The constant C in Eq 20 takes into account that the stress state near the crack tip is not the same as in a tensile test, so that the corresponding yield strength and fracture strain are also not the same as those found in a tensile test. The important

point is that toughness scales with flow stress and ductility. In addition, crack-tip blunting (manifested in the length, ρ) is related to ductility. The greater the ductility, the more extensive this blunting.

Material toughnesses vary widely due to variations in material strengths and ductilities. As a rule, increasing σ_y reduces G_{Ic} because of the associated ductility reduction. In terms of toughness, the lessened ductility more than compensates for the strength increase because of the additional effect that ductility has on crack blunting. (However, since K_{Ic} scales with E as well as G_{Ic}, a stiff material will have a greater fracture toughness than a pliable one at an equivalent G_{Ic}.)

Toughnesses range from as high as 10^7 J/m^2 (for tough metals) to as low as about 0.5 J/m^2 (for room-temperature glass). Above their ductile-to-brittle transition temperature, body-centered cubic transition metals and alloys have high toughness. Below this temperature their yield strengths are strongly temperature dependent, and this is accompanied by a substantial ductility reduction. The result is that low-temperature toughnesses of these metals are only on the order of 100 J/m^2. This is still high compared to typical values of G_{Ic} for ceramics (on the order of 30 J/m^2). Since there is usually some (limited) crack-tip deformation in ceramics, their toughnesses exceed that of glass, for which G_{Ic} arises solely from the fracture surface energy. No plastic deformation accompanies room-temperature crack propagation in glass, and the crack-tip radius is on the order of the atomic diameter.

As implied, G_{Ic} (and, therefore, K_{Ic}) is temperature dependent, reflecting the temperature variation of σ_y and ε_f. Yield strengths are not very temperature sensitive for fcc metals and alloys, and G_{Ic} and K_{Ic} are only mildly temperature dependent for this material class as a result. This is not so for structural bcc metals, which manifest a strong temperature dependence of σ_y, as discussed above. Their low-temperature increase in σ_y is accompanied by a heterogeneous pattern of plastic deformation that disproportionately reduces ductility. The result is a sharp temperature sensitivity to G_{Ic} and K_{Ic}. Indeed, the ductile-to-brittle transition in bcc metals often takes place over a narrow temperature range. Results from impact tests mirror this effect. Some ceramics, such as ionic salts, display somewhat similar behavior. Salt transition temperatures, though, (e.g., 650 K for NaCl) are generally higher.

Fracture may take place in essentially "flaw-free" materials; flaw-free meaning here that preexisting crack sizes are too small to cause material fracture. Virgin glass fibers, before they detrimentally interact with the environment, are essentially flaw-free, and their strengths border on the stress needed to rupture atomic bonds. Crystalline solids prone to brittle fracture seldom exhibit such high strengths. When their flaws are of a size less than about the grain diameter, heterogeneous plastic deformation precedes fracture. The "misaccommodation" between plastically deforming and nondeforming regions produces a stress concentration sufficient to nucleate a crack. Lengths of these cracks are on the order of the grain diameter; so this parameter substitutes for crack length in calculation of σ_F (Eq 8). Similar considerations apply to ceramics, but in this instance the misaccommodation often arises from a lack of slip systems (see the section "Crystalline Defects" in this article). For both flaw-free bcc metals and ceramics, σ_F increases with decreases in grain size.

What microstructural alterations might improve fracture toughness? We know that reducing σ_y almost invariably increases K_{Ic}. However, there is a limit to the usefulness of strength reduction for this purpose; too low a value of σ_y means that design is concerned with preventing plastic deformation rather than fracture (Fig. 25). Thus, there are tradeoffs between toughness and strength. Toughness can be improved without significant reduction in strength through processing improvements. Examples include reducing nonmetallic phases (typically oxides, phosphides, etc.) in steels. These brittle inclusions reduce toughness because they fracture in front of the crack tip, causing "leap frogging" of the crack to the inclusion. Since the inclusions do not reduce σ_y, "cleaner" materials are tougher than "dirty" ones at the same strength levels. Furthermore, manipulation of the morphology of the phases in a two-phase material can have a significant effect on fracture toughness.

Ceramics are toughened to an extent by grain size reductions. However, fracture toughnesses of even fine-grained ceramics are only about 5 MPa$\sqrt{\text{m}}$ (4.5 ksi$\sqrt{\text{in.}}$). This can be compared to a "brittle" metal, for which K_{Ic} might be about 30 MPa$\sqrt{\text{m}}$ (27 ksi$\sqrt{\text{in.}}$). Low ceramic toughnesses have hampered their use. Recent advances have improved the situation somewhat. The ceramic ZrO_2 has several allotropic forms. When added as a particulate to other ceramics, ZrO_2 can impart toughness in the following way. The stress intensity at a crack tip is sufficient to induce an allotropic, martensitic transformation in the dispersed ZrO_2. The associated transformation work represents additional fracture work, increasing G_{Ic} and K_{Ic}. Toughening by this mechanism has raised K_{Ic} values of certain ceramics to about 16 MPa$\sqrt{\text{m}}$ (14 ksi$\sqrt{\text{in.}}$). While this is still low, it is approaching a range where, with appropriate care, ceramics could be used in more demanding situations.

Composite toughening has been discussed in the section "Composite Materials" in this article. Only a few additional comments are necessary here. Toughening a ceramic by dispersing a ductile phase within it decreases σ_y while improving fracture resistance. The additional fracture work due to the particles depends on the crack path taken. If the ductile phase fractures in the wake of a propagating crack, the ductile phase fracture work adds to G_{Ic}. If, on the other hand, cracks deflect along the dispersed phase-matrix interfaces, the energy associated with generating these interfaces represents the increment in G_{Ic}.

Toughnesses of thermoplastics are not impressive, even though their malleabilities may be great. This is a result of the comparatively low strengths and moduli of thermoplastics. This does not mean that thermoplastics cannot be used in applications calling for "tough" materials. For example, Lexan (a polycarbonate) is used as protective equipment in contact sports such as football and hockey. Finally, even at temperatures below their glass transition temperatures, thermoplastics have fracture toughnesses much greater than those of inorganic glasses.

Microstructure and High-Temperature Fracture

Creep fracture occurs as follows. Internal voids first nucleate during creep deformation and then grow. When the void volume fraction reaches a critical level, fracture takes place. The voids that are precursors to fracture may reside within grains or, as is more common, along grain boundaries. The accelerating creep rate prior to fracture (Stage III creep; Fig. 21) is often a manifestation of void presence.

Void nucleation is not fully understood. However, it comes about as a result of strain "misaccommodation" of the same nature that causes crack nucleation in some low-temperature fracture. For the high-temperature case, two adjacent grains might have inherently different creep rates. If the rates cannot be made to match, a gap forms between the grains. Higher steady-state creep rates cause voids to form earlier on during creep.

While details of void nucleation remain murky, void growth is not. Voids grow by the same mechanisms that cause creep deformation. Thus an important conclusion: any material alteration that leads to a lower creep rate also improves creep fracture resistance. Note the distinction to low-temperature mechanical behavior, where increases in strength reduce fracture resistance and vice-versa.

One serious issue, extrapolation of short-time experimental results to long-time service situations, arises in high-temperature design. As described above, stress versus time to fracture tests are conducted at stress-temperature combinations for which failure occurs in "reasonable" times. However, intended high-temperature lives are frequently much longer. That is, materials are used at lower stresses and/or temperatures than those employed for laboratory assessment. Suitable means for extrapolating laboratory results must therefore be utilized.

A common extrapolation technique uses the Larson-Miller (LM) parameter (Fig. 32). The data displayed in Fig. 32(a) come from laboratory tests that measured creep fracture times over a range of stress and temperature; they are summarized as a plot of the (logarithm of) applied stress versus (logarithm of) the fracture time. The LM parameter is defined as:

$$\mathrm{LM} = T(\log t_f + C) \qquad \textbf{(Eq 21)}$$

where $\log t_f$ is log (to the base 10) of the fracture time (in hours), T is the absolute temperature, and C is a constant having a value close to 20. An LM diagram is constructed by plotting the stress logarithmically versus LM, and the constant C is

determined by curve fitting. Results of such a procedure are shown in Fig. 32(b). Note that all data fall within a narrow scatter band, regardless of the test temperature. Curves like that in Fig. 32(b) are then used for extrapolation.

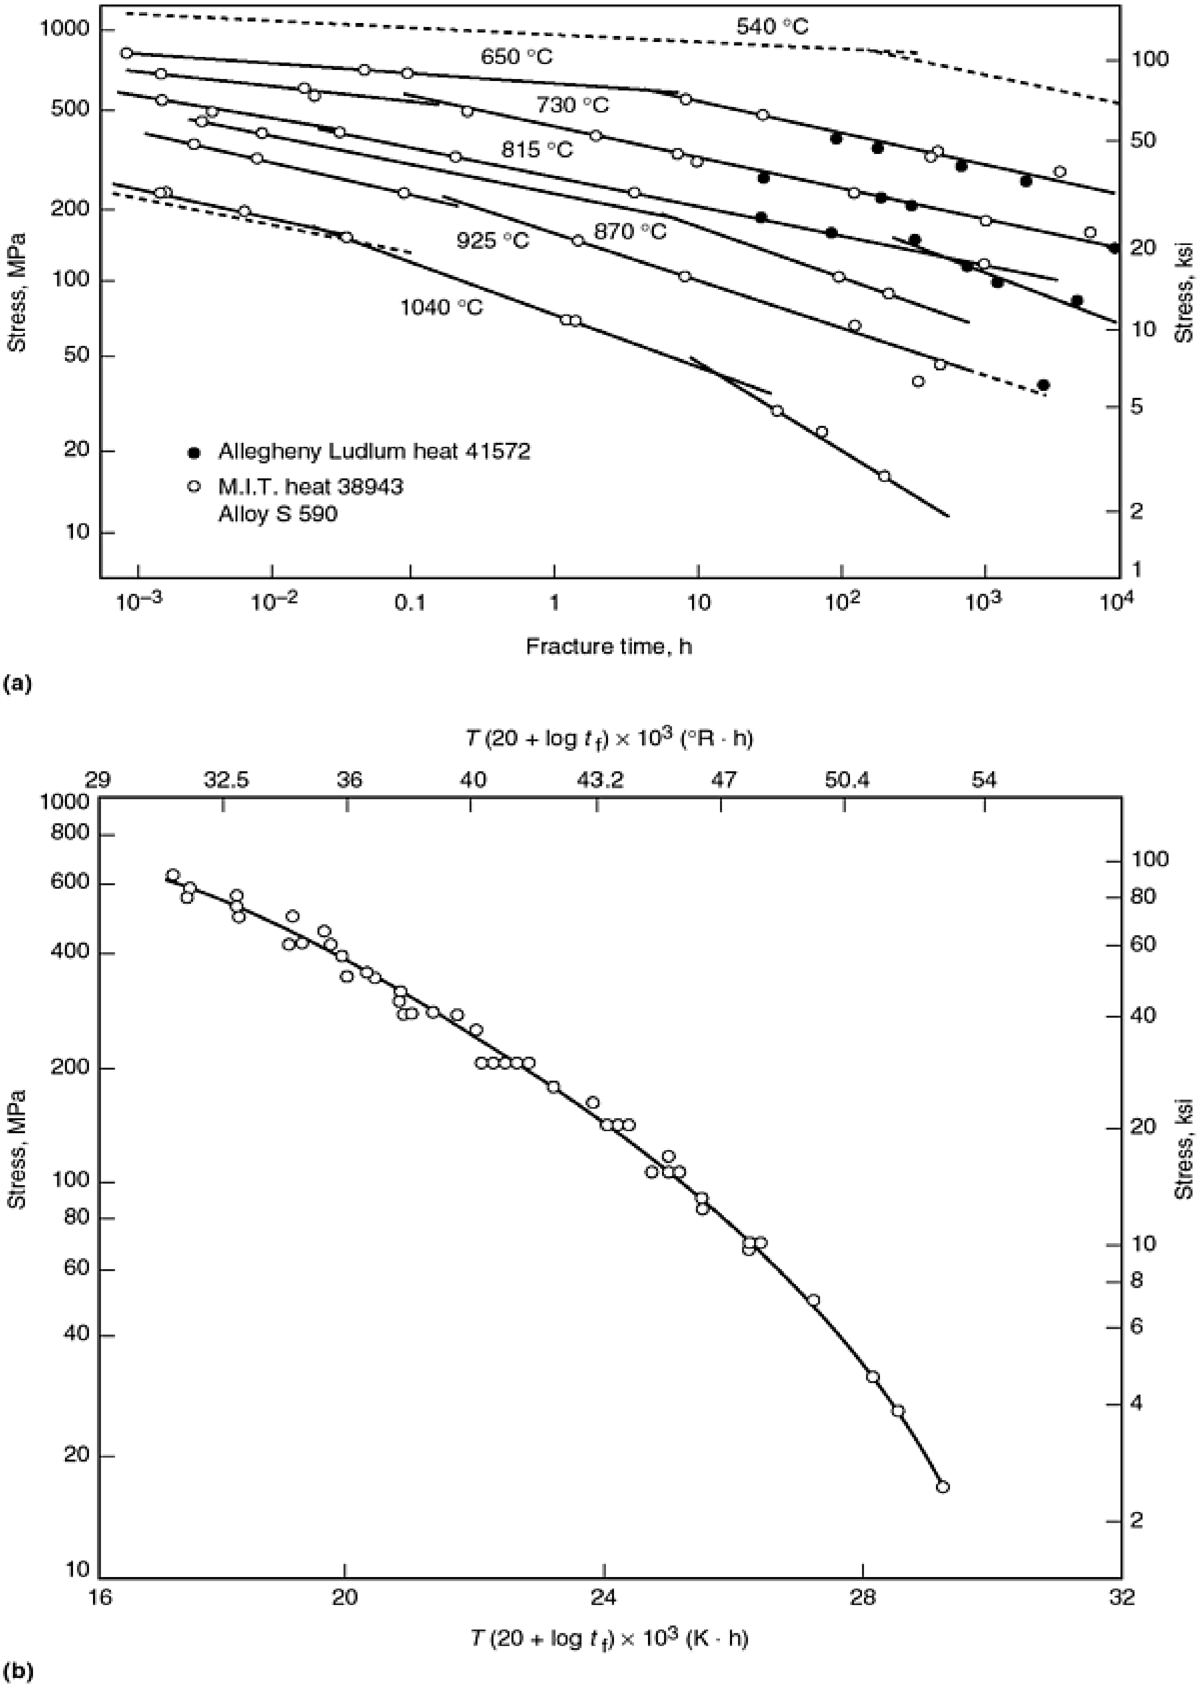

Fig. 32 (a) Stress-creep fracture times for an iron-base alloy at different temperatures. Source: Ref 11. (b) Larson-Miller master plot of the same data. This diagram permits fracture times to be estimated at stress-

temperature combinations other than those illustrated in (a). Source: Ref 12

Some caution is required when extrapolating to lower stresses, the usual situation. In particular, there are often changes in dominant creep mechanism (e.g., from power-law to diffusional creep) when stress is lowered. When this is so, fracture times estimated via the LM technique are greater than they actually are. Thus the procedure is not conservative. However, considerable engineering practice, coupled with appropriate safety factors, permits the LM procedure to be usefully employed in high-temperature design. Further information on high-temperature material design is given in the article "Design for High-Temperature Applications" in this Volume.

Microstructure and Fatigue Failure

Fatigue is the most consternating of material failures. It has been estimated that somewhere on the order of 85% of identifiable metallic failures involve fatigue. Design against fatigue is an overriding concern in many aerospace applications, but any component that experiences a time-varying stress is potentially prone to fatigue failure. Examples include automotive drive shafts, springs, and rotating parts. Even bridges fatigue. "Old" bridges were designed to statically support their weight plus that of the bridge traffic. This approach was successful; static collapse of a bridge is rare. Yet the recent spate of bridge failures in the United States shows that the slight load fluctuations on bridge structural components (often in combination with corrosive effects) can cause structural failure after decades of service and many millions of load cycles.

The processes leading to fatigue failure are as follows. Surface or interior imperfections (a machining mark, for example, or perhaps a material inclusion) produce stress concentrations that, under the action of a cyclical stress, nucleate a crack. The crack then slowly grows until it attains a size at which the material "fast fractures." The relation between the maximum applied cyclical stress and the crack length at fracture is given by Eq 8 (i.e., fast fracture is defined by fracture mechanics).

The distance the crack advances per stress cycle during slow growth is related to a parameter ΔK:

$$\Delta K = A\,(\Delta\sigma)(c)^{1/2} \qquad \textbf{(Eq 22)}$$

where $\Delta\sigma$ is the algebraic difference between the maximum and minimum applied stress (the stress range) and A is a material constant. Thus, ΔK is to fatigue crack growth as the stress intensity factor is to fast fracture.

Slow crack growth rates are readily measured, and the relationship between these rates and ΔK can thereby be determined. Were the vast majority of material life to lie within the slow crack growth regime, it would then be a simple matter to determine fatigue life. Unfortunately, this situation pertains only to *low-cycle fatigue* (i.e., to fatigue taking place at high stress ranges). For *high-cycle fatigue,* most of the life is spent in crack nucleation. Materials can therefore be made more resistant to high-cycle fatigue by delaying crack nucleation. Since many fatigue cracks initiate on surfaces, surface hardening can be beneficial. Surfaces of ferrous materials can be case hardened (i.e., their surfaces made to contain more carbon than their interiors) or martensitically hardened. Ferrous and other metals can also have their surfaces hardened by cold working. "Shot peening," in which the surface is bombarded by small hardened balls that plastically deform it and additionally induce beneficial residual compressive stresses, is one way of accomplishing this.

As with design against static fracture, fatigue design often assumes that the material contains surface or interior cracks, and that some idea of their size is known a priori. Reasonable estimates on fatigue life can then be made using concepts described above. The difficulty is that if the sizes of fatigue cracks nucleated during service are greater than those to which preexisting cracks have grown at the time of this nucleation, the design process is not conservative. Regular inspection of cyclically stressed parts provides another means of preventing fatigue failures. Further information on design against fatigue is provided in the article "Design for Fatigue Resistance" in this Volume.

Effects of Composition, Processing, and Structure on Properties of Irons and Steels

Bruce L. Bramfitt, Homer Research Laboratories, Bethlehem Steel Corporation

Introduction

THE PROPERTIES of irons and steels are linked to the chemical composition, processing path, and resulting microstructure of the material; this correspondence has been known since the early part of the twentieth century. Figure 1 shows the route to attain properties. For a particular iron and steel composition, most properties depend on microstructure. These properties are called structure-sensitive properties, for example, yield strength and hardness. The structure-insensitive properties, for example, electrical conductivity, are not discussed in this chapter. Processing is a means to develop and control microstructure, for example, hot rolling, quenching, and so forth. In this article, the role of these factors is described in both theoretical and practical terms, with particular focus on the role of microstructure.

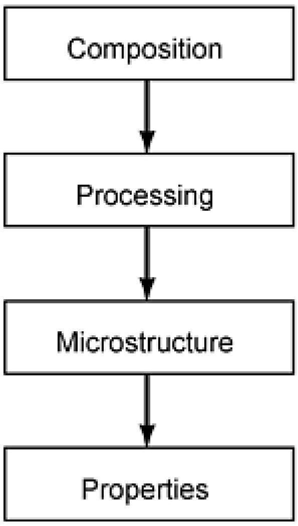

Fig. 1 Relationship among composition, processing, microstructure, and properties

Effects of Composition, Processing, and Structure on Properties of Irons and Steels

Bruce L. Bramfitt, Homer Research Laboratories, Bethlehem Steel Corporation

Basis of Material Selection

In order to select a material for a particular component, the designer must have an intimate knowledge of what properties are required. The composition, mechanical, and physical properties of most irons and steels can be found in the *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook,* and in Ref 1. The compositions of selected steels are listed in Tables 1, 2, 3, and 4 of this article. Mechanical properties are listed in Table 5. Consideration must be given to the environment (corrosive, high temperature, etc.) and how the component will be fabricated (welded, bolted, etc.). Once these property requirements are established the material selection process can begin. Some of the properties to be considered are:

Mechanical properties

- **Strength**
  - Tensile strength (ultimate strength)
  - Yield strength
  - Compressive strength
- **Hardness**
- **Toughness**
  - Notch toughness
  - Fracture toughness
- **Ductility**
  - Total elongation
  - Reduction in area
- **Fatigue resistance**

Other properties/characteristics

- Formability
  - Drawability
  - Stretchability
  - Bendability
- Wear resistance
  - Abrasion resistance
  - Galling resistance
  - Sliding wear resistance

Adhesive wear resistance
Machinability
Weldability

Source: Ref 1

(a) The following notes refer to boron, copper, lead, and silicon additions. Boron: standard killed carbon steels, which are generally fine grain, may be produced with a boron treatment addition to improve hardenability. Such steels are produced to a range of 0.0005 to 0.003% B. These steels are identified by inserting the letter B between the second and third numerals of the AISI or SAE number, such as 10B46. Copper: when copper is required, 0.20% min is generally specified. Lead: standard carbon steels can be produced with a lead range of 0.15 to 0.35% to improve machinability. Such steels are identified by inserting the letter L between the second and third numerals of the AISI or SAE number, such as 12L15 and 10L45. Silicon: it is not common practice to produce the 12*xx* series of resulfurized and rephosphorized steels to specified limits for silicon because of its adverse effect on machinability. When silicon ranges or limits are required for resulfurized or nonresulfurized steels, however, these values apply: a range of 0.08% for maximum silicon contents up to 0.15% inclusive, a range of 0.10% for maximum silicon contents over 0.15 to 0.20% inclusive, a range of 0.15% for maximum silicon contents over 0.20 to 0.30% inclusive, and a range of 0.20% for maximum silicon contents over 0.30 to 0.60% inclusive. Example: maximum silicon content is 0.25%, range is 0.10 to 0.25%.

(b) Standard grades for wire rod and wire only.

(c) 0.15 to 0.35% Pb.

Table 2 Compositions of selected low-alloy steels

Small quantities of certain elements not specified or required are present; maximum contents of incidental elements are: 0.35% Cu, 0.25% Ni, 0.20% Cr, and 0.06% Mo; standard alloy steel may also be produced with 0.15 to 0.35% Pb and are identified with an L inserted between the second and third numerals of the AISI-SAE number (for example, 41L40)

(a) Electric furnace steel.

(b) Includes 0.10 to 0.15% V.

(c) Includes 0.15% minimum V.

(d) 0.0005 to 0.003% B.

Table 3 Compositions of selected stainless and heat-resisting steels

Compositions are maximum unless otherwise stated.

Source: Ref 1

(a) All values are estimated minimum values; type 1100 series steels are rated on the basis of 0.10% max Si or coarse-grain melting practice; the mechanical properties shown are expected minimums for the sizes ranging from 19 to 31.8 mm (0.75 to 1.25 in.).

(b) Most data are for 25 mm (1 in.) diam bar.

In the selection process, what is required for one application may be totally inappropriate for another application. For example, steel beams for a railway bridge require a totally different set of properties than the steel rails that are attached to the wooden ties on the bridge deck. In designing the bridge, the steel must have sufficient strength to withstand substantial applied loads. In fact, the designer will generally select a steel with higher strength than actually required. Also, the designer knows that the steel must have fracture toughness to resist the growth and propagation of cracks and must be capable of being welded so that structural members can be joined without sacrificing strength and toughness. The steel bridge must also be corrosion resistant. This can be provided by a protective layer of paint. If painting is not allowed, small amounts of certain alloying elements such as copper and chromium can be added to the steel to inhibit or reduce corrosion rates. Thus, the steel selected for the bridge would be a high-strength low-alloy (HSLA) structural steel such as ASTM A572, grade 50 or possibly a weathering steel such as ASTM A588. A typical HSLA steel has a ferrite-pearlite microstructure as seen in Fig. 2 and is microalloyed with vanadium and/or niobium for strengthening. (*Microalloying* is a term used to describe the process of using small additions of carbonitride forming elements--titanium, vanadium, and niobium--to strengthen steels by grain refinement and precipitation hardening.)

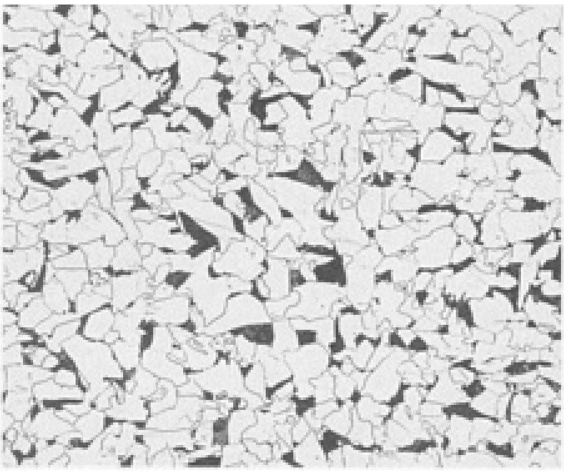

Fig. 2 Microstructure of a typical HSLA structural steel (ASTM A572, grade 50). 2% nital + 4% picral etch. 200×

On the other hand, the steel rails must have high strength coupled with excellent wear resistance. Modern rail steels consist of a fully pearlitic microstructure with a fine pearlite interlamellar spacing, as shown in Fig. 3. Pearlite is unique because it is a lamellar composite consisting of 88% soft, ductile ferrite and 12% hard, brittle cementite (Fe_3C). The hard cementite plates provide excellent wear resistance, especially when embedded in soft ferrite. Pearlitic steels have high strength and are fully adequate to support heavy axle loads of modern locomotives and freight cars. Most of the load is applied in compression. Pearlitic steels also have relatively poor toughness and cannot generally withstand impact loads without failure. The rail steel could not meet the requirements of the bridge builder, and the HSLA structural steel could not meet the requirements of the civil engineer who designed the bridge or the rail system.

Fig. 3 Microstructure of a typical fully pearlitic rail steel showing the characteristic fine pearlite interlamellar spacing. 2% nital + 4% picral etch. 500×

A similar case can be made for the selection of cast irons. A cast machine housing on a large lathe requires a material with adequate strength, rigidity, and durability to support the applied load and a certain degree of damping capacity in order to rapidly attenuate (dampen) vibrations from the rotating parts of the lathe. The cast iron jaws of a crusher require a material with substantial wear resistance. For this application, a casting is required because wear-resistant steels are very difficult to machine. For the machine housing, gray cast iron is selected because it is relatively inexpensive, can be easily cast, and has the ability to dampen vibrations as a result of the graphite flakes present in its microstructure. These flakes are dispersed throughout the ferrite and pearlite matrix (Fig. 4). The graphite, being a major nonmetallic constituent in the gray iron, provides a tortuous path for sound to travel through the material. With so many flakes, sound waves are easily reflected and the sound dampened over a relatively short distance. However, for the jaw crusher, damping capacity is not a requirement. In this case, an alloy white cast iron is selected because of its high hardness and wear resistance. The white cast iron microstructure shown in Fig. 5 is graphite free and consists of martensite in a matrix of cementite. Both of these constituents are very hard and thus provide the required wear resistance. Thus, in this example the gray cast iron would not meet the requirements for the jaws of a crusher and the white cast iron would not meet the requirements for the lathe housing.

Effects of Composition, Processing, and Structure on Properties of Irons and Steels

Bruce L. Bramfitt, Homer Research Laboratories, Bethlehem Steel Corporation

Role of Microstructure

In steels and cast irons, the microstructural constituents have the names ferrite, pearlite, bainite, martensite, cementite, and austenite. In most all other metallic systems, the constituents are not named, but are simply referred to by a Greek letter (α, β, γ, etc.) derived from the location of the constituent on a phase diagram. Ferrous alloy constituents, on the other hand, have been widely studied for more than 100 years. In the early days, many of the investigators were petrographers, mining engineers, and geologists. Because minerals have long been named after their discoverer or place of origin, it was natural to similarly name the constituents in steels and cast irons.

It can be seen that the four examples described above have very different microstructures: the structural steel has a ferrite + pearlite microstructure; the rail steel has a fully pearlitic microstructure; the machine housing (lathe) has a ferrite + pearlite matrix with graphite flakes; and the jaw crusher microstructure contains martensite and cementite. In each case, the microstructure plays the primary role in providing the properties desired for each application. From these examples, one can see how material properties can be tailored by microstructural manipulation or alteration. Knowledge about microstructure is thus paramount in component design and alloy development. In this section, each microstructural constituent will be described with particular reference to the properties that can be developed by appropriate manipulation of the microstructure through deformation (e.g., hot and cold rolling) and heat treatment. Further details about these microstructural constituents can be found in Ref 2, 3, 4, 5, and 6.

Ferrite

A wide variety of steels and cast irons fully exploit the properties of ferrite. However, only a few commercial steels are completely ferritic. An example of the microstructure of a fully ferritic, ultralow carbon steel is shown in Fig. 6.

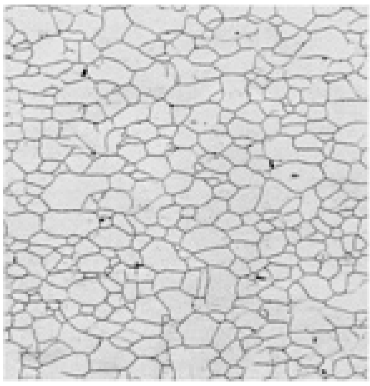

Fig. 6 Microstructure of a fully ferritic, ultralow carbon steel. Marshalls etch + HF, 300×. Courtesy of A.O. Benscoter, Lehigh University

Ferrite is essentially a solid solution of iron containing carbon or one or more alloying elements such as silicon, chromium, manganese, and nickel. There are two types of solid solutions: interstitial and substitutional. In an interstitial solid solution, elements with small atomic diameter, for example, carbon and nitrogen, occupy specific interstitial sites in the body-centered cubic (bcc) iron crystalline lattice. These sites are essentially the open spaces between the larger iron atoms. In a substitutional solid solution, elements of similar atomic diameter replace or substitute for iron atoms. The two types of solid solutions impart different characteristics to ferrite. For example, interstitial elements like carbon and nitrogen can easily diffuse through the open bcc lattice, whereas substitutional elements like manganese and nickel diffuse with great difficulty. Therefore, an interstitial solid solution of iron and carbon responds quickly during heat treatment, whereas substitutional solid solutions behave sluggishly during heat treatment, such as in homogenization.

According to the iron-carbon phase diagram (Fig. 7(a)), very little carbon (0.022% C) can dissolve in ferrite (αFe), even at the eutectoid temperature of 727 °C (1330 °F). (The iron-carbon phase diagram indicates the phase regions that exist over a wide carbon and temperature range. The diagram represents equilibrium conditions. Figure 7(b) shows an expanded iron-carbon diagram with both the eutectoid and eutectic regions.) At room temperature, the solubility is an order of magnitude less (below 0.005% C). However, even at these small amounts, the addition of carbon to pure iron increases the room-temperature yield strength of iron by more than five times, as seen in Fig. 8. If the carbon content exceeds the solubility limit of 0.022%, the carbon forms another phase called cementite (Fig. 9). Cementite is also a constituent of pearlite, as seen in Fig. 10. The role of cementite and pearlite on the mechanical properties of steel is discussed below.

The influence of solid-solution elements on the yield strength of ferrite is shown in Fig. 11. Here one can clearly see the strong effect of carbon on increasing the strength of ferrite. Nitrogen, also an interstitial element, has a similar effect. Phosphorus is also a ferrite strengthener. In fact, there are commercially available steels containing phosphorus for strengthening. These steels are the rephosphorized steels (type 1211 to 1215 series). Compositions and mechanical property data for these steels can be found in Tables 1 and 5.

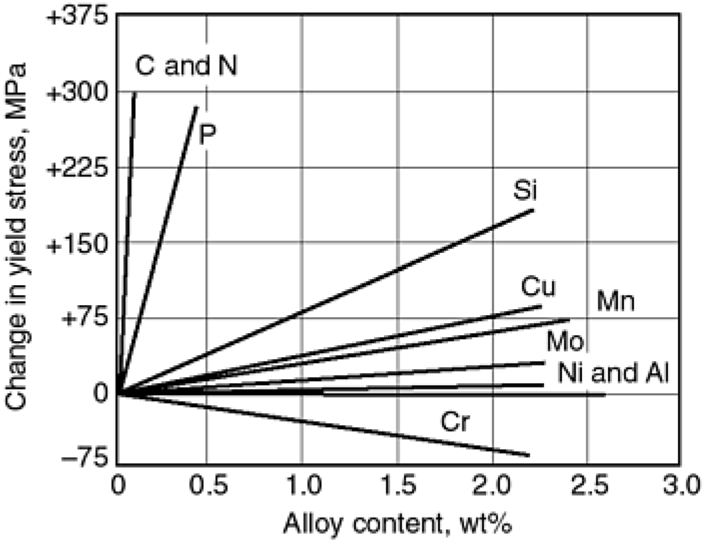

Fig. 11 Influence of solid-solution elements on the changes in yield stress of low-carbon ferritic steels. Source: Ref 5

In Fig. 11, the substitutional solid solution elements of silicon, copper, manganese, molybdenum, nickel, aluminum, and chromium are shown to have far less effect as ferrite strengtheners than the interstitial elements. In fact, chromium, nickel, and aluminum in solid solution have very little influence on the strength of ferrite.

In addition to carbon (and other solid-solution elements), the strength of a ferritic steel is also determined by its grain size according to the Hall-Petch relationship:

$$\sigma_y = \sigma_o + k_y d^{-1/2} \quad \textbf{(Eq 1)}$$

where σ_y is the yield strength (in MPa), σ_o is a constant, k_y is a constant, and d is the grain diameter (in mm).

The grain diameter is a measurement of size of the ferrite grains in the microstructure, for example, note the grains in the ultralow carbon steel in Fig. 6. Figure 12 shows the Hall-Petch relationship for a low-carbon fully ferritic steel. This relationship is extremely important for understanding structure-property relationships in steels. Control of grain size through thermomechanical treatment, heat treatment, and/or microalloying is vital to the control of strength and toughness of most steels. The role of grain size is discussed in more detail later in this article.

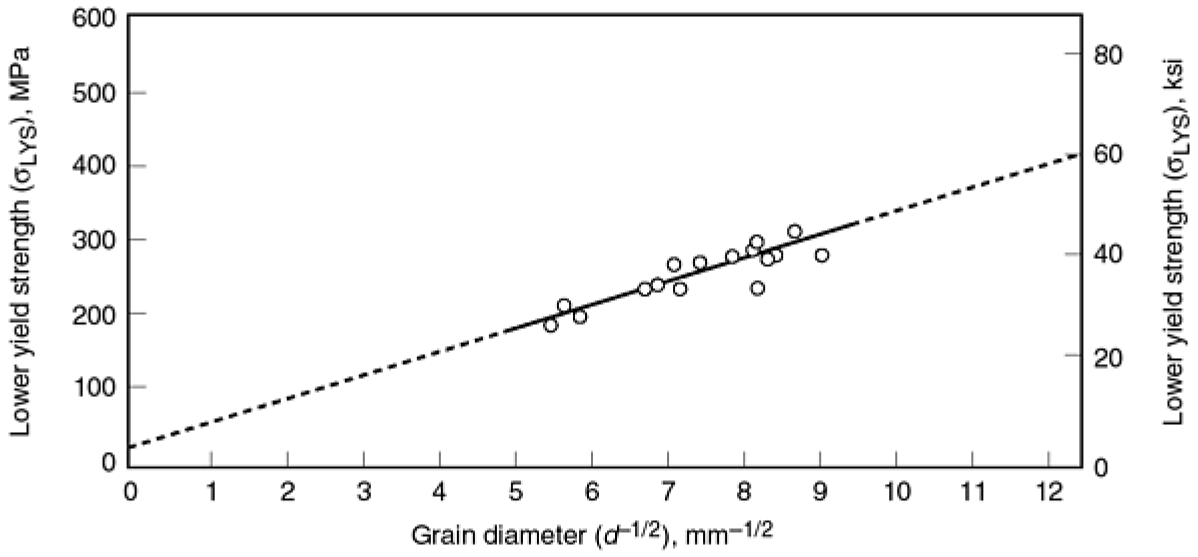

Fig. 12 Hall-Petch relationship in low-carbon ferritic steels. Source: Ref 8

There is a simple way to stabilize ferrite, thereby expanding the region of ferrite in the iron-carbon phase diagram, namely by the addition of alloying elements such as silicon, chromium, and molybdenum. These elements are called ferrite stabilizers because they stabilize ferrite at room temperature through reducing the amount of γ solid solution (austenite) with the formation of what is called a γ-loop as seen at the far left in Fig. 13. This iron-chromium phase diagram shows that ferrite exists up above 12% Cr and is stable up to the melting point (liquidus temperature). An important fully ferritic family of steels is the iron-chromium ferritic stainless steels. These steels are resistant to corrosion, and are classified as type 405, 409, 429, 430, 434, 436, 439, 442, 444, and 446 stainless steels. These steels range in chromium content from 11 to 30%. Additions of molybdenum, silicon, niobium, aluminum, and titanium provide specific properties. Ferritic stainless steels have good ductility (up to 30% total elongation and 60% reduction in area) and formability, but lack strength at elevated temperatures compared with austenitic stainless steels. Room-temperature yield strengths range from 170 to about 440 MPa (25 to 64 ksi), and room-temperature tensile strengths range from 380 to about 550 MPa (55 to 80 ksi). Table 5 lists the mechanical properties of some of the ferritic stainless steels. Type 409 stainless steel is widely used for automotive exhaust systems. Type 430 free-machining stainless steel has the best machinability of all stainless steels other than that of a low-carbon, free-machining martensitic stainless steel (type 416).

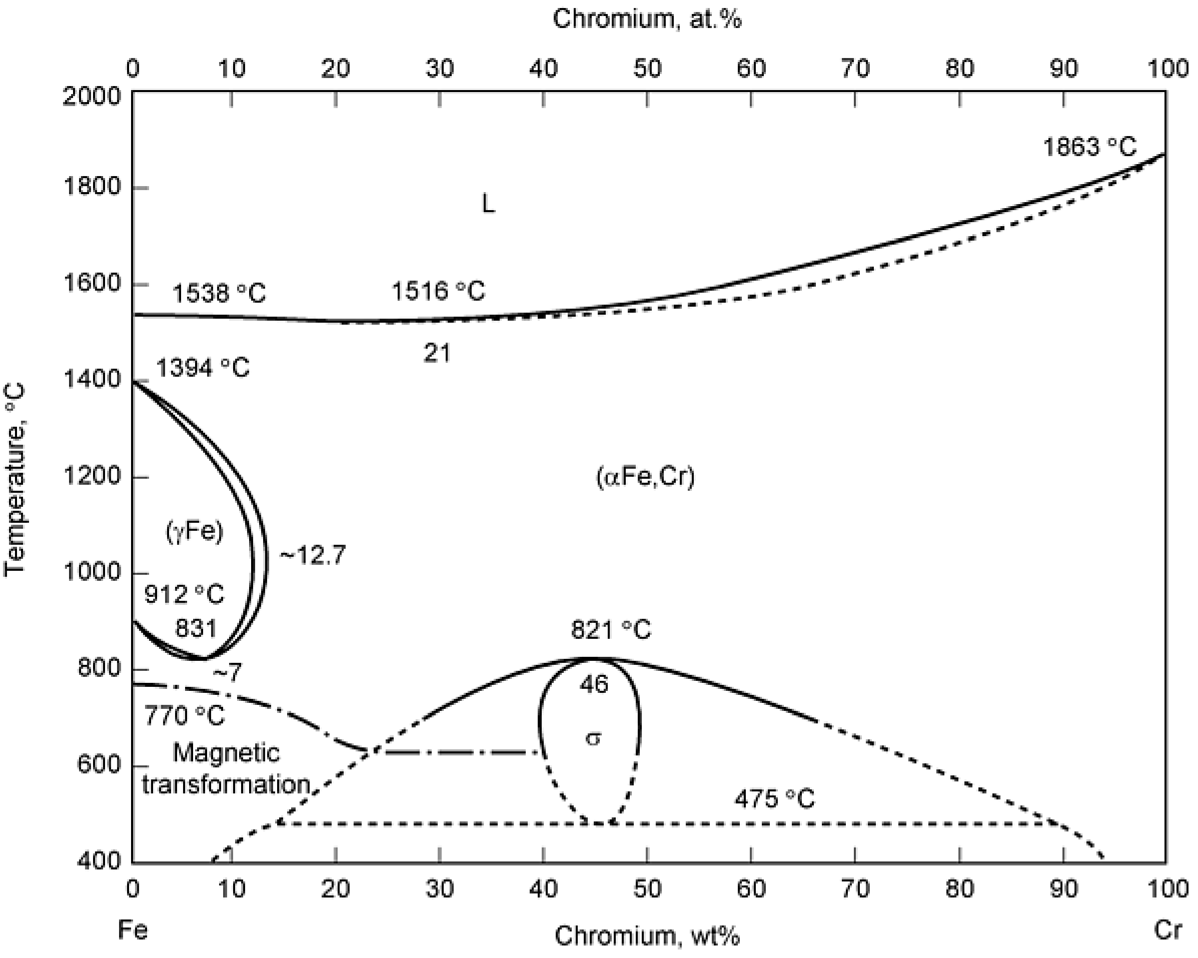

Fig. 13 Iron-chromium phase diagram. Source: Ref 9

Another family of steels utilizing a ferrite stabilizer (γ-loop) are the iron-silicon ferritic alloys containing up to about 6.5% Si (carbon-free). These steels are of commercial importance because they have excellent magnetic permeability and low core loss. High-efficiency motors and transformers are produced from these iron-silicon electrical steels (aluminum can also substitute for silicon in them).

Over the past 20 years or so, a new breed of very-low-carbon fully ferritic sheet steels has emerged for applications requiring exceptional formability (see Fig. 6). These are the interstitial-free (IF) steels for which carbon and nitrogen are reduced in the steelmaking process to very low levels, and any remaining interstitial carbon or nitrogen is tied up with small amounts of alloying elements (e.g., titanium or niobium) that form preferentially carbides and nitrides. These steels have very low strength, but are used to produce components that are difficult or impossible to form from other steels. Very-low-carbon, fully ferritic steels (0.001% C) are now being manufactured for automotive components that harden during the paint-curing cycle. These steels are called bake-hardening steels, and have controlled amounts of carbon and nitrogen that combine with other elements, such as titanium and niobium, during the baking cycle (175 °C, or 350 °F, for 30 min). The process is called aging, and the strength derives from the precipitation of titanium/niobium carbonitrides at the elevated temperature.

Another form of very-low-carbon, fully ferritic steel is motor lamination steel. The carbon is removed from these steels by a process known as decarburization. The decarburized (carbon-free) ferritic steel has good permeability and sufficiently low core loss (not as low as the iron-silicon alloys) to be used for electric motor laminations, that is, the stacked steel layers in the rotor and stator of the motor.

As noted previously, a number of properties are exploited in fully ferritic steels:

- *Iron-silicon steels:* Exceptional electrical properties

- *Iron-chromium steels:* Good corrosion resistance
- *Interstitial-free steels:* Exceptional formability
- *Bake-hardening steels:* Strengthens during paint cure cycle
- *Lamination steels:* Good electrical properties

Pearlite

As the carbon content of steel is increased beyond the solubility limit (0.02% C) on the iron-carbon binary phase diagram, a constituent called pearlite forms. Pearlite is formed by cooling the steel through the eutectoid temperature (the temperature of 727 °C in Fig. 7(a) and 7(b)) by the following reaction:

$$\text{Austenite} \leftrightarrow \text{cementite} + \text{ferrite} \qquad \textbf{(Eq 2)}$$

The cementite and ferrite form as parallel plates called lamellae (Fig. 14). This is essentially a composite microstructure consisting of a very hard carbide phase, cementite, and a very soft and ductile ferrite phase. A fully pearlitic microstructure is formed at the eutectoid composition of 0.78% C. As can be seen in Fig. 3 and 14, pearlite forms as colonies where the lamellae are aligned in the same orientation. The properties of fully pearlitic steels are determined by the spacing between the ferrite-cementite lamellae, a dimension called the interlamellar spacing, λ, and the colony size. A simple relationship for yield strength has been developed by Heller (Ref 10) as follows:

$$\sigma_y = -85.9 + 8.3\,(\lambda^{-1/2}) \qquad \textbf{(Eq 3)}$$

where σ_y is the 0.2% offset yield strength (in MPa) and $\lambda$is the interlamellar spacing (in mm). Figure 15 shows Heller's plot of strength versus interlamellar spacing for fully pearlitic eutectoid steels.

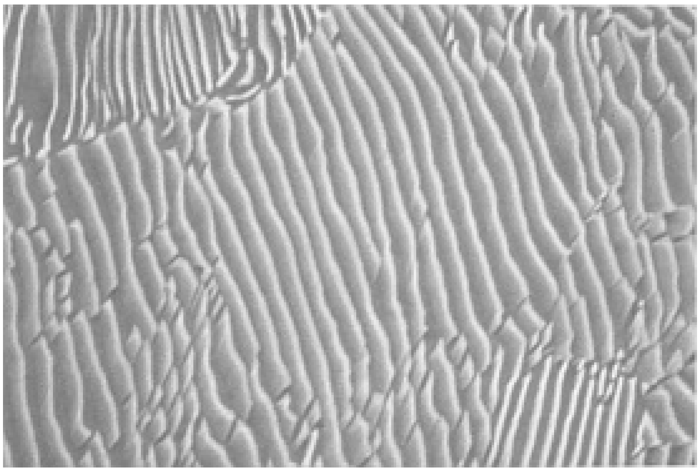

Fig. 14 SEM micrograph of pearlite showing ferrite and cementite lamellae. 4% picral etch. 10,000×

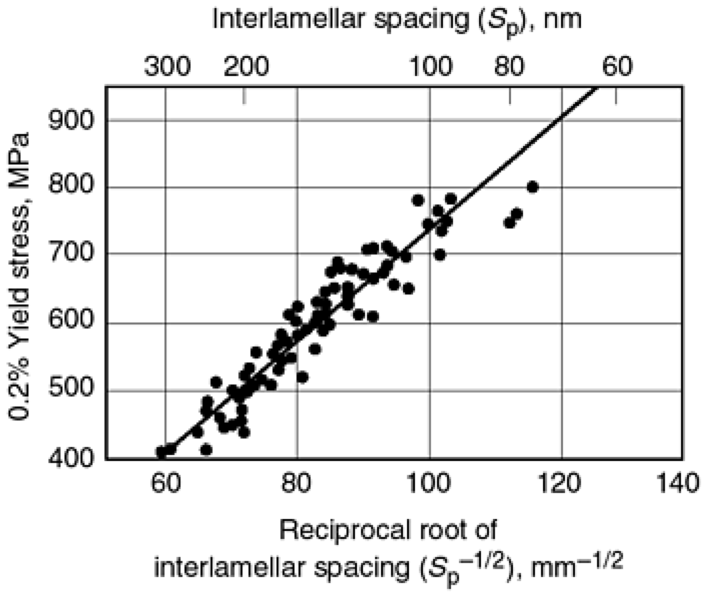

Fig. 15 Relationship between pearlite interlamellar spacing and yield strength for eutectoid steels. Source: Ref 10

It has also been shown by Hyzak and Bernstein (Ref 11) that strength is related to interlamellar spacing, pearlite colony size, and prior-austenite grain size, according to the following relationship:

$$YS = 52.3 + 2.18(\lambda^{-1/2}) - 0.4(d_c^{-1/2}) - 2.88(d^{-1/2}) \quad \textbf{(Eq 4)}$$

where *YS* is the yield strength (in MPa), d_c is the pearlite colony size (in mm), and *d* is the prior-austenite grain size (in mm). From Eq 3 and 4, it can be seen that the steel composition does not have a major influence on the yield strength of a fully pearlitic eutectoid steel. There is some solid-solution strengthening of the ferrite in the lamellar structure (see Fig. 11).

The thickness of the cementite lamellae can also influence the properties of pearlite. Fine cementite lamellae can be deformed, compared with coarse lamellae, which tend to crack during deformation.

Although fully pearlitic steels have high strength, high hardness, and good wear resistance, they also have poor ductility and toughness. For example, a low-carbon, fully ferritic steel will typically have a total elongation of more than 50%, whereas a fully pearlitic steel (e.g., type 1080) will typically have a total elongation of about 10% (see Table 5). A low-carbon fully ferritic steel will have a room-temperature Charpy V-notch impact energy of about 200 J (150 ft · lbf), whereas a fully pearlitic steel will have room-temperature impact energy of under 10 J (7 ft · lbf). The transition temperature (i.e., the temperature at which a material changes from ductile fracture to brittle fracture) for a fully pearlitic steel can be approximated from the following relationship (Ref 11):

$$TT = 217.84 - 0.83(d_c^{-1/2}) - 2.98(d^{-1/2}) \quad \textbf{(Eq 5)}$$

where *TT* is the transition temperature (in °C).

From Eq 5, one can see that both the prior-austenite grain size and pearlite colony size control the transition temperature of a pearlitic steel. Unfortunately, the transition temperature of a fully pearlitic steel is always well above room temperature. This means that at room temperature the general fracture mode is cleavage, which is associated with brittle fracture. Therefore, fully pearlitic steels should not be used in applications where toughness is important. Also, pearlitic steels with carbon contents slightly or moderately higher than the eutectoid composition (called hypereutectoid steels) have even poorer toughness.

From Eq 4 and 5, one can see that for pearlite, strength is controlled by interlamellar spacing, colony size, and prior-austenite grain size, and toughness is controlled by colony size and prior-austenite grain size.

Unfortunately, these three factors are rather difficult to measure. To determine interlamellar spacing, a scanning electron microscope (SEM), or a transmission electron microscope (TEM) is needed in order to resolve the spacing. Generally, a magnification of 10,000× is adequate, as seen in Fig. 14. Special statistical procedures have been developed to determine an accurate measurement of the spacing (Ref 12). The colony size and especially the prior austenite grain size are very difficult to measure and require a skilled metallographer using the light microscope or SEM and special etching procedures.

Because of poor ductility/toughness, there are only a few applications for fully pearlitic steels, including railroad rails and wheels and high-strength wire. By far, the largest tonnage application is for rails. A fully pearlitic rail steel provides excellent wear resistance for railroad wheel/rail contact. Rail life is measured in millions of gross tons (MGT) of travel and current rail life easily exceeds 250 MGT. The wear resistance of pearlite arises from the unique morphology of the ferrite-cementite lamellar composite where a hard constituent is embedded into a soft-ductile constituent. This means that the hard cementite plates do not abrade away as easily as the rounded cementite particles found in other steel microstructures, that is, tempered martensite and bainite, which will be discussed later. Wear resistance of a rail steel is directly proportional to hardness. This is shown in Fig. 16, which indicates less weight loss as hardness increases. Also, wear resistance (less weight loss) increases as interlamellar spacing decreases, as shown in Fig. 17. Thus, the most important microstructural parameter for controlling hardness and wear resistance is the pearlite interlamellar spacing. Fortunately, interlamellar spacing is easy to control and is dependent solely on transformation temperature.

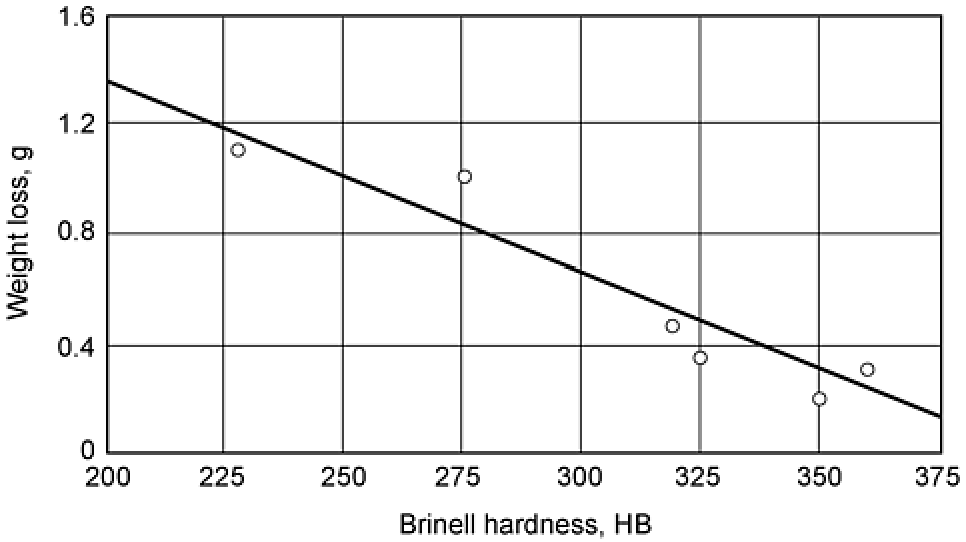

Fig. 16 Relationship between hardness and wear resistance (weight loss) for rail steels. Source: Ref 13

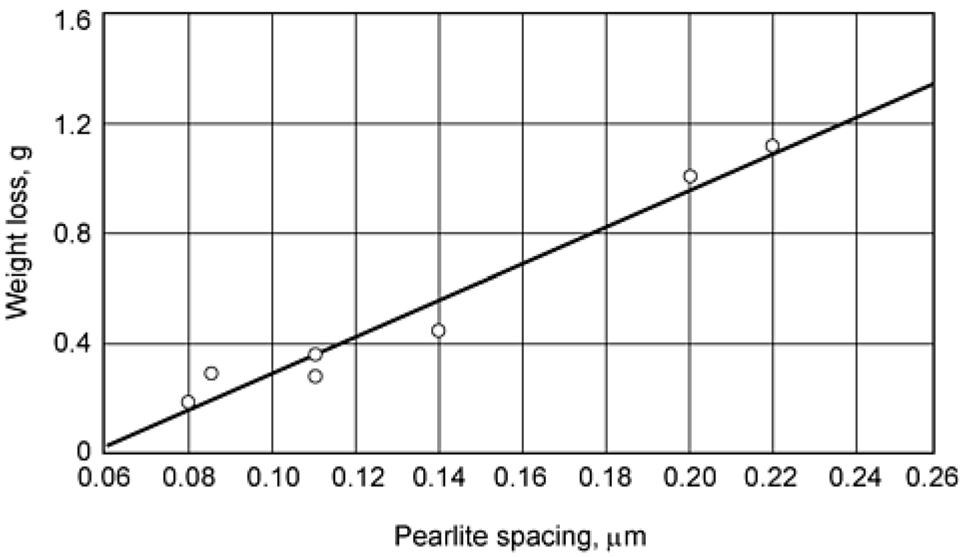

Fig. 17 Relationship between pearlite interlamellar spacing and wear resistance (weight loss) for rail steels. Source: Ref 13

Figure 18 shows a continuous cooling transformation (CCT) diagram for a typical rail steel. A CCT diagram is a time versus temperature plot showing the regions at which various constituents--ferrite, pearlite, bainite, and martensite--form during the continuous cooling of a steel component. Usually several cooling curves are shown with the associated start and finish transformation temperatures of each constituent. These diagrams should not be confused with isothermal transformation (IT or TTT) diagrams, which are derived by rapidly quenching very thin specimens to various temperatures, and maintaining that temperature (isothermal) until the specimens begin to transform, partially transform, and fully transform, at which time they are quenched to room temperature. An IT diagram does not represent the transformation behavior in most processes where steel parts are continuously cooled, that is, air cooled, and so forth.

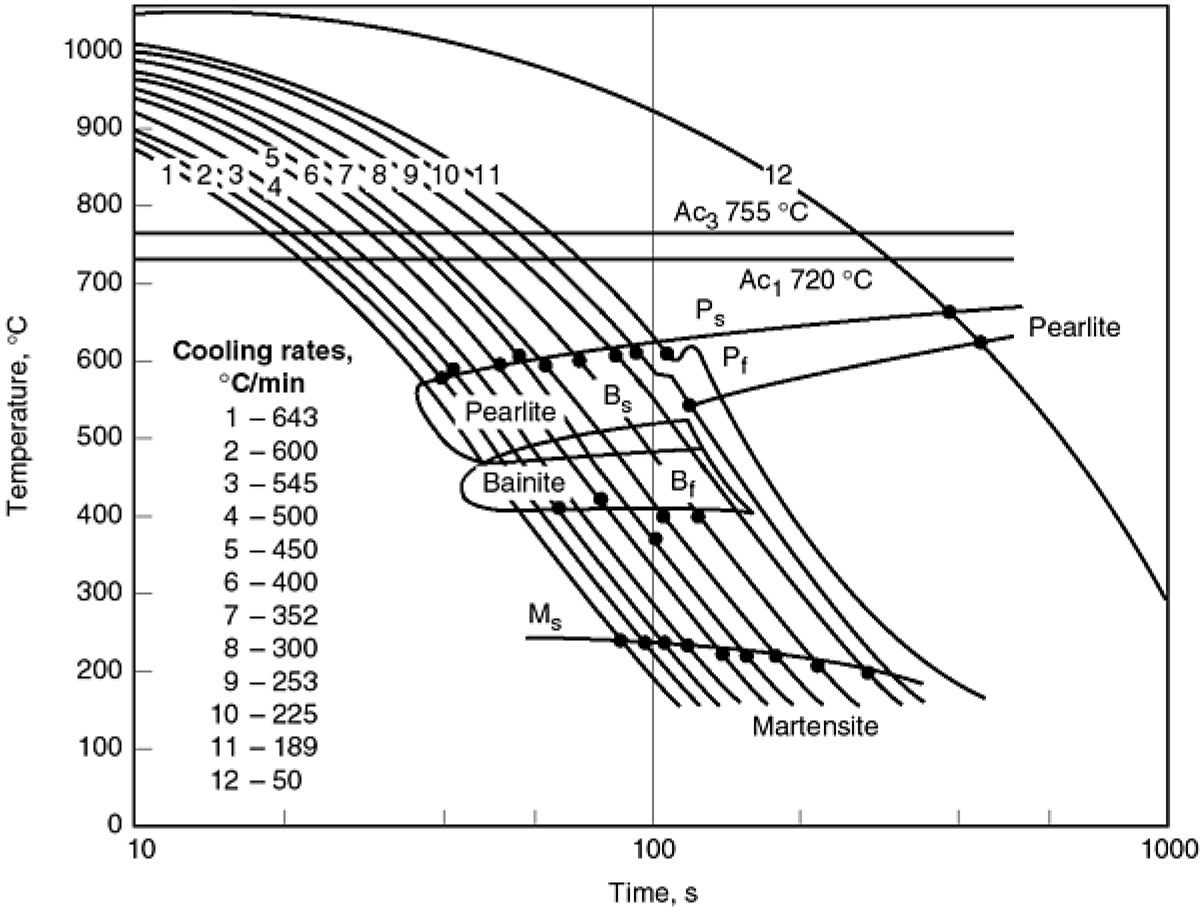

Fig. 18 A CCT diagram of a typical rail steel (composition: 0.77% C, 0.95% Mn, 0.22% Si, 0.014% P, 0.017% S, 0.010% Cr). Source: Ref 14

As shown in Fig. 18, the pearlite transformation temperature (indicated by the pearlite-start curve, P_s) decreases with increasing cooling rate. The hardness of pearlite increases with decreasing transformation temperature. Thus, in order to provide a rail steel with the highest hardness and wear resistance, one must cool the rail from the austenite at the fastest rate possible to obtain the lowest transformation temperature. This is done in practice by a process known as head hardening, which is simply an accelerated cooling process using forced air or water sprays to achieve the desired cooling rate (Ref 15). Because only the head of the rail contacts the wheel of the railway car and locomotive, only the head requires the higher hardness and wear resistance.

Another application for a fully pearlitic steel is high-strength wire (e.g., piano wire). Again, the composite morphology of lamellar ferrite and cementite is exploited, this time during wire drawing. A fully pearlitic steel rod is heat treated by a process known as patenting. During patenting, the rod is transformed at a temperature of about 540 °C (1000 °F) by passing it through a lead or salt bath at this temperature. This develops a microstructure with a very fine pearlite interlamellar spacing because the transformation takes place at the nose of the CCT diagram, that is, at the lowest possible pearlite transformation temperature (see Fig. 18). The rod is then cold drawn to wire. Because of the very fine interlamellar spacing, the ferrite and cementite lamellae become aligned along the wire axis during the deformation process. Also, the fine cementite lamella tend to bend and deform as the wire is elongated during drawing. The resulting wire is one of the strongest commercial products available; for example, a commercial 0.1 mm (0.004 in.) diam wire can have a tensile strength in the range of 3.0 to 3.3 GPa (439 to 485 ksi), and in special cases a tensile strength as high as 4.8 GPa can be obtained. These wires are used in musical instruments because of the sound quality developed from the high tensile stresses applied in stringing a piano and violin and are also used in wire rope cables for suspension bridges.

Ferrite-Pearlite. The most common structural steels produced have a mixed ferrite-pearlite microstructure. Their applications include beams for bridges and high-rise buildings, plates for ships, and reinforcing bars for roadways. These steels are relatively inexpensive and are produced in large tonnages. They also have the advantage of being able to be produced with a wide range of properties. The microstructure of typical ferrite-pearlite steels is shown in Fig. 19.

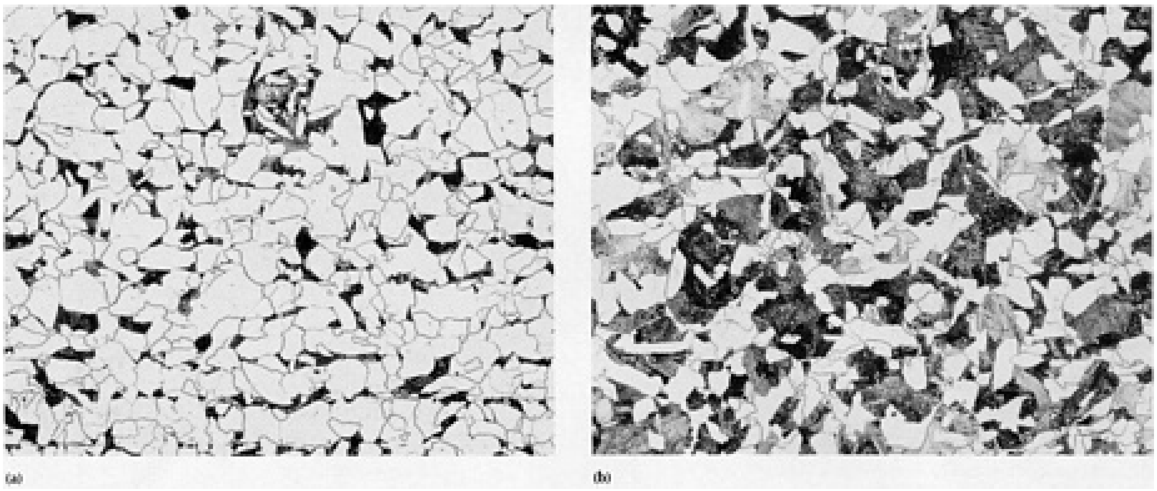

Fig. 19 Microstructure of typical ferrite-pearlite structural steels at two different carbon contents. (a) 0.10% C. (b) 0.25% C. 2% nital + 4% picral etch. 200×

In most ferrite-pearlite steels, the carbon content and the grain size determine the microstructure and resulting properties. For example, Fig. 20 shows the effect of carbon on tensile and impact properties. The ultimate tensile strength steadily increases with increasing carbon content. This is caused by the increase in the volume fraction of pearlite in the microstructure, which has a strength much higher than that of ferrite. Thus, increasing the volume fraction of pearlite has a profound effect on increasing tensile strength.

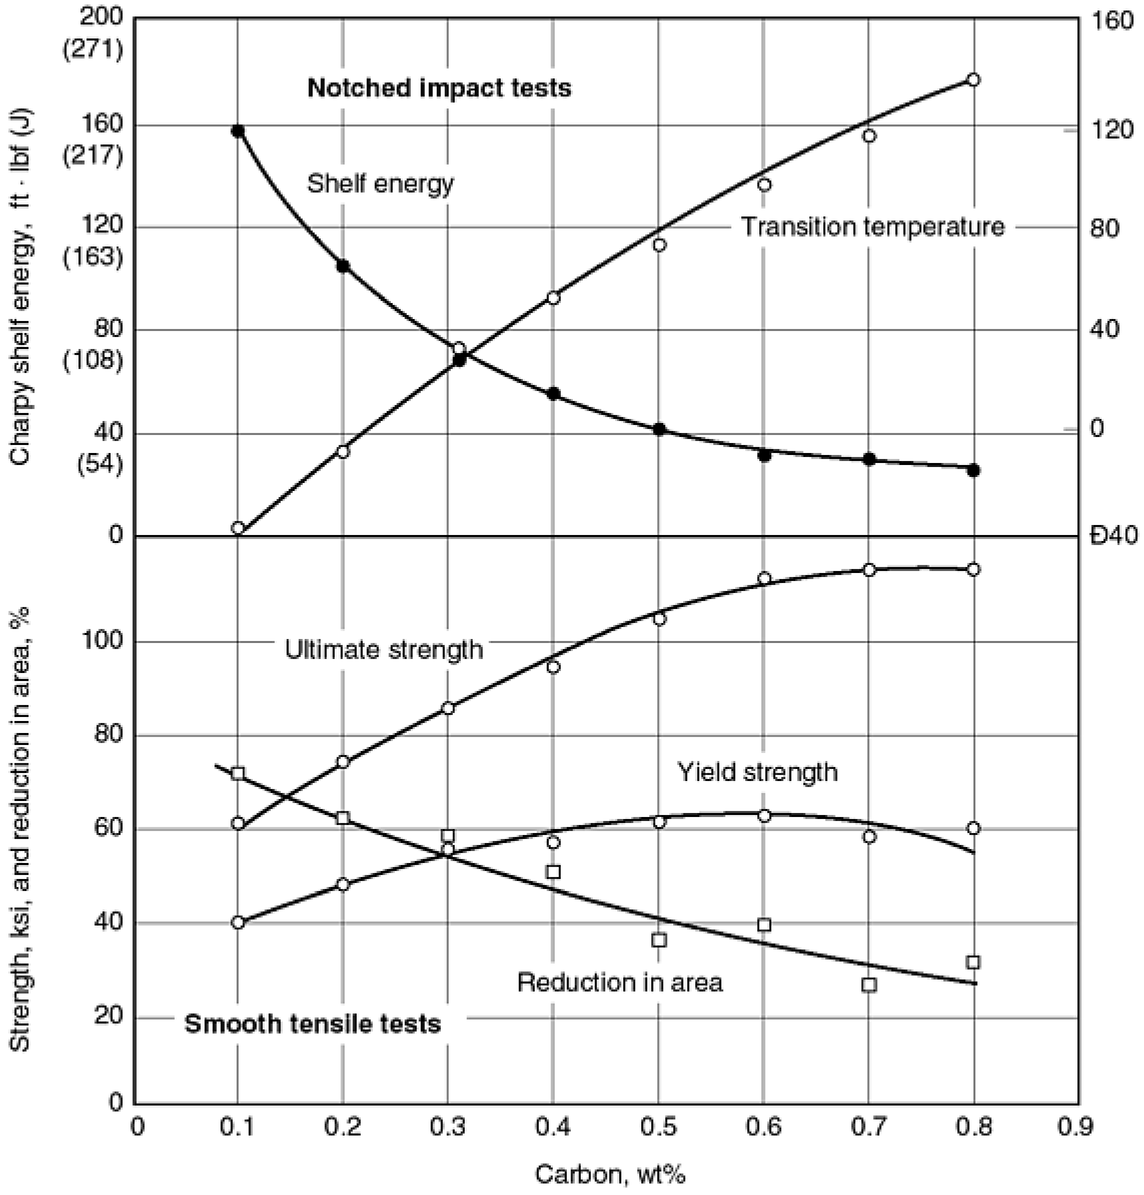

Fig. 20 Mechanical properties of ferrite-pearlite steels as a function of carbon content. Source: Ref 2

However, as seen in Fig. 20, the yield strength is relatively unaffected by carbon content, rising from about 275 MPa (40 ksi) to about 415 MPa (60 ksi) over the range of carbon content shown. This is because yielding in a ferrite-pearlite steel is controlled by the ferrite matrix, which is generally considered to be the continuous phase (matrix) in the microstructure. Therefore, pearlite plays only a minor role in yielding behavior.

From Fig. 20, one can also see that ductility, as represented by reduction in area, steadily decreases with increasing carbon content. A steel with 0.10% C has a reduction in area of about 75%, whereas a steel with 0.70% C has a reduction in area of only 25%. Percent total elongation would show a similar trend, however, with values much less than percent reduction in area.

Much work has been done to develop empirical equations for ferrite-pearlite steels that relate strength and toughness to microstructural features, for example, grain size and percent of pearlite as well as composition. One such equation for ferrite-pearlite steels under 0.25% C is as follows (Ref 16):

$$YS = 53.9 + 32.34\,(\text{Mn}) + 83.2(\text{Si}) + 354.2(N_f) + 17.4(d^{-1/2}) \quad \textbf{(Eq 6)}$$

where Mn is the manganese content (%), Si is the silicon content (%), N_f is the free nitrogen content (%), and *d* is the ferrite grain size (in mm). Equation 6 shows that carbon content (percent pearlite) has no effect on yield strength, whereas the yield strength in Fig. 20 increases somewhat with carbon content. According to Eq 6, manganese, silicon, and nitrogen have a pronounced effect on yield strength, as does grain size. However, in most ferrite-pearlite steels nitrogen is quite low (under 0.010%) and thus has minimal effect on yield strength. In addition, as discussed below, nitrogen has a detrimental effect on impact properties.

The regression equation for tensile strength for the same steels is as follows (Ref 16):

$$TS = 294.1 + 27.7(\mathrm{Mn}) + 83.2(\mathrm{Si}) + 3.9(\mathrm{P}) + 7.7(d^{-1/2}) \quad \textbf{(Eq 7)}$$

where *TS* is the tensile strength (in MPa) and P is pearlite content (%). Thus, in distinction to yield strength, the percentage of pearlite in the microstructure plays an important role on tensile strength.

Toughness of ferrite-pearlite steels is also an important consideration in their use. It has long been known that the absorbed energy in a Charpy V-notch test is decreased by increasing carbon content, as seen in Fig. 21. In this graph of impact energy versus test temperature, the shelf energy decreases from about 200 J (150 ft · lbf) for a 0.11% C steel to about 35 J (25 ft · lbf) for a 0.80% C steel. Also, the transition temperature increases from about -50 to 150 °C (-60 to 300 °F) over this same range of carbon content. The effect of carbon is due mainly to its effect on the percentage of pearlite in the microstructure. This is reflected in the regression equation for transition temperature below (Ref 16):

$$TT = -19 + 44(\mathrm{Si}) + 700(N_f^{1/2}) + 2.2(\mathrm{P}) - 11.5(d^{-1/2}) \quad \textbf{(Eq 8)}$$

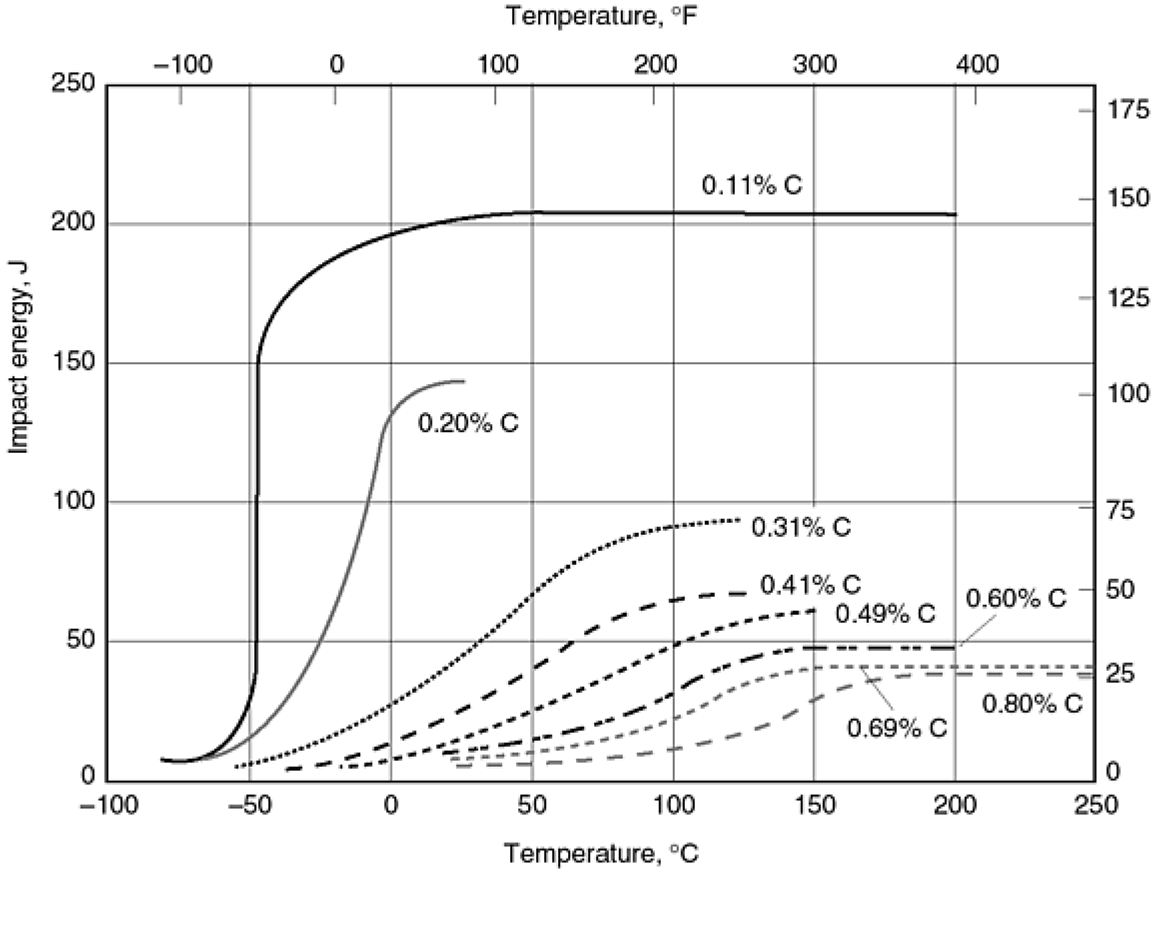

Fig. 21 Effect of carbon content in ferrite-pearlite steels on Charpy V-notch transition temperature and shelf energy. Source: Ref 17

It can be seen in all these relationships that ferrite grain size is an important parameter in improving both strength and toughness. It can also be seen that while pearlite is beneficial for increasing tensile strength and nitrogen is beneficial for increasing yield strength, both are harmful to toughness. Therefore, methods to control the grain size of ferrite-pearlite steels have rapidly evolved over the past 25 years. The two most important methods to control grain size are controlled rolling and microalloying. In fact, these methods are used in conjunction to produce strong, tough ferrite-pearlite steels.

Controlled rolling is a thermomechanical treatment in which steel plates are rolled below the recrystallization temperature of austenite. This process results in elongation of the austenite grains. Upon further rolling and subsequent cooling to room temperature, the austenite-to-ferrite transformation takes place. The ferrite grains are restricted in their growth because of the "pancake" austenite grain morphology. This produces the fine ferrite grain size required for higher strength and toughness.

Microalloying is the term applied to the addition of small amounts of special alloying elements (vanadium, niobium, or titanium) that aid in retarding austenite recrystallization, thus allowing a wide window of rolling temperatures for controlled rolling. Without retarding recrystallization, as in normal hot rolling, the pancake-type grains do not form and a fine grain size cannot be developed. Microalloyed steels are used in a wide variety of high tonnage applications including structural steels for the construction industry (bridges, multistory buildings, etc.), reinforcing bar, pipe for gas transmission, and numerous forging applications.

Bainite

Like pearlite, bainite is a composite of ferrite and cementite. Unlike pearlite, the ferrite has an acicular morphology and the carbides are discrete particles. Because of these morphological differences, bainite has much different property characteristics than pearlite. In general, bainitic steels have high strength coupled with good toughness, whereas pearlitic steels have high strength with poor toughness.

Another difference between bainite and pearlite is the complexity of the bainite morphologies compared with the simple lamellar morphology of pearlite. The morphologies of bainite are still being debated in the literature. For years, since the classic work of Bain and Davenport in the 1930s (Ref 18), there were two classifications of bainite: upper and lower bainite. This nomenclature was derived from the temperature regions at which bainite formed during isothermal (constant temperature) transformation. Upper bainite formed isothermally in the temperature range of 400 to 550 °C (750 to 1020 °F), and lower bainite formed isothermally in the temperature range of 250 to 400 °C (480 to 750 °F). Examples of the microstructure of upper and lower bainite are shown in Fig. 22. One can see that both types of bainite have an acicular morphology, with upper bainite being coarser than lower bainite. The true morphological differences between the microstructures can only be determined by electron microscopy. Transmission electron micrographs of upper and lower bainite are shown in Fig. 23. In upper bainite, the iron carbide phase forms at the lath boundaries, whereas in lower bainite, the carbide phase forms on particular crystallographic habit planes within the laths. Because of these differences in morphology, upper and lower bainite have different mechanical properties. Lower bainite, with a fine acicular structure and carbides within the laths, has higher strength and higher toughness than upper bainite with its coarser structure.

etch. 500×

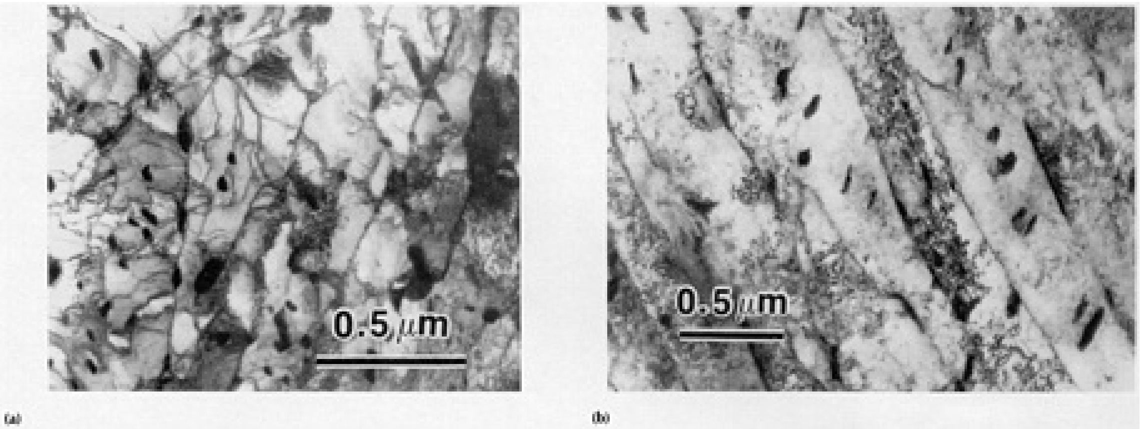

Fig. 23 TEM micrographs of (a) upper bainite and (b) lower bainite in a Cr-Mo-V rotor steel

Because during manufacture most steels undergo continuous cooling rather than isothermal holding, the terms upper and lower bainite can become confusing because "upper" and "lower" are no longer an adequate description of morphology. Bainite has recently been reclassified by its morphology, not by the temperature range in which it forms (Ref 19). For example, a recent classification of bainite yields three distinct types of morphology.

- *Class 1* (B_1): Acicular ferrite associated with *intra*lath (plate) iron carbide, that is, cementite (replaces the term "lower bainite")
- *Class 2* (B_2): Acicular ferrite associated with *inter*lath (plate) particles or films of cementite and/or austenite (replaces the term "upper bainite")
- *Class 3* (B_3): Acicular ferrite associated with a constituent consisting of discrete islands of austenite and/or martensite

The bainitic steels have a wide range of mechanical properties depending on the microstructural morphology and composition; for example, yield strength can range from 450 to 950 MPa (65 to 140 ksi), and tensile strength from 530 to 1200 MPa (75 to 175 ksi). Another aspect of a bainitic steel is that a single composition, $\frac{1}{2}$ Mo-B steel for example, can yield a bainitic microstructure over a wide range of transformation temperatures. The CCT diagram for this steel is shown in Fig. 24. Note that for this steel the bainite start (B_s) temperature is almost constant at 600 °C (1110 °F). This flat transformation region is important because transformation temperature plays an important role in the development of microstructure. A constant transformation temperature permits the development of a similar microstructure and properties over a wide range of cooling rates. This has many advantages in the manufacturing of bainitic steels and is particularly advantageous in thick sections where a wide range in cooling rates is found from the surface to the center of the part.

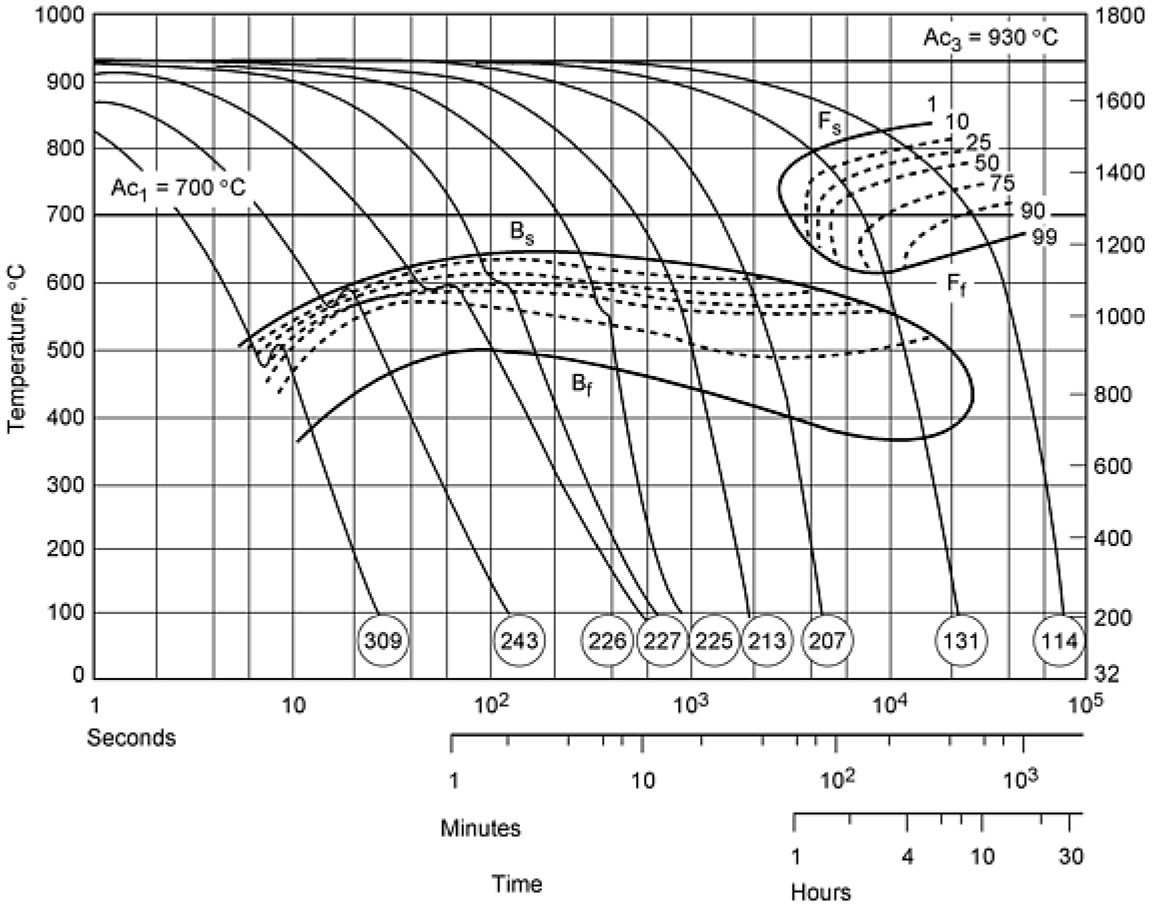

Fig. 24 A CCT diagram of a $\frac{1}{2}$ Mo-B steel. Composition: 0.093% C, 0.70% Mn, 0.36% Si, 0.51% Mo, 0.0054% B. Austenitized at Ac_3 + 30 °C for 12 min. B_s, bainite start; B_f, bainite finish; F_s, ferrite start; F_f, ferrite finish. Numbers in circles indicate hardness (HV) after cooling to room temperature. Source: Ref 20

In designing a bainitic steel with a wide transformation region, it becomes critical that the pearlite and ferrite regions are pushed as far to the right as possible on the CCT diagram; that is, pearlite and ferrite form only at slow cooling rates. Alloying elements such as nickel, chromium, and molybdenum (and manganese) are selected for this purpose.

For low-carbon bainitic steels, the relationship between transformation temperature and tensile strength is shown in Fig. 25 (martensite will be discussed in next section of this article). Note the rapid increase in tensile strength as the transformation temperature decreases. For these steels, a regression equation for tensile strength has been developed as follows (Ref 21):

$$TS = 246.4 + 1925(C) + 231(Mn + Cr) + 185(Mo) + 92(W) + 123(Ni) + 62(Cu) + 385(V + Ti) \quad \textbf{(Eq 9)}$$

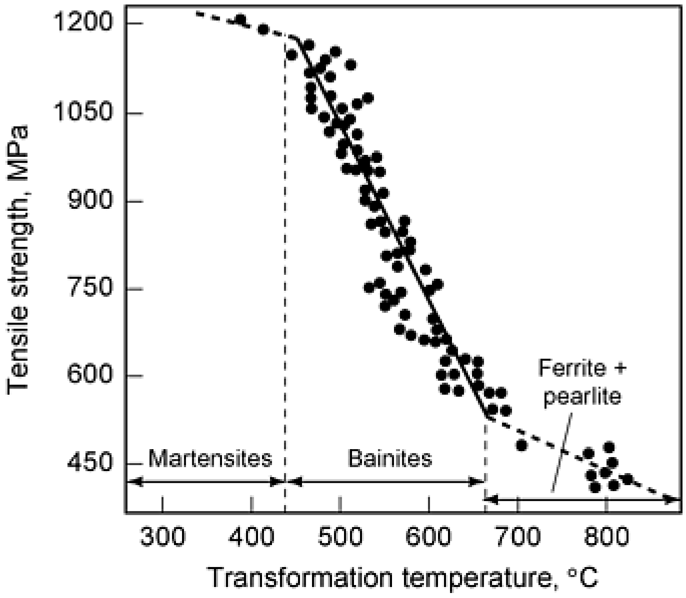

Fig. 25 Relationship between transformation temperature and tensile strength of ferrite-pearlite, bainitic, and martensitic steels. Source: Ref 5

In addition to the elements carbon, nickel, chromium, molybdenum, vanadium, and so forth, it is well known that boron in very small quantities (for example, 0.003%) has a pronounced effect on retarding the ferrite transformation. Thus, in a boron-containing steel (e.g., $\frac{1}{2}$ Mo + B), the ferrite nose in the CCT diagram is pushed to slower cooling rates. Boron retards the nucleation of ferrite on the austenite grain boundaries and, in doing so, permits bainite to be formed (Fig. 24). Whenever boron is added to steel, it must be prevented from combining with other elements such as oxygen and nitrogen. Generally, aluminum and titanium are added first in order to lower the oxygen and nitrogen levels of the steel. Even when adequately protected, the effectiveness of boron decreases with increasing carbon content and austenite grain size.

Attempts have been made to quantitatively relate the microstructural features of bainite to mechanical properties. One such relationship is (Ref 22):

$$YS = -194 + 17.4(d^{-1/2}) + 15(n^{1/4}) \quad \textbf{(Eq 10)}$$

where *YS* is the 0.2% offset yield strength (in MPa), ***d*** is the bainite lath size (mean linear intercept) (in mm), and ***n*** is the number of carbides per mm^2 in the plane of section.

With bainitic steels, the lath width of the bainite obeys a Hall-Petch relationship as shown in Fig. 26. The lath size is directly related to the austenite grain size and decreases with decreasing bainite transformation temperature. Because of the fine microstructure of bainite, the measurement of lath size and carbide density can only be done by scanning or transmission electron microscopy (SEM or TEM).

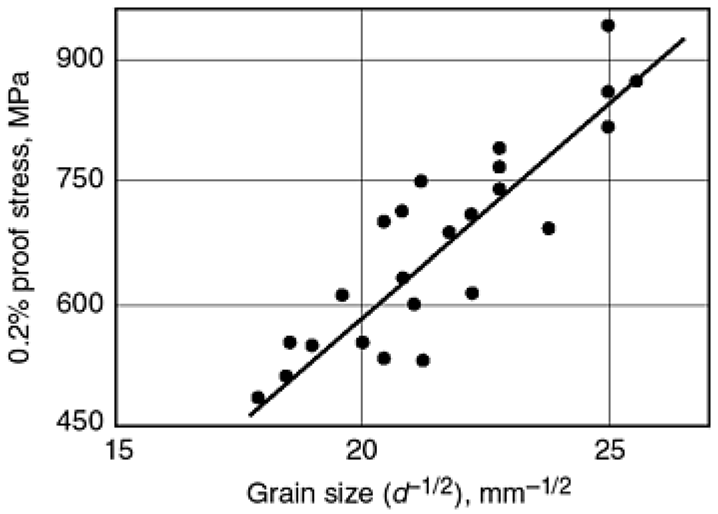

Fig. 26 Relationship between bainite lath width (grain size) and yield strength. Source: Ref 5

In low-carbon bainitic steels, type B_2 (upper) bainite has inferior toughness to type B_1 (lower) bainite. In both cases, strength increases as the transition temperature decreases. In type B_2 (upper) bainite, the carbides are much coarser than in type B_1 (lower) bainite and have a tendency to crack and initiate cleavage (brittle) fracture. In type B_1 bainite, the small carbides have less tendency to fracture. One can lower the transition temperature in type B_1 bainitic steels by providing a finer austenite grain size through lower-temperature thermomechanical treatment and grain refinement.

Bainitic steels are used in many applications including pressure vessels, backup rolls, turbine rotors, die blocks, die-casting molds, nuclear reactor components, and earthmoving equipment. One major advantage of a bainitic steel is that an optimal strength/toughness combination can be produced without expensive heat treatment, for example, quenching and tempering as in martensitic steels.

Martensite

Martensite is essentially a supersaturated solid solution of carbon in iron. The amount of carbon in martensite far exceeds that found in solid solution in ferrite. Because of this, the normal body-centered cubic (bcc) lattice is distorted in order to accommodate the carbon atoms. The distorted lattice becomes body-centered tetragonal (bct). In plain-carbon and low-alloy steels, this supersaturation is generally produced through very rapid cooling from the austenite phase region (quenching in water, iced-water, brine, iced-brine, oil or aqueous polymer solutions) to avoid forming ferrite, pearlite, and bainite. Some highly alloyed steels can form martensite upon air cooling (see the discussion of maraging steels later in this section). Depending on carbon content, martensite in its quenched state can be very hard and brittle, and, because of this brittleness, martensitic steels are usually tempered to restore some ductility and increase toughness.

Reference to a CCT diagram shows that martensite only forms at high cooling rates in plain-carbon and low-alloy steels. A CCT diagram for type 4340 is shown in Fig. 27, which indicates that martensite forms at cooling rates exceeding about 1000 °C/min. Most commercial martensitic steels contain deliberate alloying additions intended to suppress the formation of other constituents--that is ferrite, pearlite, and bainite--during continuous cooling. This means that these constituents form at slower cooling rates, allowing martensite to form at the faster cooling rates, for example, during oil and water quenching. This concept is called hardenability and is essentially the capacity of a steel to harden by rapid quenching. Most all the conventional alloying elements in steel promote hardenability. For example, type 4340 steel shown in Fig. 27 has significant levels of carbon, manganese, nickel, copper, and molybdenum to promote hardenability. More details about hardenability can be found in Ref 2.

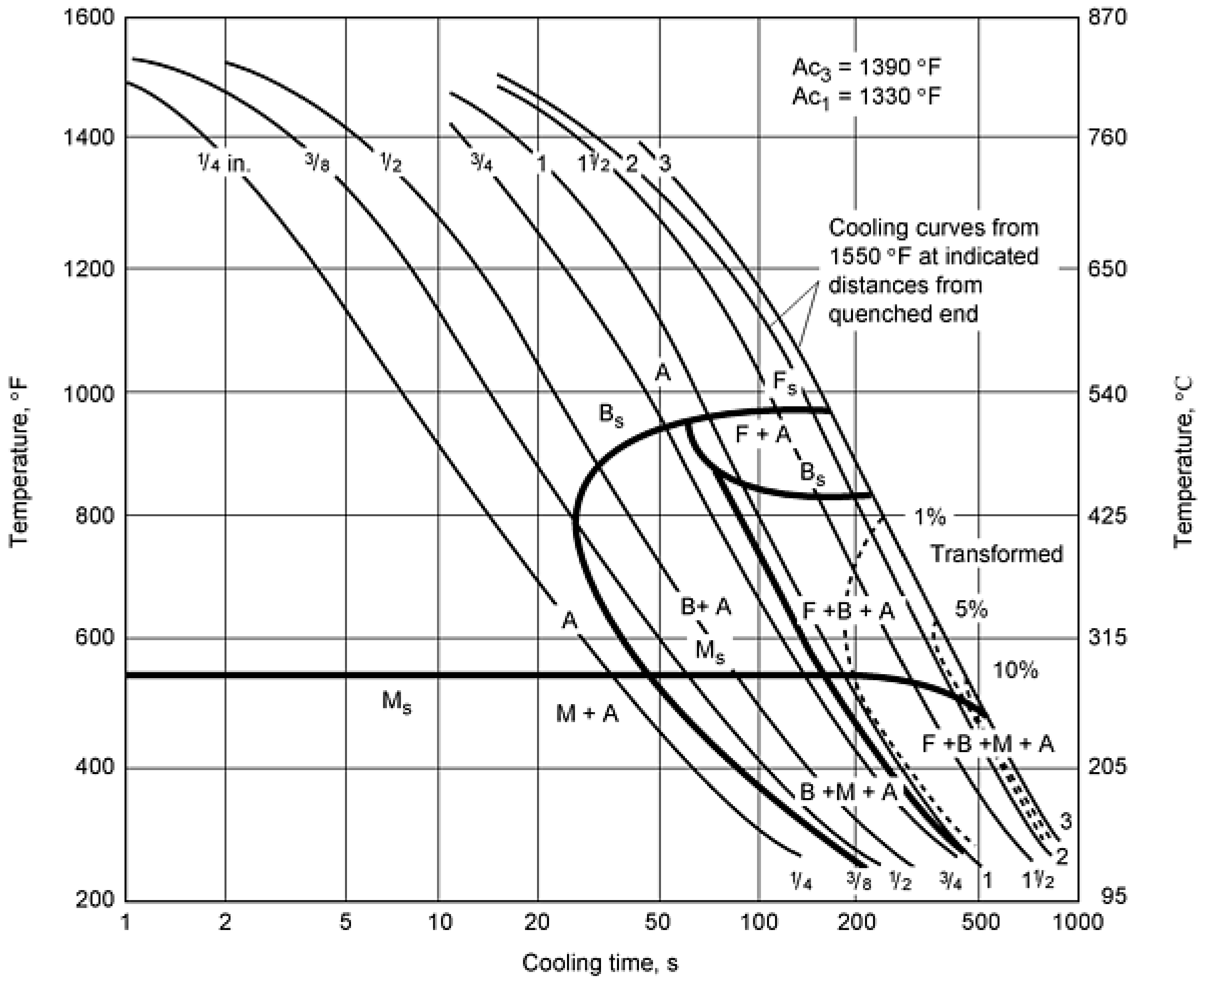

Fig. 27 The CCT diagram for type 4340 steel austenitized at 845 °C (1550 °F). Source: Ref 22

The martensite start temperature (M_s) for type 4340 is 300 °C(570 °F). Carbon lowers the M_s temperature, as shown in Fig. 28, and alloying elements such as carbon, manganese, chromium, nickel, and molybdenum also lower M_s temperature. Many empirical equations have been developed over the past 50 years relating M_s temperature to composition. One recent equation by Andrews (Ref 24) is:

$$M_s\ (°C) = 539 - 423(C) - 30.4(Mn) - 12.1(Cr) - 17.7(Ni) - 7.5(Mo) \qquad \textbf{(Eq 11)}$$

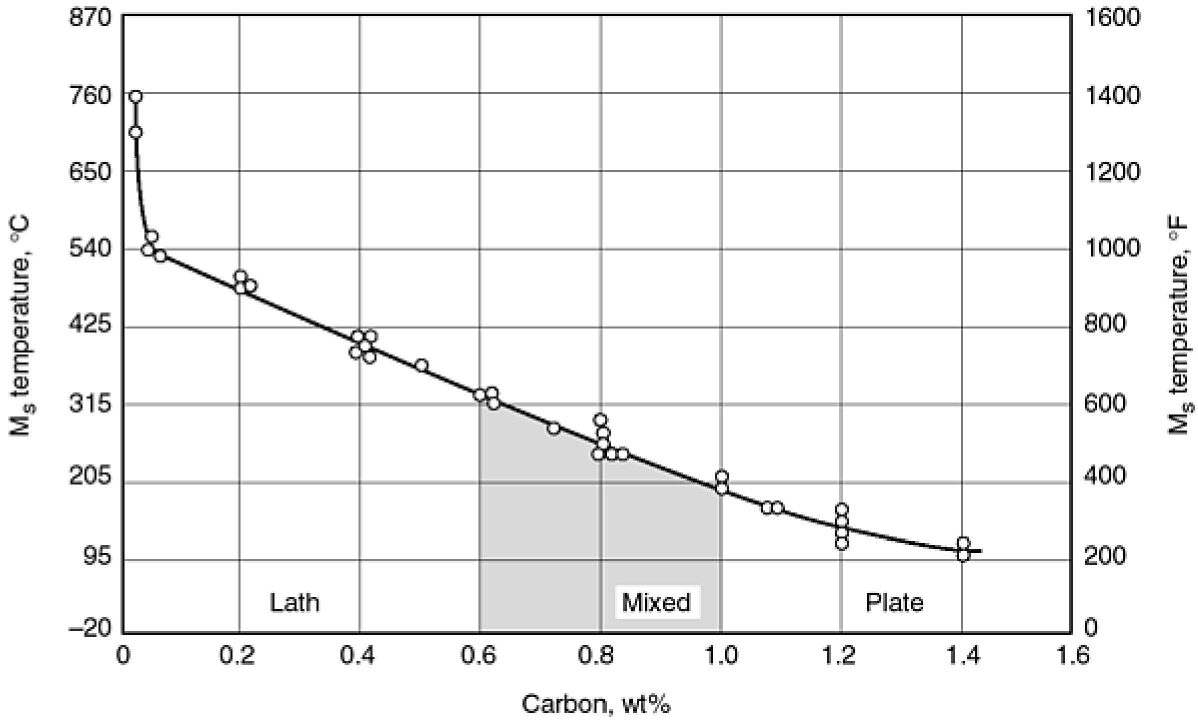

Fig. 28 Effect of carbon content on M_s temperature in steels. Source: Ref 6

With sufficient alloy content, the M_s temperature can be below room temperature, which means that the transformation is incomplete and retained austenite can be present in the steel.

The microstructure of martensitic steels can be generally classed as either lath martensite, plate martensite, or mixed lath and plate martensite. In plain carbon steels, this classification is related to carbon content, as shown in Fig. 28. Lath martensite forms at carbon contents up to about 0.6%, plate martensite is found at carbon contents greater than 1.0%, and a mixed martensite microstructure forms for carbon contents between 0.6 and 1.0%. An example of lath martensite is shown in Fig. 29 and plate martensite in Fig. 30. Generally, plate martensite can be distinguished from lath martensite by its plate morphology with a central mid-rib. Also, plate martensite may contain numerous microcracks, as shown in Fig. 31. These form during transformation when a growing plate impinges on an existing plate. Because of these microcracks, plate martensite is generally avoided in most applications. The important microstructural units measured in lath martensite are lath width and packet size. A packet is a grouping of laths having a common orientation.

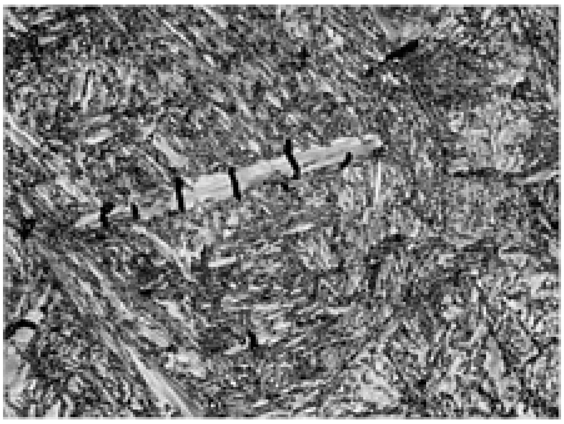

Fig. 31 Microcracks formed in plate martensite. 4% picral + HCl/sodium metabisulfite etch. 1000×

Plain-carbon and low-alloy martensitic steels are rarely used in the as-quenched state because of poor ductility. To increase ductility, these martensitic steels are tempered (reheated) to a temperature below 650 °C (1200 °F). During tempering, the carbon that is in supersaturated solid solution precipitates on preferred crystallographic planes (usually the octahedral {111} planes) of the martensitic lattice. Because of the preferred orientation, the carbides in a tempered martensite have a characteristic arrangement as seen in Fig. 32.

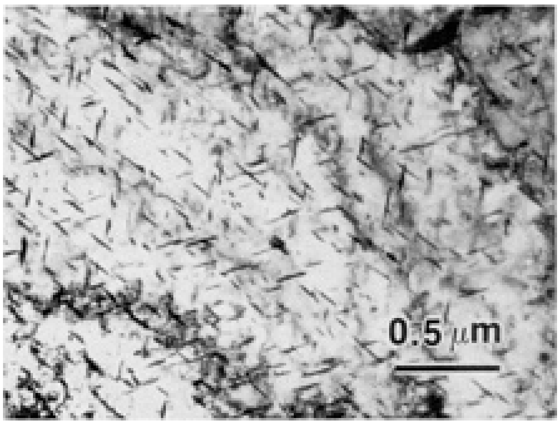

Fig. 32 TEM micrograph showing carbide morphology in tempered martensite

Tempered martensite has similar morphological features to type B_1 (lower) bainite. However, a distinction can be made in terms of the orientation differences of the carbide precipitates. This can be seen by comparing type B_1 bainite in Fig. 23 with tempered martensite in Fig. 32. However, unless the carbide morphology is observed it is very difficult to distinguish between B_1 bainite and tempered martensite.

The hardness of martensite is determined by its carbon content, as shown in Fig. 33. Martensite attains a maximum hardness of 66 HRC at carbon contents of 0.8 to 1.0%. The reason that the hardness does not monotonically increase with carbon is that retained austenite is found when the carbon content is above about 0.4% (austenite is much softer than martensite). Figure 34 shows the increase in volume percent retained austenite with increasing carbon content. Yield strength also increases with increasing carbon content as seen in Fig. 35. This empirical relationship between the yield strength and carbon content for untempered low-carbon martensite is (Ref 25):

$$YS \text{ (MPa)} = 413 + 17.2 \times 10^5(C^{1/2}) \qquad \textbf{(Eq 12)}$$

Lath martensite packet size also has an influence on the yield strength, as shown in Fig. 36. The linear behavior follows a Hall-Petch type relationship of ($d^{-1/2}$).

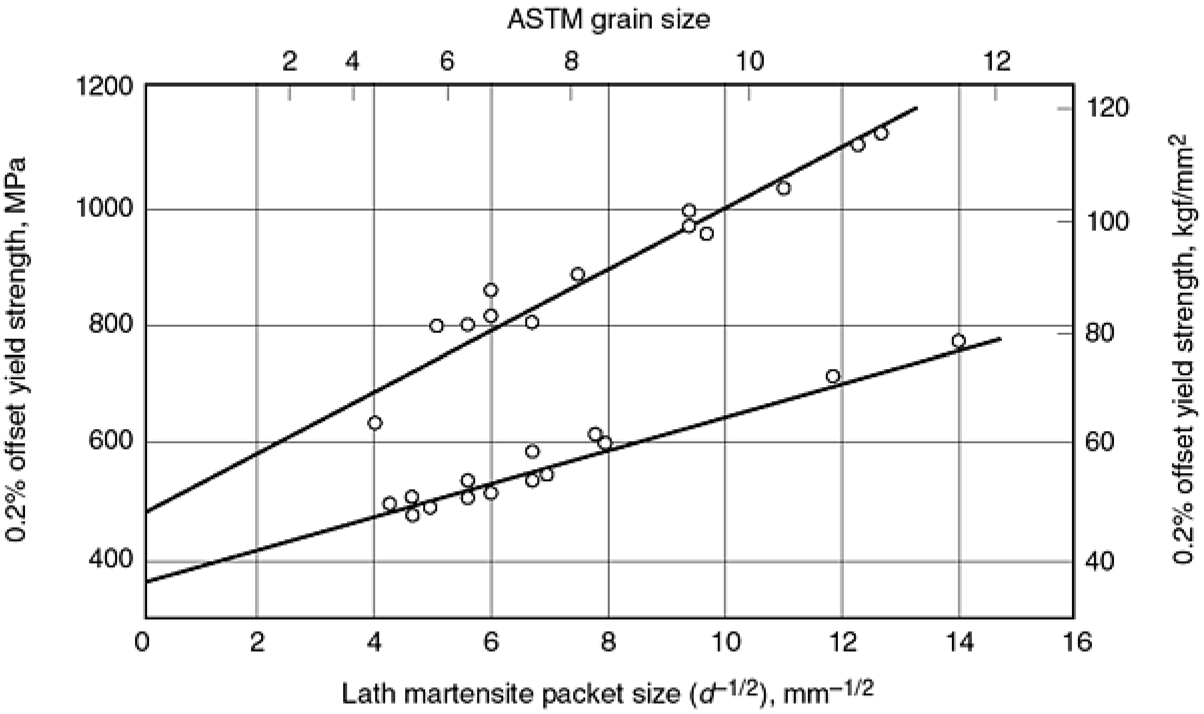

Fig. 36 Relationship between lath martensite packet size (*d*) and yield strength of Fe-0.2%C (upper line) and Fe-Mn (lower line) martensites. Source: Ref 2

Most martensitic steels are used in the tempered condition where the steel is reheated after quenching to a temperature less than the lower critical temperature (Ac_1). Figure 37 shows the decrease in hardness with tempering temperature for a number of carbon levels. Plain-carbon or low-alloy martensitic steels can be tempered in lower or higher temperature ranges, depending upon the balance of properties required. Tempering between 150 and 200 °C (300 and 390 °F) will maintain much of the hardness and strength of the quenched martensite and provide a small improvement in ductility and toughness (Ref 26). This treatment can be used for bearings and gears that are subjected to compression loading. Tempering above 425 °C (796 °F) significantly improves ductility and toughness but at the expense of hardness and strength. The effect of tempering temperature on the tensile properties of a typical oil-quenched low-alloy steel (type 4340) is shown in Fig. 38. These data are for a 13.5 mm (0.53 in.) diam rod quenched in oil. The as-quenched rod has a hardness of 601 HB. Note that by tempering at 650 °C (1200 °F), the hardness (see *x*-axis) decreased to 293 HB; or to less than half the as-quenched hardness. The tensile strength has decreased from 1960 MPa (285 ksi) at a 200 °C (400 °F) tempering temperature to 965 MPa (141 ksi) at a 650 °C (1200 °F) tempering temperature. However, the ductility, represented by total elongation and reduction in area, increases dramatically. The tempering process can be retarded by the addition of certain alloying elements such as vanadium, molybdenum, manganese, chromium, and silicon. Also, for tempering, temperature is much more important than time at temperature.

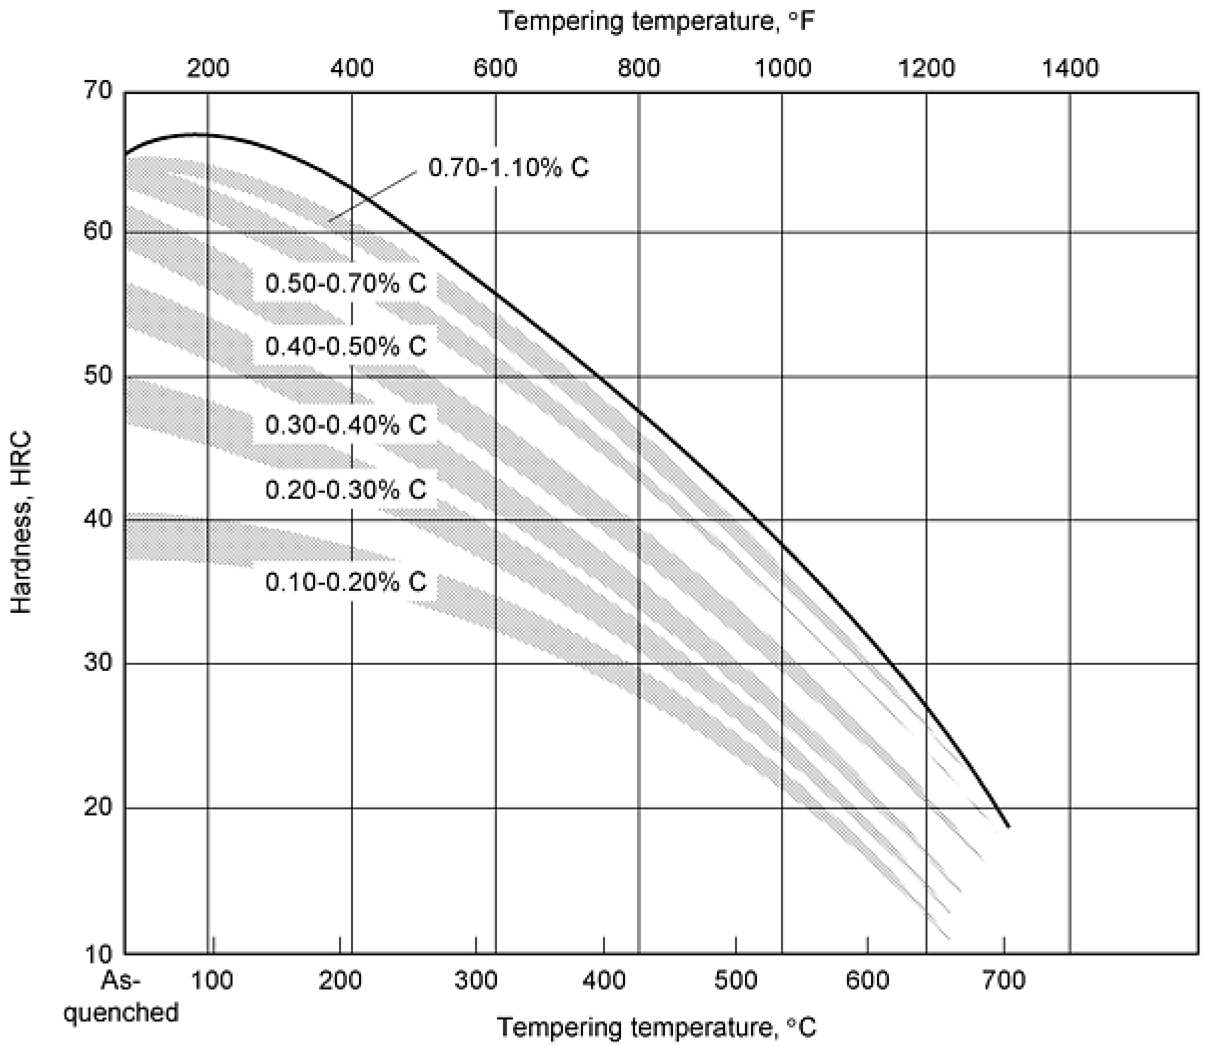

Fig. 37 Decrease in the hardness of martensite with tempering temperature for various carbon contents. Source: Ref 2

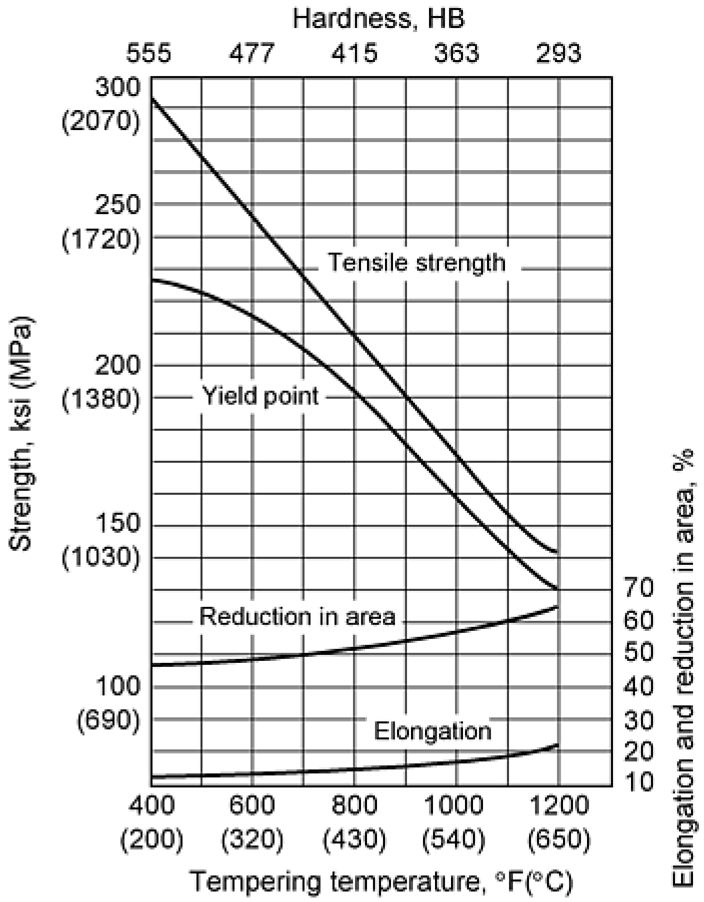

Fig. 38 Effect of tempering temperature on the mechanical properties of type 4340 steel. Source: Ref 2

Temper embrittlement is possible during the tempering of alloy and low-alloy steels. This embrittlement occurs when quenched-and-tempered steels are heated in, or slow cooled through the 340 to 565 °C (650 to 1050 °F) temperature range. Embrittlement occurs when the embrittling elements, antimony, tin, and phosphorus, concentrate at the austenite grain boundaries and create intergranular segregation that leads to intergranular fracture. The element molybdenum has been shown to be beneficial in preventing temper embrittlement.

The large variation in mechanical properties of quenched-and-tempered martensitic steels provides the structural designer with a large number of property combinations. Data, like that shown in Fig. 38, are available in Volume 1 of *ASM Handbook* as well as from other sources. Hardnesses of quenched-and-tempered steels can be estimated by a method established by Grange, et al. (Ref 27). The general equation for hardness is:

$$HV = HV_C + \Delta HV_{Mn} + \Delta HV_P + \Delta HV_{Si} + \Delta HV_{Ni} + \Delta HV_{Cr} + \Delta HV_{Mo} + \Delta HV_V \qquad \textbf{(Eq 13)}$$

where HV is the estimated hardness value (Vickers).

In order to use this relationship, one must determine the hardness value of carbon (HV_C) from Fig. 39. For example, if one assumes that a tempering temperature of 540 °C (1000 °F) is used and the carbon content of the steel is 0.2% C, the HV_C value after tempering will be 180 HV. Second, the effect of each alloying element must be determined from a figure such as Fig. 40. This graph represents a tempering temperature of 540 °C (1000 °F). Graphs representing other tempering temperatures can be found in Ref 27.

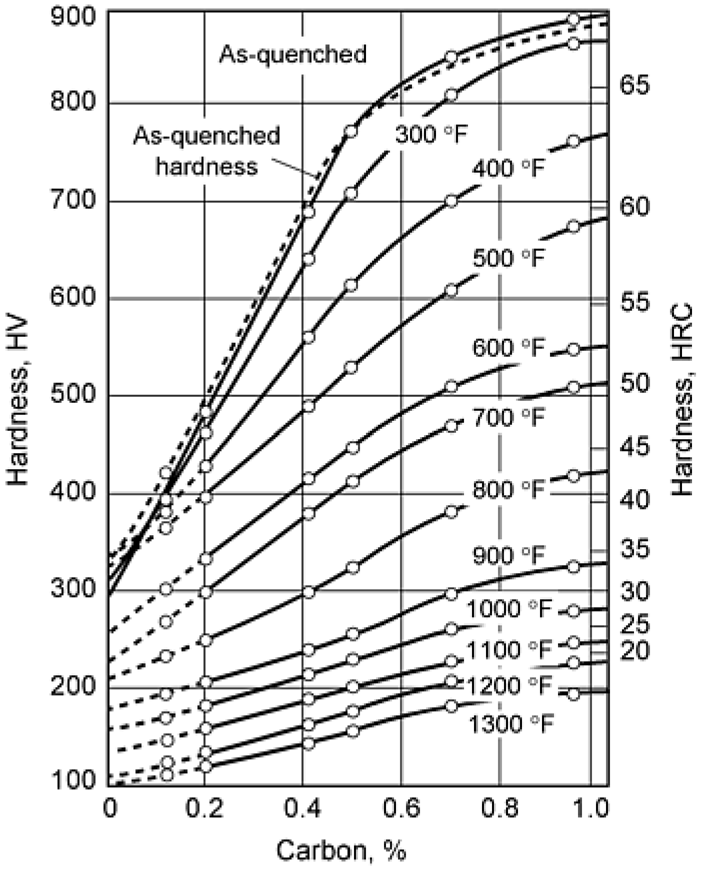

Fig. 39 Relationship between hardness of tempered martensite with carbon content at various tempering temperatures. Source: Ref 2

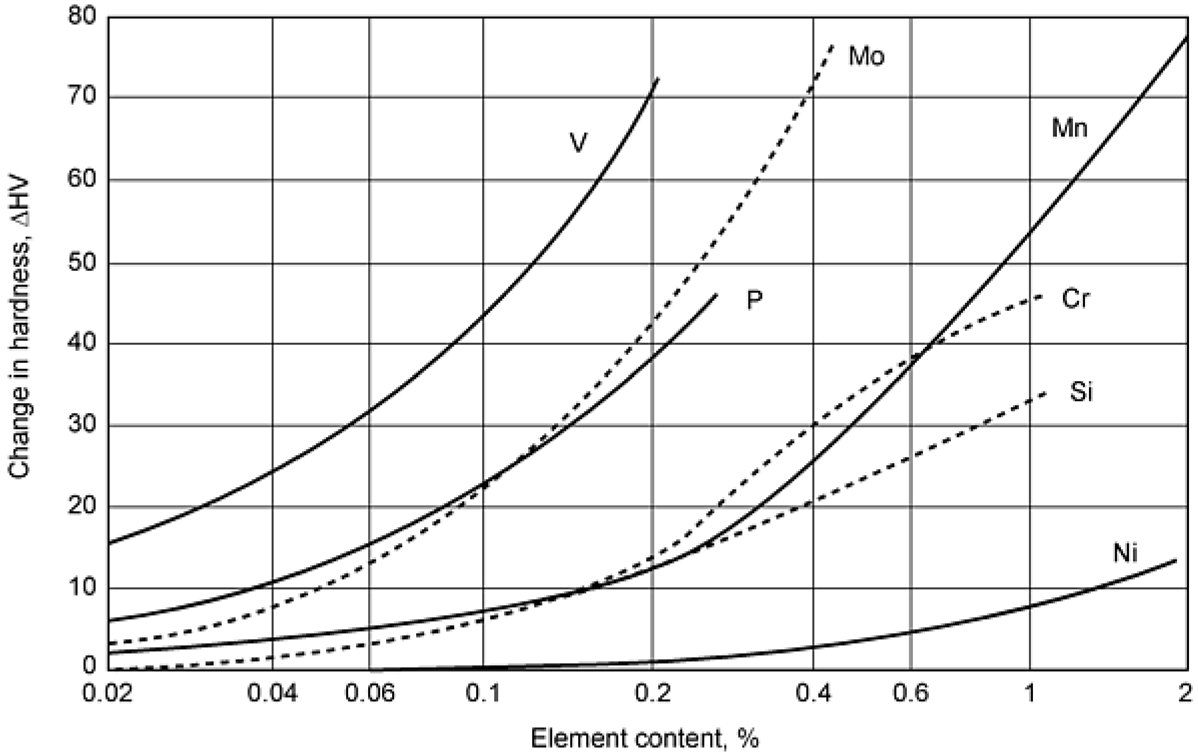

Fig. 40 Effect of alloying elements on the retardation or softening during tempering at 540 °C (1000 °F)

relative to iron-carbon alloys. Source: Ref 2

To illustrate the use of the Grange, et al. method, the same type 4340 steel shown in Fig. 38 is used. The composition of the steel is 0.41% C, 0.67% Mn, 0.023% P, 0.018% S, 0.26% Si, 1.77% Ni, 0.78% Cr, and 0.26% Mo. Assuming a 540 °C (1000 °F) tempering temperature, the estimated hardness value for carbon is 210 HV. From Fig. 39, the hardness values for each of the other alloying elements are:

Element	Content, %	Hardness, HV
C	0.41	210
Mn	0.67	38
P	0.023	7
Si	0.26	15
Ni	1.77	12
Cr	0.78	43
Mo	0.26	55
Total hardness		**380**

According to Fig. 38, the hardness value after tempering at 540 °C (1000 °F) was 363 HB (see Brinell hardness values along *x*-axis). From the ASTM E 48 conversion table (included in *Mechanical Testing,* Volume 8 of *ASM Handbook*), a Brinell hardness of 363 HB equates to a Vickers hardness of 383 HV. The calculated value of 380 HV (in the table above) is very close to the actual measured value of 383 HV. Thus, this method can be used to estimate a specific hardness value after a quenching-and-tempering heat treatment for a low-alloy steel. Also, as a rough approximation, the derived Brinell hardness value can be used to estimate tensile strength by the following equation (calculated from ASTM E 48 conversion table):

$$TS\ (\text{MPa}) = -42.3 + 3.6\ \text{HB} \qquad \textbf{(Eq 14)}$$

For the above example, a type 4340 quenched-and-tempered (540 °C, or 1000 °F) steel with a calculated hardness of 363 HB would have an estimated tensile strength from Eq 14 of 1265 MPa (183 ksi). From Table 5, this measured tensile strength of a type 4340 quenched-and-tempered (540 °C, or 1000 °F) steel is 1255 MPa (182 ksi).

It is seen that quenched-and-tempered martensitic steels provide a wide range of properties. The design engineer can choose from a large number of plain-carbon and low-alloy steels (Tables 1 and 2). In addition to this large list of steels, there are two other commercially important categories of fully martensitic steels, namely, martensitic stainless steels (Table 3) and maraging steels (Table 4).

Like the ferritic stainless steels, martensitic stainless steels (e.g., type 403, 410, 414, 416, 420, 422, 431, and 440) are high chromium-iron alloys (12 to 18% Cr), but with deliberate additions of carbon (0.12 to 1.2% C). These steels use carbon in order to stabilize austenite in iron-chromium alloys (Fig. 13). The expanded region of austenite is called the γ-loop. In the Fe-Cr phase diagram (without C), the γ-loop extends to about 12% Cr (see Fig. 13). With carbon additions, austenite can exist up to 25% Cr. These steels can be heat treated much like those of the low-alloy steels. However, martensitic stainless steels, with such high chromium contents, can form martensite on air cooling, even in thick sections. Martensitic stainless steels are considered high-strength stainless steels because they can be treated to achieve a yield strength between 550 MPa (80 ksi) and 1.7 GPa (250 ksi). On the other hand, ferritic stainless steels, which do not contain carbon, are not considered high-strength steels because their yield strength range is only 170 to 450 MPa (25 to 64 ksi). Because of their high strength and hardness, coupled with corrosion resistance, martensitic stainless steels are used for knives and other applications requiring a cutting edge as well as some tool steel applications.

Maraging steels are a separate class of martensitic steels and are considered ultrahigh-strength steels with yield strength levels as high as 2.5 GPa (360 ksi), as seen in Table 5. In addition to extremely high strength, the maraging steels have excellent ductility and toughness. These very-low carbon steels contain 17.5 to 18% Ni, 8.5 to 12.5% Co, 4 to 5% Mo, 0.20 to 1.8% Ti, and 0.10 to 0.15% Al. Because of the high alloy content, especially the cobalt addition, they are very expensive. Their high strength is developed by austenitizing at 850 °C (1560 °F), followed by air cooling to room temperature to form lath martensite. However, the martensitic constituent in maraging steels is relatively soft--28 to 35 HRC--which is an advantage because the component can be machined to final form directly upon cooling. The final stage of strengthening is through an aging process, carried out at 480 °C (900 °F) for 3 h. During aging, the hardness increases to about 51 to 58 HRC depending on the grade of maraging steel. The aging treatment promotes the precipitation of a rodlike intermetallic compound Ni_3Mo. These precipitates can only be observed at high magnification (e.g., by TEM). The precipitates strengthen the surrounding matrix as they form during aging. Full hardening can be developed, even in very thick sections. Maraging steels are used for die-casting molds and aluminum hot-forging dies as well as numerous aircraft and missile components.

Austenite

Austenite does not exist at room temperature in plain-carbon and low-alloy steels, other than as small amounts of retained austenite that did not transform during rapid cooling. However, in certain high-alloy steels, such as the austenitic stainless steels and Hadfield austenitic manganese steel, austenite is the microstructure. In these steels, sufficient quantities of alloying elements that stabilize austenite at room temperature are present (e.g., manganese and nickel). The crystal structure of austenite is face-centered cubic (fcc) as compared to ferrite, which has a (bcc) lattice. A fcc alloy has certain desirable characteristics; for example, it has low-temperature toughness, excellent weldability, and is nonmagnetic. Because of their high alloy content, austenitic steels are usually corrosion resistant. Disadvantages are their expense (because of the alloying elements), their susceptibility to stress-corrosion cracking (certain austenitic steels), their relatively low yield strength, and the fact that they cannot be strengthened other than by cold working, interstitial solid-solution strengthening, or precipitation hardening.

The austenitic stainless steels (e.g., type 301, 302, 303, 304, 305, 308, 309, 310, 314, 316, 317, 321, 330, 347, 348, and 384) generally contain from 6 to 22% Ni to stabilize the austenite at room temperature. They also contain other alloying elements, such as chromium (16 to 26%) for corrosion resistance, and smaller amounts of manganese and molybdenum. The widely used type 304 stainless steel contains 18 to 20% Cr and 8 to 10.5% Ni, and is also called 18-8 stainless steel. From Table 5, the yield strength of annealed type 304 stainless steel is 290 MPa (40 ksi), with a tensile strength of about 580 MPa (84 ksi). However, both yield and tensile strength can be substantially increased by cold working as shown in Fig. 41 (see Table 5). However, the increase in strength is offset by a substantial decrease in ductility, for example, from about 55% elongation in the annealed condition to about 25% elongation after cold working.

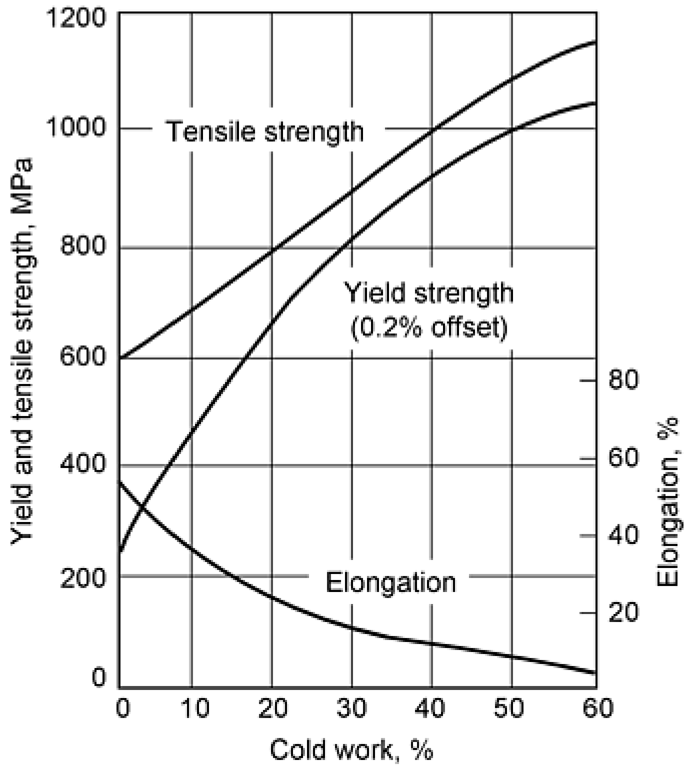

Fig. 41 Influence of cold work on mechanical properties of type 304 stainless steel. Source: Ref 4

Some austenitic stainless steels (type 200, 201, 202, and 205) employ interstitial solid-solution strengthening with nitrogen addition. Austenite, like ferrite, can be strengthened by interstitial elements such as carbon and nitrogen. However, carbon is usually excluded because of the deleterious effect associated with precipitation of chromium carbides on austenite grain boundaries (a process called sensitization). These chromium carbides deplete the grain-boundary regions of chromium, and the denuded boundaries are extremely susceptible to corrosion. Such steels can be desensitized by heating to high temperature to dissolve the carbides and place the chromium back into solution in the austenite. Nitrogen, on the other hand, is soluble in austenite and is added for strengthening. To prevent nitrogen from forming deleterious nitrides, manganese is added to lower the activity of nitrogen in the austenite, as well as to stabilize the austenite. For example, type 201 stainless steel has composition ranges of 5.5 to 7.5% Mn, 16 to 18% Cr, 3.5 to 5.5% Ni, and 0.25% N. The other type 2*xx* series of steels contain from 0.25 to 0.40% N.

Another important austenitic steel is austenitic manganese steel. Developed by Sir Robert Hadfield in the late 1890s, these steels remain austenitic after water quenching and have considerable strength and toughness. A typical Hadfield manganese steel will contain 10 to 14% Mn, 0.95 to 1.4% C, and 0.3 to 1% Si. Solution annealing is necessary to suppress the formation of iron carbides. The carbon must be in solid solution to stabilize the austenite. When completely austenitic, these steels can be work hardened to provide higher hardness and wear resistance. A work-hardened Hadfield manganese steel has excellent resistance to abrasive wear under heavy loading. Because of this characteristic, these steels are ideal for jaw crushers and other crushing and grinding components in the mining industry. Also, Hadfield manganese steels have long been used for railway frogs (components used at the junction point of two railroad lines).

Ferrite-Cementite

When plain-carbon steels are heated to temperatures just below the lower critical temperature (Ac_1), the process of spheroidization takes place. Figure 42 shows a fully spheroidized steel microstructure. The microstructure before spheroidization is pearlite. During spheroidization, the cementite lamellae of the pearlite must change morphology to form spheroids. The process is controlled by the diffusion rate of carbon and portions of the lamellae must "pinch-off" (dissolve), and that dissolved carbon must diffuse to form a spheroid from the remaining portions of lamellae. This process takes several hours. Spheroidization takes place in less time when the starting microstructure is martensite or tempered martensite. In this process, the spheroidized carbides are formed by growth of carbides formed during tempering.

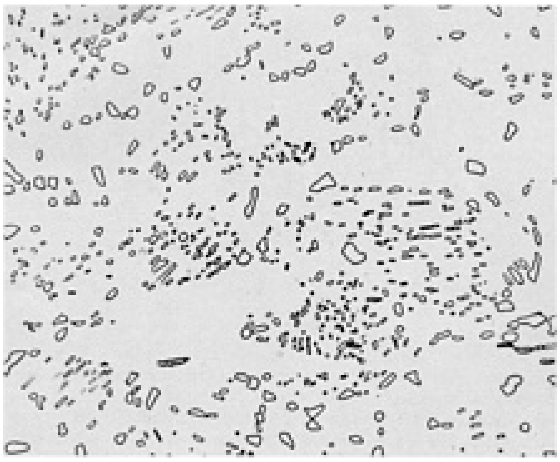

Fig. 42 Microstructure of a fully spheroidized steel. 4% picral etch. 1000×

A fully spheroidized structure leads to improved machinability. A steel in its fully spheroidized state is in its softest possible condition. Some steels, such as type 1020, are spheroidized before cold forming into tubing because spheroidized steels have excellent formability.

Ordinary low-carbon, cold-rolled, and annealed sheet steels have ferritic microstructures with a small amount of grain-boundary cementite, as shown in Fig. 9. These carbides nucleate and grow on the ferrite grain boundaries during the annealing process, which takes place in the lower portion of the intercritical temperature region (i.e., the region between the A_3 and A_1 temperatures shown in the iron-carbon diagram, Fig. 7(a) and 7(b)). Many modern-day automotive sheet steels are produced with very low carbon levels to avoid these grain-boundary carbides because they degrade formability.

Ferrite-Martensite

A relatively new family of steels called dual-phase steels consists of a microstructure of about 15 to 20% martensite in a matrix of ferrite. The microstructure of a typical dual-phase steel is shown in Fig. 43. In most plain-carbon and low-alloy steels, the presence of martensite in the microstructure is normally avoided because of the deleterious effect that martensite has on ductility and toughness. However, when the martensite is embedded in a matrix of ferrite, it imparts desirable characteristics. One desirable characteristic is that dual-phase steels do not exhibit a yield point. Figure 44 compares the stress-strain behavior of four steels: plain carbon, SAE 950X, and SAE 980X, which exhibit a yield point with the fourth, a dual-phase steel (GM 980X). This means that the cosmetically unappealing Lüders bands that form during the discontinuous yielding (i.e., yield point) are absent in a dual-phase steel. Also note in Fig. 44 that the dual-phase steel has much more elongation than the SAE 980X of similar tensile strength. These characteristics are especially important in formability.

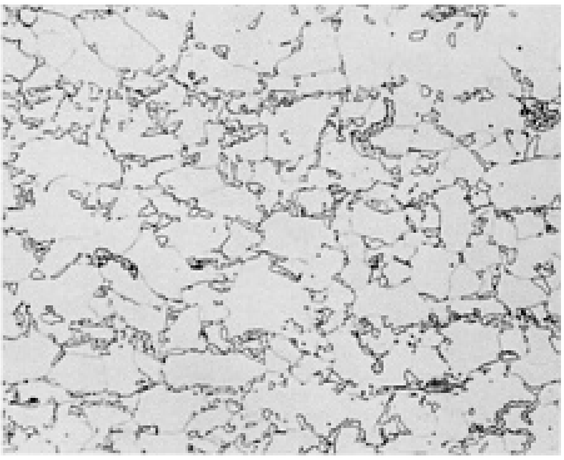

Fig. 43 Microstructure of a typical dual-phase steel. 2% nital etch. 250×

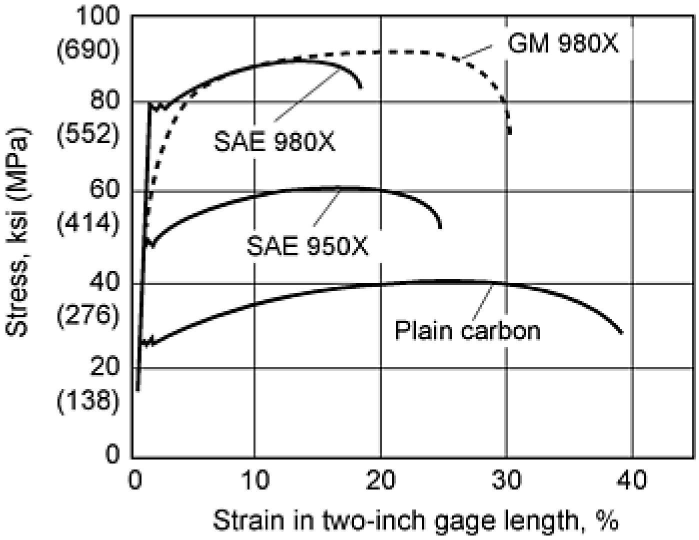

Fig. 44 Comparison of the stress-strain curves of three discontinuously yielding sheet steels (plain carbon, SAE 950X, and SAE 980X) and a dual-phase steel (GM 980X). In addition to the differences in yielding behavior, note the higher percentage of uniform elongation in the dual-phase steel compared with the conventional SAE 980X of similar tensile strength. Source: Ref 2

A unique characteristic of a ferrite-martensite dual-phase steel is its substantial work hardening capacity. This allows the steel to strengthen while being deformed. By proper design of the stamping dies, this behavior can be exploited to produce a high-strength component. Most conventional high-strength steels have limited formability because their high strength is developed prior to the forming process.

Graphite

When carbon contents of iron-carbon alloys exceed about 2%, there is a tendency for graphite to form (see Fe-C diagram in Fig. 7(b)). This is especially true in gray cast iron in which graphite flakes are a predominant microstructural feature (Fig. 4). Gray cast iron has been used for centuries because it melts at a lower temperature than steel and is easy to cast into various shapes. Also, the graphite flakes impart good machinability, acting as chip breakers, and they also provide excellent damping capacity. Damping capacity is important in machines that are subject to vibration. However, gray cast iron is limited to applications that do not require toughness or ductility, for example, total elongation of less than 1%. The flake morphology of the graphite provides for easy crack propagation under applied stress.

Gray cast irons usually contain 2.5 to 4% C, 1 to 3% Si, and 0.1 to 1.2% Mn. The graphite flakes can be present in five different morphologies as seen in Fig. 45. Type A, because of its random orientation and distribution, is preferred in many applications, for example, cylinders of internal combustion engines. The matrix of a typical gray cast iron is usually pearlite. However, ferrite-pearlite or martensitic microstructures can be developed by special heat treatments. As a structural material, gray cast iron is selected for its high compressive strength, which ranges from 572 to 1293 MPa (83 to 188 ksi), although tensile strengths of gray iron range only from 152 to 431 MPa (22 to 63 ksi). Gray cast irons are used in a wide variety of applications, including automotive cylinder blocks, cylinder heads and brake drums, ingot molds, machine housings, pipe, pipe fittings, manifolds, compressors, and pumps.

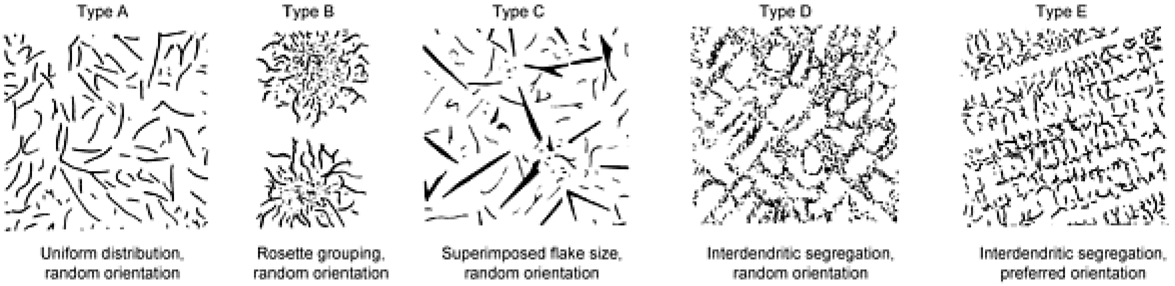

Fig. 45 Classification of different graphite flake morphology

Another form of graphite in cast iron is spheroidal graphite found in ductile cast irons (also called nodular cast irons). The microstructure of a typical ductile cast iron is shown in Fig. 46. This form of graphite is produced by a process called inoculation, in which a magnesium or cerium alloy is thrust into molten cast iron immediately prior to the casting operation. These elements form intermetallic compounds that act as a nucleating surface for graphite. With a spherical morphology, the graphite no longer renders the cast iron brittle as do graphite flakes in gray cast iron. Ductile irons have much higher ductility and toughness than gray iron and thus expand the use of this type of ferrous alloy. Most ductile iron castings are used in the as-cast form. However, heat treatment can be employed to alter the matrix microstructure to obtain desired properties. The matrix can be fully ferritic, fully pearlitic, fully martensitic, or fully bainitic, depending on composition and heat treatment. The yield strength of typical ductile cast irons ranges from 276 to 621 MPa (46 to 76 ksi), and their tensile strengths range from 414 to 827 MPa (60 to 120 ksi). Total elongation ranges from about 3 to 18%. Heat treated, austempered ductile irons have yield strengths ranging from 505 to 950 MPa (80 to 138 ksi), tensile strengths ranging from 860 to 1200 MPa (125 to 174 ksi), and total elongations ranging from 1 to 10%. Uses for ductile iron include gears, crankshafts, paper-mill dryer rolls, valve and pump bodies, steering knuckles, rocker arms, and various machine components.

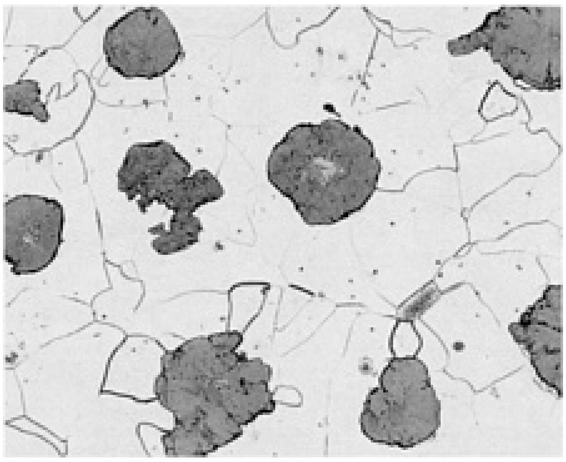

Fig. 46 Microstructure of a typical ductile (nodular) cast iron showing graphite in the form of spheroids. 2% nital etch. 200×. Courtesy of A.O. Benscoter, Lehigh University

Malleable cast iron encompasses yet another form of graphite called temper carbon. The microstructure of a typical malleable cast iron is shown in Fig. 47. This form of graphite is produced by the heat treatment of white cast iron, which does not contain graphite, but does contain a high percentage of cementite. When a white cast iron is heated for an extended period of time (about 60 h) at a temperature of 960 °C (1760 °F), the cementite decomposes into austenite and graphite. By slow cooling from 960 °C (1760 °F), the austenite transforms into ferrite or pearlite, depending on the cooling rate and the diffusion rate of carbon. The ductility and toughness of malleable iron falls between that of ductile cast iron and gray cast iron. Because white iron can only be produced in cast sections up to about 100 mm (4 in.) thick, malleable iron is thus limited in section size. The yield strength of typical malleable cast irons ranges from 207 to 621 MPa (30 to 70 ksi), and the tensile strength ranges from 276 to 724 MPa (40 to 105 ksi). Total elongation ranges from 1 to 18%. Applications for malleable iron include pipe fittings, valves, crankshafts, transmission gears, and connecting rods.

Cementite

A major microstructural constituent in white cast iron is cementite. The microstructure of a typical white cast iron is shown in Fig. 48. The cementite forms by a eutectic reaction during solidification:

$$\text{Liquid} \leftrightarrow \text{Cementite} + \text{Austenite} \qquad \textbf{(Eq 15)}$$

The eutectic constituent in white cast iron is called ledeburite and has a two-phase morphology shown as the smaller particles in the white matrix in Fig. 49. The eutectic is shown in the Fe-C binary diagram in Fig. 7(b). The austenite in the eutectic (as well as the austenite in the primary phase) transforms to pearlite, ferrite-pearlite, or martensite, depending on cooling rate and composition (e.g., in Fig. 47 the austenite transformed to pearlite). Because of the high percentages of cementite, white cast irons are used in applications requiring excellent wear and abrasion resistance. These irons contain high levels of silicon, chromium, nickel, and molybdenum and are termed alloy cast irons. Such applications include steel mill rolls, grinding mills, and jaw crushers for the mining industry. Hardness is the primary mechanical property of white cast iron and ranges from 321 to 400 HB for pearlitic white iron and 400 to 800 HB for alloy (martensitic) white irons.

Effects of Composition, Processing, and Structure on Properties of Irons and Steels

Bruce L. Bramfitt, Homer Research Laboratories, Bethlehem Steel Corporation

---

Evolution of Microstructural Change in Steel Products

It is interesting to study how microstructural and compositional changes have evolved in certain steel products. In some products, these changes have taken place over a 150-year span, and in other products over just a few decades. Examples of long-time evolution are rail steel and ductile/malleable cast iron, and an example of a short-term evolution is automotive sheet steel.

Evolution of Rail Steels. Up until the 1860s, most rails in the United States were either cast iron, wrought iron, or plain carbon steel imported from England. The steel rails were much preferred because the cast iron rails were brittle and the wrought iron rails were soft and had poor wear resistance. In 1865, the first steel rails were produced in the United States and since then, steel has become the dominant rail material.

Early steel rails had carbon contents much below the current eutectoid carbon level. This is because higher carbon content rails had a tendency to fracture and cause serious derailments. Not until the 1930s did railroad engineers realize that the problem was not the higher carbon content, but hydrogen. Laboratory and commercial studies proved that the problem of premature failure was caused by hydrogen flakes, or what the rail engineers called shatter cracks. Practices were put in place in the late 1930s to remove hydrogen by slow cooling of the rails during the manufacturing process in order to allow the hydrogen to diffuse out of the rails.

With this problem solved, the carbon content of rail steel quickly rose to eutectoid levels (0.76 to 0.82%). With this increase in carbon, the wear resistance increased and the railroads could haul heavier axle loads. Unfortunately, as axle load steadily increased from the 1940s to the 1980s, even the fully pearlitic rails began to wear more rapidly. During this time, it was discovered that if one produced a finer pearlite interlamellar spacing, the hardness of the rail increased as did the wear resistance. This led to manufacturing processes in which accelerated cooling was employed to attain a finer pearlite interlamellar spacing. These processes included oil quenching (in the 1940s), forced-air cooling, water-spray cooling, and aqueous-polymer quenching (in the 1980s).

Large improvements in wear resistance were obtained by these new processes, and it was soon discovered that rail life was no longer determined by the rail wearing out. Indeed, rail life in the 1990s is now determined by fatigue life and fracture toughness. The fatigue life could be improved by cleaner steels (fewer inclusions), but fracture toughness could not be improved sufficiently in a fully pearlitic steel, even by finer interlamellar spacings. That is, the pearlitic steel has essentially been pushed to its limit as serving as a rail steel. Thus, a revolutionary change must take place in rail steel technology. One such possible change is to completely switch from a fully pearlitic microstructure to a fully bainitic microstructure. Rail producers around the world are currently investigating high-strength bainitic rail steels. A German rail manufacturer has an experimental bainitic steel rail in track.

This example is used to illustrate how the demands in the field produce evolutionary microstructural, property, and processing changes to keep pace. However, as these demands increase, there comes a point where a revolutionary change must take place because the useful properties attributed to the original microstructure have been fully exhausted.

Evolution of Cast Iron. Another historic evolutionary change in microstructure took place in the manufacture of cast iron. Both gray and white cast iron, being among the earliest ferrous materials, were brittle and could not be fabricated into shapes other than those made by the casting process. Although quite useful, gray and white cast iron were relegated to simple shapes such as cooking pots, cannon balls, window sashes, stove panels, and radiators that did not demand a material with ductility or malleability. The reason for the lack of ductility is the flake-shaped graphite in gray cast iron and the cementite networks in white cast irons. The only way to attain ductility and malleability and therefore expand the usefulness of these irons was to alter the microstructure. The first commercial success was that of R.A.F. de Réaumer, a French metallurgist, in 1720. Réaumer used the process of decarburization of white cast iron by packing the castings in iron ore and heating the material to "bright redness" for several days. The lengthy heat treatment allowed the cementite to decompose into iron and carbon. The iron ore provided oxygen for decarburization. The final casting was completely free of cementite and the microstructure was fully ferritic or a mixture of ferrite and pearlite. Because the process depended on decarburization (and thus carbon diffusion), only thin castings could be treated in this way. In larger castings, cementite remained in the thicker sections, thus limiting their usefulness.

About 110 years later, S. Boyden of the United States invented what is known today as malleable iron. The advantage of malleable iron was that the process did not depend on days and weeks of decarburization, but depended on the decomposition of the cementite in white cast iron into iron and "free-carbon." This free-carbon formed as particles of carbon called "temper carbon," (see Fig. 47). The Boyden process involved a heat treatment of only 30 h and large castings could be heat treated. This process of microstructure alteration greatly expanded the usefulness of cast iron for more than a century and a half.

Another microstructural alteration process was invented in the 1960s. Here liquid cast iron is inoculated with a magnesium alloy, resulting in spheroids, rather than flakes, of graphite forming during solidification. The cast iron is called ductile iron and has a microstructure as shown in Fig. 46. The matrix in ductile iron can consist of ferrite, pearlite, ferrite-pearlite, martensite, or bainite, depending on alloy composition and heat treatment. Currently, austempered ductile irons, with a bainitic matrix, provide high strength and toughness heretofore not achieved in a cast iron product. Ductile iron castings now replace many components that were historically produced from plain-carbon and low-alloy steels. This evolutionary path of microstructural alteration in cast iron is an important example of the role microstructure plays in the development of structure-sensitive mechanical properties.

Evolution of Steel Sheet. An example of rapid-paced evolutionary change is in sheet steel for the automotive industry. For years, automobiles were produced using inexpensive, low-carbon sheet steel. However, during the oil crisis in 1974, the drastic increase in the price of gasoline and the Western world's almost total dependence on imported oil, mandated improved fuel economy for automobiles. This translated into production of lighter weight automobiles; this, in turn, created a revolution in sheet steel metallurgy. Since the oil crisis, ordinary low-strength, low-carbon sheet steel has been replaced by a number of higher-strength sheet steels requiring new process technology. These new steels include the high-strength, precipitation-strengthened steels, the dual-phase and tri-phase steels, and the bake-hardenable steels. Also, new coating techniques have been developed to protect these new steels from corrosion. This rapid change in automobile sheet steel is one example of the importance of basic understanding of metallurgy and the application of physical metallurgy to engineering product design.

Effects of Composition, Processing, and Structure on Properties of Nonferrous Alloys

Ronald N. Caron, Olin Corporation; James T. Staley, Alcoa Technical Center

Introduction

A BROAD RANGE OF PROPERTIES are available with commercially available nonferrous alloys; this articles provides an overview of these alloys and describes the specific microstructure/property relationships that are used to make specific properties available to designers of structural applications. Control of the microstructure during processing is as important for fabricability as it is for providing the desired engineering properties in the final product. Manufacturing alloy components with the desired structural properties requires applying the proper choice of processing method to the alloy composition capable of delivering those desired properties. Alloy and process development have sought to improve upon the properties available with metals by adjusting alloy additions along with processing parameters to meet the requirements of new technology. This process is ongoing today with the base alloys available for centuries (iron, copper, tin) as well as with the newer base alloys currently recruited to meet modern needs with unique property requirements (titanium, tungsten, niobium). When currently available alloys fall short of meeting the needs of the newest structural designs, the solution will be found as it has in the past by cooperative alloy/process development efforts with the supplier of the particular base-alloy system that has the properties closest to the particular design need.

No metal or alloy is entirely unique; similarities in process and property characteristics do exist among the wide variety of commercially available nonferrous alloys. However, each metal and alloy offers unique combinations of useful physical, chemical, and structural properties that are made available by its particular composition and the proper choice of processing method. This article focuses on the monolithic form of nonferrous alloys. However, it should be recognized that these alloys are also used in structural combinations, either as simple or complex composites, or with coatings in order to provide even more unique, economical combinations of useful properties. The importance of availability and cost are generally ignored in the following discussion except where these attributes are significant.

Detailed information and additional references to the literature on processing and property characteristics of nonferrous alloys are provided in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials,* Volume 2 of *ASM Handbook* (Ref 1). Basic data on nonferrous alloy phase relationships are found in *Alloy Phase Diagrams,* Volume 3 of *ASM Handbook* (Ref 2).

Aluminum and Aluminum Alloys

Aluminum alloys are second in use only to steel as structural metals. More than 500 alloys are registered with the Aluminum Association. Typical tensile strengths of aluminum alloy products range from 45 MPa (6.5 ksi) for 1199-O sheet to almost 700 MPa (100 ksi) for 7055-T77511 extruded products. The low density combined with high strength have made aluminum alloys the standard material for applications such as aircraft, where specific strength (strength-to-weight ratio) is a major design consideration. Because of their corrosion resistance, moderate strength, and good ductility, they are also used for a wide variety of applications including beverage cans; building and construction; marine, rail, truck, and auto transportation; and tool and jig plate.

Wrought aluminum products are produced using all available metalworking techniques, and castings are made using all standard solidification processes. Their properties depend on a complex interaction of chemical composition and microstructural features developed during solidification, thermal treatments, and (for wrought products) deformation processing. Although pure aluminum is very resistant to corrosion because of the presence of a film of aluminum oxide, corrosion resistance generally decreases with increasing alloy content, so tempers have been developed to improve the corrosion resistance of the highly alloyed materials.

Comprehensive information about the properties, processing, and applications of aluminum alloys is provided in the *ASM Specialty Handbook: Aluminum and Aluminum Alloys* (Ref 3). Other useful reference sources are listed as Ref 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, and 17.

Aluminum Alloy Phase Diagrams

Although few products are sold and used in their equilibrium condition, equilibrium phase diagrams are an essential tool in understanding effects of composition and both solidification and solid-state thermal processing on microstructure. For aluminum alloys, phase diagrams are used to determine solidification and melting temperatures, the solidification path, and the equilibrium phases that form and their dissolution temperatures. In addition to determining appropriate temperatures for casting and thermal treatments, phase diagrams are used to determine the maximum levels for ancillary element additions of certain elements to prevent the crystallization of coarse primary particles. The most important liquid-to-solid transformations for aluminum alloys are the eutectic and the peritectic. Examples of phase diagrams illustrating eutectic and peritectic reactions are discussed in the following paragraphs, and phase diagrams for aluminum alloys can be found in Ref 2, 3, 10, 11, and 17.

The eutectic reaction is illustrated by the aluminum-copper system (Fig. 1). When the liquidus temperature of aluminum-rich alloys is reached during solidification, the liquid begins to solidify into a solid solution of copper in aluminum (α-aluminum). As temperature approaches the solidus, the α-aluminum becomes more enriched with copper. When the temperature falls below the solidus temperature in alloys containing less than the maximum solubility, 5.7% Cu, solidification is complete. At temperatures below the solvus, Al_2Cu particles precipitate, depleting the α-aluminum of copper. When cooled to room temperature under near-equilibrium conditions, the α-aluminum contains little copper, so strength is low. To increase strength, the material must be solution heat treated, quenched, and aged to develop metastable precipitates as described later in this section. In alloys containing more than 5.7% Cu, some liquid remains when the eutectic temperature is reached. This liquid solidifies at this temperature by a eutectic reaction to α-aluminum and Al_2Cu intermetallic particles. On cooling below the eutectic temperature, the α-aluminum rejects copper as Al_2Cu precipitates. It is important to realize that the eutectic reaction can occur in alloys containing less than the maximum solid solubility under commercial casting conditions, even though the equilibrium phase diagram does not predict that. Consequently, Al_2Cu particles form during solidification of most aluminum alloy ingots and shaped castings. Therefore, they are "preheated" or homogenized to dissolve the intermetallic particles.

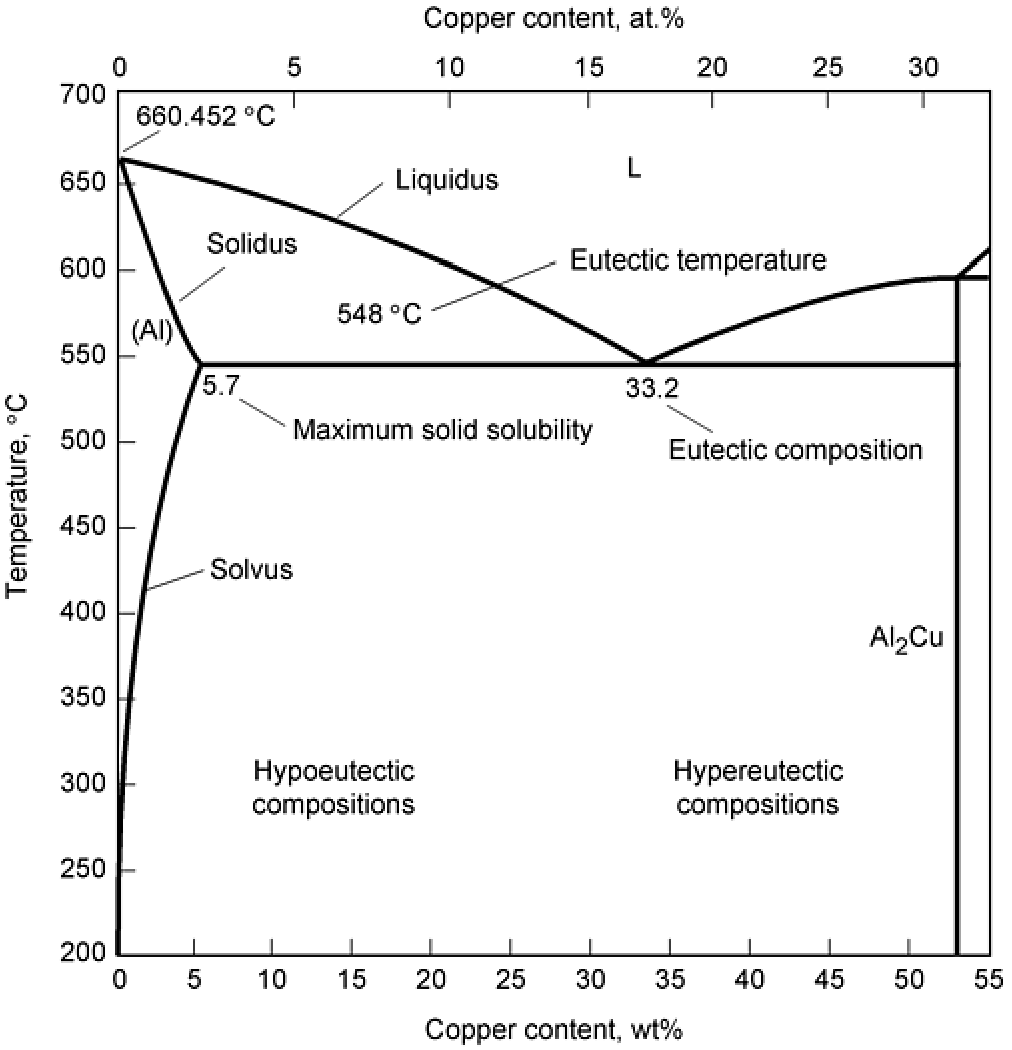

Fig. 1 Aluminum-copper phase diagram illustrating the eutectic reaction

The peritectic reaction in aluminum alloys is typified by the aluminum-chromium system (Fig. 2). During equilibrium solidification of alloys containing more than the peritectic composition, 0.41% Cr, but less than the maximum solid solubility of 0.77%, an intermetallic compound, Al_7Cr, forms when the liquidus temperature is reached. When the temperature falls to the peritectic temperature, 661 °C, the remaining liquid along with the Al_7Cr transforms to α-aluminum. Under commercial solidification conditions, however, the primary particles of Al_7Cr would not have the opportunity to transform to α-aluminum, so they would remain. Consequently, maximum chromium limits are established so that all of the chromium remains in supersaturated solid solution in the ingot. It precipitates as chromium-bearing dispersoids during ingot preheat.

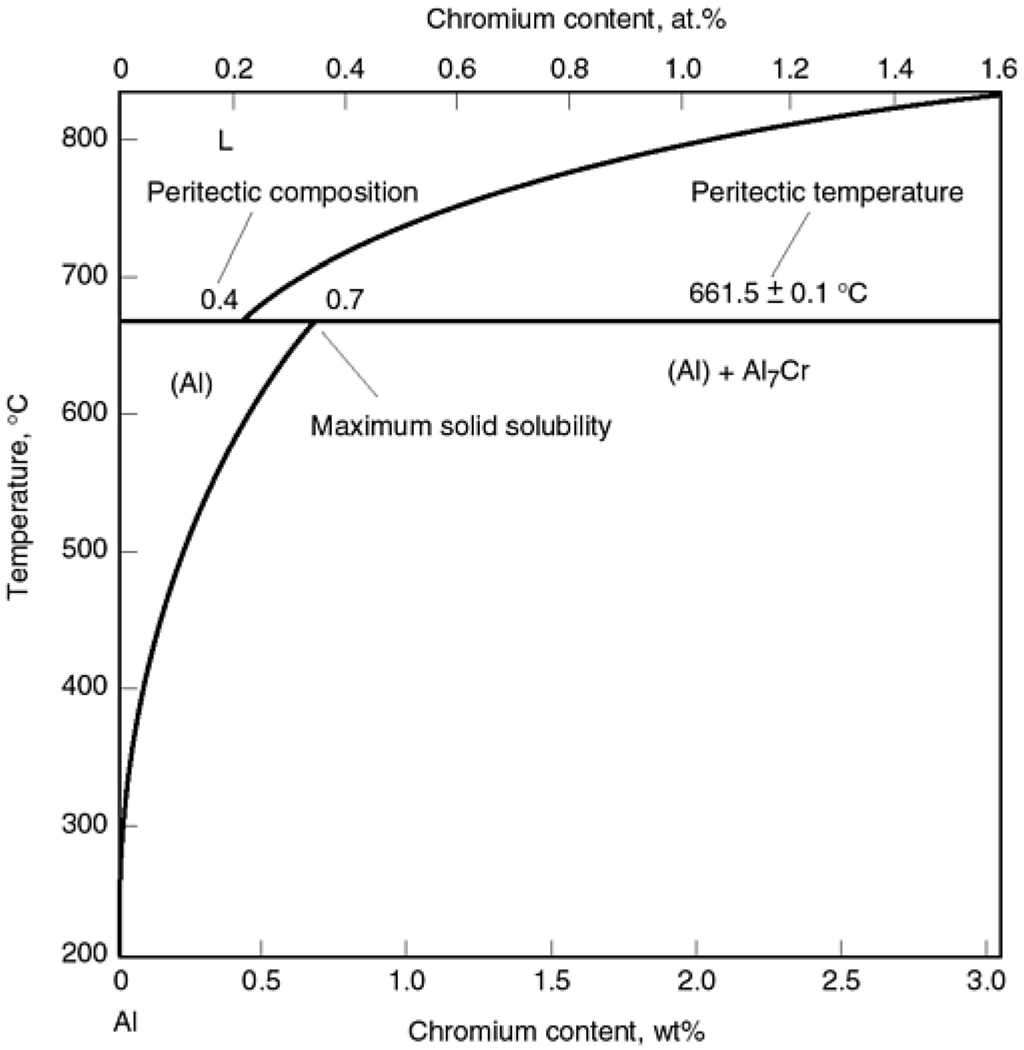

Fig. 2 Aluminum-chromium phase diagram illustrating the peritectic reaction

Aluminum Alloy Impurity and Alloying Elements

All commercial aluminum alloys contain iron and silicon as well as two or more elements intentionally added to enhance properties. The phases formed and the function of the alloying elements are described.

Iron. Virtually all aluminum alloys contain some iron that is an impurity remaining after refining bauxite and smelting. The phase diagram predicts that during solidification of an aluminum-iron alloy containing a few tenths of a percent of iron, most of the iron remains in the liquid phase until a eutectic of solid solution plus Al_3Fe intermetallic constituent particles having a monoclinic crystal structure freezes. Depending on solidification rate and on the presence of other elements such as manganese, constituent particles of the metastable orthorhombic Al_6Fe phase can form instead of the equilibrium Al_3Fe. The maximum solid solubility of iron in aluminum is 0.05%, but the solubility is much lower in most structural alloys.

Silicon. This element is also a ubiquitous impurity in commercial aluminum alloys. Two ternary phases, cubic α-$Al_{12}Fe_3Si$ and monoclinic β-$Al_9Fe_2Si_2$, form by a eutectic reaction. At low silicon contents, almost all of the iron is present as Al_3Fe. With increasing silicon contents, first the α- then the β-Al-Fe-Si phases appear. Phases in commercial products may not be those predicted by the equilibrium phase diagrams because of the long times at high temperatures required to approach equilibrium. In large amounts, silicon improves castability and fluidity. Consequently, it is used in 4*xxx* brazing sheet and in 3*xx.x* and 4*xx.x* casting alloys. Silicon ranges from about 5 to 20% in casting alloys. Hypereutectic alloys (those containing >12.6% Si, the eutectic composition) are used for engine blocks because the primary silicon particles are wear resistant. Some 3*xx.x* casting alloys contain small additions of magnesium to render them capable of being age hardened.

Silicon is deliberately added to some alloys containing magnesium to provide precipitation hardening. The Al-Mg-Si system is the basis for the 6*xxx* alloys. At low magnesium contents, elemental silicon may be present as second-phase particles. As magnesium increases, both silicon particles and equilibrium hexagonal Mg_2Si constituents may be present. At higher magnesium contents, only Mg_2Si is present. Ternary alloys are strengthened by precipitation of metastable precursors to Mg_2Si. With the addition of copper, a complex quaternary $Al_4CuMg_5Si_4Q$ phase can form. A precursor to this quaternary phase strengthens Al-Cu-Mg-Si alloys.

Manganese. The aluminum-manganese system is the basis for the oldest aluminum alloys. Such alloys, known as 3*xxx*, are the most widely used wrought alloys because of their excellent formability and resistance to corrosion. Commercial aluminum-manganese alloys contain both iron and silicon. During solidification of commercial size ingots, some of the manganese forms Al_6(Mn,Fe) and cubic Al_{12}(Fe,Mn) Si by eutectic reactions. The remaining manganese remains in solution and is precipitated during the ingot preheat as Al_{12}(Mn,Fe)Si and Al_6(Mn,Fe) dispersoids. These dispersoids strengthen the material and control recrystallized grain size. In alloys containing copper, manganese precipitates as $Al_{20}Cu_2Mn_3$ dispersoid particles. Effects on strength are minor, but the dispersoids aid in grain size control after solution heat treatment.

Magnesium. The aluminum-magnesium system is the basis for the wrought 5*xxx* and cast 5*xx.x* non-heat-treatable aluminum alloys, which provide excellent combinations of strength and corrosion resistance by solid-solution strengthening and work hardening. Although in principle this phase diagram exhibits a positively sloping solvus, a necessary condition for a precipitation-hardening system, difficulty in nucleating the face-centered cubic (fcc) Al_3Mg_2 precipitates has precluded commercialization of heat-treatable aluminum-magnesium alloys, unless they contain enough silicon, copper, or zinc to form Mg_2Si, Al-Cu-Mg, or Al-Zn-Mg precipitates.

Copper. The aluminum-copper system is the basis for the wrought 2*xxx* and cast 2*xx.x* alloys, and many other heat-treatable alloys contain copper. In commercial aluminum-copper alloys, some of the copper chemically combines with aluminum and iron to form either tetragonal Al_7Cu_2Fe or orthorhombic α(Al,Cu,Fe) constituent particles during solidification. These constituents cannot be dissolved during subsequent thermal treatments, but one can transform to the other during thermal treatments of ingots or castings. During heat treatment of aluminum-copper alloys containing little magnesium, Al_2Cu precipitates as the strengthening phase.

Adding magnesium to aluminum-rich aluminum-copper alloys results in the formation of the Al_2CuMg phase by eutectic decomposition. Metastable precursors to face-centered orthorhombic Al_2CuMg precipitates are used to strengthen several structural alloys used in the aerospace industry because they confer a desirable combination of strength, fracture toughness, and resistance to the growth of fatigue cracks.

Zinc. This element confers little solid-solution strengthening or work hardening to aluminum, but Al-Zn-Mg precipitates provide the basis for the 7*xxx* wrought alloys and the 7*xx.x* cast alloys. Two phases can form by eutectic decomposition in commercial Al-Zn-Mg alloys: hexagonal $MgZn_2$ and body-centered cubic (bcc) $Al_2Mg_3Zn_3$. Depending on the zinc/magnesium ratio, copper-free alloys are strengthened by metastable precursors to either $MgZn_2$ or $Al_2Mg_3Zn_3$. In Al-Zn-Mg-Cu alloys, copper and aluminum substitute for zinc in $MgZn_2$ to form $Mg(Zn,Cu,Al)_2$. Al_2CuMg particles can also form in these alloys by eutectic decomposition and solid-state precipitation.

Chromium. In commercial alloys, the solubility can be reduced to such an extent that Al_7Cr primary particles can form by a peritectic reaction at chromium contents lower than that indicated by the binary aluminum-chromium phase diagram. Because coarse primary particles are harmful to ductility, fatigue, and fracture toughness, the upper limits of chromium depend on the amount and nature of the other alloying and impurity elements. In 5*xxx* alloys, fcc cubic $Al_{18}Mg_3Cr_2$ dispersoids precipitate during ingot preheating. In 7*xxx* alloys, the composition of the dispersoids is closer to $Al_{12}Mg_2Cr$. Chromium dispersoids contribute to strength in non-heat-treatable alloys and control grain size and degree of recrystallization in heat-treatable alloy products.

Zirconium. This element also forms a peritectic with aluminum. The phase diagram predicts that the equilibrium Al_3Zr phase is tetragonal, but fine dispersoids of metastable cubic Al_3Zr form during ingot preheating treatments. Most 7*xxx* and some 6*xxx* and 5*xxx* alloys developed since the 1960s contain small amounts of zirconium, usually less than 0.15%, to form Al_3Zr dispersoids for recrystallization control.

Lithium. This element reduces the density and increases the modulus of aluminum alloys. In binary alloys it forms metastable Al_3Li precipitates and combines with aluminum and copper in Al-Cu-Li alloys to form a large number of Al-

Cu-Li phases. Because of its high cost relative to other alloying elements, lithium alloys have been found to be cost effective thus far only in space and military applications.

Aluminum Alloy Designation System

The alloy designation system classifies alloys by their composition. In the United States, aluminum alloys are designated by two distinct four-digit systems, one for wrought aluminum (Table 1) and one for cast products (Table 2). The system for designating wrought alloys has been adopted worldwide. No worldwide system for designating aluminum casting alloys exists; European manufacturers often use tradenames as identification.

Table 1 Designation system for wrought aluminum alloys

Aluminum, at least 99.00%	**1*xxx***
Aluminum alloys grouped by major alloying elements:	
Copper	2*xxx*
Manganese	3*xxx*
Silicon	4*xxx*
Magnesium	5*xxx*
Magnesium and silicon	6*xxx*
Zinc	7*xxx*
Other element	8*xxx*

The last two digits indicate the aluminum purity or identify the aluminum alloy. The second digit indicates modifications of the original alloy or impurity limits.

Table 2 Designation system for cast aluminum alloys

Aluminum, at least 99.00%	**1*xx.x***
Aluminum alloys grouped by major alloying elements:	
Copper	2*xx.x*
Silicon with added copper or manganese	3*xx.x*
Silicon	4*xx.x*
Magnesium	5*xx.x*

Zinc	7*xx.x*
Tin	8*xx.x*
Other element	9*xx.x*

The second two digits indicate the aluminum purity or identify the aluminum alloy. The last digit indicates the product form, castings (*xxx*.0) or foundry ingot (*xxx*.1 and *xxx*.2). A modification of the original alloy or impurity limits is designated by a serial letter before the numerical designation. The series 6*xx.x* is unused.

Nominal compositions for several wrought structural alloys are presented in Tables 3 and 4. Nominal compositions of several casting alloys are presented in Table 5.

Table 3 Nominal chemical compositions of selected 3*xxx* and 5*xxx* aluminum alloys

Aluminum Alloy Temper Designation System

The temper designation system (Table 6) classifies tempers by certain thermal and mechanical processes that control strength and other characteristics of both wrought and cast aluminum alloy products. In general, wrought alloys in the 2*xxx*, 6*xxx*, and 7*xxx* series and cast alloys in the 2*xx.x*, 3*xx.x*, and 7*xx.x* series are referred to as heat-treatable alloys because they can be precipitation hardened and are used in T tempers. Typical tensile properties of heat-treatable wrought and cast alloy products are presented in Tables 7 and 8, respectively. The remaining are referred to as non-heat-treatable alloys and are strengthened by solid-solution strengthening, dispersion strengthening and, for wrought alloys, work hardening. They are used in either O or H tempers. Typical tensile properties of wrought non-heat-treatable alloy sheet products are presented in Table 9.

Table 6 Temper designation system for aluminum alloys

Designation	Processing	Comments
F	As fabricated	Products of shaping processes in which no special control over thermal conditions or work hardening is employed.
O	Annealed	Wrought products that are annealed to obtain the lowest strength temper and to cast products that are annealed to improve ductility and dimensional stability.
H	Work hardened (wrought products only)	Products that have their strength increased by work hardening, with or without supplementary treatments to produce some reduction in strength. The H is always followed by two or more digits.
H1	Work hardened only	The number following this designation indicates the degree of work hardening.
H2	Work hardened and partially annealed	Products that are work hardened more than the desired final amount and then reduced in strength by partial annealing. The number following this designation indicates the degree of work hardening after the product has been partially annealed.
H3	Work hardened and stabilized	Products that are work hardened and whose properties are stabilized either by a low-temperature thermal treatment or as a result of heat introduced during fabrication. The number following this designation indicates the degree of work hardening remaining after the stabilization procedure.
W	Solution heat treated	An unstable temper applicable only to alloys that spontaneously age at room temperature after solution heat treatment. This designation is specific only when the period of natural aging is indicated. For example, W $\frac{1}{2}$ h
T	Thermally treated to produce stable properties other than F, O, or H	Products that are thermally treated, with or without supplementary work hardening, to produce stable tempers. The T is always followed by one or more digits.
T3	Solution treated, quenched, cold worked, and naturally aged to a substantially stable condition	Products that are cold worked after solution treatment and the effect of cold work is recognized in mechanical property limits.
T4	Solution treated, quenched, and naturally aged to a substantially stable condition	Products that are either not cold worked after solution heat treatment or are cold worked and the effects of cold work might not be recognized in mechanical property limits.
T5	Quenched from an elevated-temperature shaping process and then artificially aged	. . .
T6	Solution heat treated, quenched, and artificially aged	Products that are either not cold worked after solution heat treatment or are cold worked and the effects of cold work might not be recognized in mechanical property limits.

T7	Solution treated, quenched, and overaged/stabilized	Wrought products that are overaged to carry them beyond a point of maximum strength to provide control of some other characteristic, usually corrosion resistance. Applies to cast products that are artificially aged after solution heat treatment to provide dimensional and strength stability.
T8	Solution treated, quenched, cold worked, and artificially aged	Products that are cold worked after solution treatment and the effect of cold work is recognized in mechanical property limits.
T9	Solution treated, quenched, artificially aged, and then cold worked	Products that are cold worked to improve strength.

O Temper. Ductility of all aluminum products is highest in this temper. Factors determining properties of annealed products depend on the alloy system. The annealed strength of unalloyed aluminum, 1*xxx* series, generally increases and ductility decreases with increasing impurity level, and the amounts of magnesium and manganese largely determine the bulk properties of 3*xxx* and 5*xxx* products. Strength increases as magnesium (solid-solution strengthening) and manganese contents (dispersion and solid-solution strengthening) increase. Ultimate tensile strength increases more significantly with increasing magnesium content than does tensile yield strength because of the potent effect of magnesium on work hardening. Parts of heat-treatable alloy products that are difficult to form are often formed in the O temper, then heat treated to a final temper.

H Tempers. Cold working of annealed material to H1 tempers increases the dislocation density. This increases strength, particularly yield strength, and decreases ductility. In unalloyed aluminum and in alloys containing little magnesium, cold working produces cells that have walls containing a high density of dislocations enclosing a volume of relatively strain-free material. In alloys containing sufficient amounts of magnesium, however, the dislocations form a tangled forest. In highly worked aluminum-magnesium alloys, rearrangement of the dislocation structure occurs over long times at room temperature. Stabilizing treatments, H3 tempers, prevent loss of strength in certain 3*xxx* and 5*xxx* alloys during subsequent long-time exposure. During partial annealing treatments, H2 tempers, cell walls either form or become more perfect, and dislocations within the cell migrate to cell boundaries. If the temperature exceeds a critical level, which depends on alloy content and strain, the cold-worked product will either partially or completely recrystallize. Materials in H2 tempers provide a combination of strength and ductility generally superior to that of material in H1 tempers. Cold-worked alloys containing above approximately 3.5% Mg and annealed alloys containing above approximately 4.5% Mg can also suffer a degradation in corrosion resistance caused by precipitation of a continuous film of Al_3Mg_2 on grain boundaries at temperatures between ambient and approximately 205 °C (400 °F). Special H116 and H321 controlled hot-rolling tempers have been developed that either avoid precipitation of Al_3Mg_2 on grain boundaries or agglomerate the precipitate to increase corrosion resistance. For a particular strength level, a higher resistance to stress corrosion is obtained by increasing magnesium and manganese rather than by increasing work hardening.

W and T Tempers. The highest strengths are obtained by precipitation hardening. The material is held for a sufficient time above the solvus to dissolve essentially all of the major alloying elements, quenched at a rate to retain most of these elements in solid solution, then aged either at room temperature (natural aging) or at a modestly elevated temperature

(artificial aging). The highest-strength alloys contain the largest concentration of the major alloying elements. For a particular alloy system, strength typically increases with increasing alloy content. Most 2*xxx* and 6*xxx* wrought alloys and 2*xx.x* and 3*xx.x* cast alloys are strengthened during natural aging by Guinier-Preston (G-P) zones, which are precursors to Al_2Cu, Al_2CuMg, Mg_2Si, or $Al_4CuMg_5Si_4$ phases. Strength of these materials increases for about 4 days, then stabilizes (T4 temper). In contrast, in 7*xxx* alloys containing G-P zone precursors to phases such as $MgZn_2$, strength continues to increase indefinitely at room temperature (W temper). The ductility in the freshly quenched (W < $\frac{1}{2}$ h temper) condition is high enough for many forming operations. Consequently, many parts are formed shortly after quenching from the solution-heat-treatment temperature. To prevent the formation of large grains during the solution treatment of formed parts, a critical amount of strain must be avoided. Although this critical strain is alloy dependent, strains near 10% are particularly troublesome for most alloys. In addition, ductility in the T4 or T3 tempers is sufficiently high that some parts can be formed successfully in this condition. Strength, particularly yield strength, increases substantially with artificial aging (T6 temper). This increase is accompanied by a loss in ductility. Strength of materials hardened by Al_2CuMg, Al_2Cu, or Al_2CuLi precipitates may be increased by cold work prior to artificial aging, T8, treatments. The increase in strength of these materials is attributed to a refinement of Al_2CuLi and of the metastable precursors to Al_2CuMg and Al_2Cu. Additions of silicon and other alloying elements can also serve to refine the size of precipitates in certain 2*xxx* alloys. Cold-finishing rod and bar products after artificial aging increases their strength (T9 temper).

The solution treatment, in most cases, is a separate operation. In particular circumstances, however, the heat from a shaping process may be sufficient to provide solution treatment. These products can be cooled after the shaping process and subsequently aged to develop useful properties (T5 temper). Some 6*xxx* alloys attain the same specified properties whether furnace solution heat treated or cooled from an elevated-temperature shaping process at a rate rapid enough to maintain sufficient silicon and magnesium in solution. In such cases, the T6 temper designation may be used.

Aluminum Alloy Microstructural Features Not Inferred from the Alloy-Temper Designation Systems

The alloy designation system defines the alloy content, and the temper-designation system identifies many of the thermal and mechanical processes that control the microstructure and, hence, the bulk properties of aluminum alloy products. Nevertheless, many metallurgical features are not specified by these systems. The features include nonmetallic inclusions, porosity, second-phase particles, grain and dislocation structure, and crystallographic texture.

Inclusions are typically oxides of aluminum and magnesium including spinel, $MgAl_2O_4$. Oxides form on the surface of molten aluminum and become entrapped when turbulent flow forces them below the surface. Filtration of the molten metal is used to control inclusions. Inclusions can give rise to problems ranging from pinholes in foil to reduced fatigue life in structural wrought products and castings.

Porosity reduces ductility and increases susceptibility to the initiation of fatigue cracks. Porosity may arise from either shrinkage during solidification or from hydrogen. Hydrogen control during solidification is extremely important because of the ten-fold decrease in the solubility of hydrogen in aluminum as it solidifies. Hydrogen-induced porosity can also occur in solid aluminum products when they are heated to high temperatures in humid environments. Provided that the hydrogen content is low enough, most of the porosity can be closed by thermomechanical treatments. Isostatic pressure can be used to close the pores in castings, and conventional forging and extrusion are effective in healing ingot porosity. Porosity in thick-rolled products is particularly difficult to close; tensile stresses in the short-transverse direction may arise during the initial rolling of thick plate because the amount of deformation per pass is limited. This stress causes pores to enlarge. With additional rolling to thinner plate, the pores heal.

Second-phase particles are divided into four classes based on their mode of formation and their ability to be dissolved: primary particles, constituents, dispersoids, and precipitates.

Primary Particles. These particles form when some phase other than aluminum solid solution separates first from the melt. Primary silicon particles form in castings when hypereutectic aluminum-silicon alloys solidify by eutectic decomposition. Ductility decreases with increasing size of the silicon particles, so size control is important. The coarse, faceted primary silicon particles are refined to a fine spherulitic structure using additives containing phosphorus. In certain casting alloys and 8*xxx* wrought alloys, primary iron-bearing constituents can form if the alloying content is such that the alloy is hypereutectic. In wrought alloys, macroscopically large, undesirable primary particles of Al_7Cr, Al_3Ti, or Al_3Zr can form by a peritectic reaction if chemical composition is not closely controlled.

Constituents. These particles may be either intermetallic compounds or essentially pure silicon that forms during solidification of hypoeutectic aluminum-silicon alloys. They range in size from a few micrometers to tens of micrometers. Constituents can be classified either as virtually insoluble or soluble. Because the low maximum solid solubility of iron in aluminum is further reduced by other alloying elements to 0.01 wt% or less, constituents containing iron are insoluble. Iron-free constituents containing silicon can be either soluble or insoluble depending on the chemical composition of the alloy. Major alloying elements can combine either with each other or with aluminum to form soluble constituent particles. Most of these soluble constituents dissolve either during ingot preheating prior to deformation processing or during the solution heat treatment of cast shapes or wrought products. Constituent size decreases with increasing solidification rate. In hypoeutectic 3*xx*.0 and 4*xx*.0 castings, modification by elements such as strontium significantly refine the flake structure of the silicon particles to a finer fibrous morphology.

Constituent particles are generally not beneficial and are detrimental to the fatigue resistance and fracture toughness of high-strength alloy products. These particles fracture at relatively low plastic strains and provide low-energy sites for the initiation and growth of cracks. Several high-purity (low iron and silicon) versions of 2024 and 7075 have been commercialized, and the maximum allowable impurity levels of all modern high-strength alloys are significantly lower than those of older alloys. Despite the harmful effects of constituents in high-strength alloys, the ability of alloy 3004-H19 to make commercially successful beverage containers relies on careful control of size, volume fraction, and distribution of Al_{12}(Fe,Mn)Si constituent particles. These constituent particles serve to "scour" the die during the drawing operation so that galling is minimized. Attempts to produce can stock from roll-cast sheet have generally not been successful because the particle size distribution in roll-cast sheet is not as effective in minimizing galling.

Dispersoids. These form by solid-state precipitation, either during ingot preheating or during the thermal heat treatment of cast shapes, of slow-diffusing supersaturated elements that are soluble in molten aluminum but which have limited solubility in solid aluminum. Manganese, chromium, or zirconium are typical dispersoid-forming elements. Unlike the precipitates that confer precipitation hardening, dispersoids are virtually impossible to dissolve completely, once precipitated. In addition to providing dispersion strengthening, the size distribution of dispersoids in wrought alloys are a key factor in controlling degree of recrystallization, recrystallized grain size, and crystallographic texture. Dispersoids in non-heat-treatable alloys also stabilize the deformation substructure during elevated-temperature exposures, for example, during paint baking.

In contrast to the commercially significant dispersion strengthening provided by dispersoids in 3*xxx* and 5*xxx* alloys, the level of dispersion strengthening afforded by dispersoids in wrought heat-treatable alloys is trivial. In 2*x*24 alloys, $Al_{20}Cu_2Mn_3$ dispersoids nucleate dislocations at the particle-matrix interface during the quench. These dislocations serve as nucleation sites for subsequent precipitation. The newer 7*xxx* alloys contain zirconium, which forms coherent Al_3Zr dispersoids while most of the older 7*xxx* alloys contain $Al_{12}Mg_2Cr$ dispersoids which exhibit incoherent interfaces. The incoherent interfaces serve to nucleate $MgZn_2$ precipitates during the quench, so alloys containing these precipitates lose a great deal of their potential to develop high strength after slow quenching (quench sensitivity). Nucleation is difficult on coherent interfaces, so the newer alloys are less quench sensitive. A number of casting alloys, and some wrought alloys, contain elements that can form either constituents or dispersoids depending on the solidification rate.

Precipitates can form during any thermal operation below the solvus. In properly solution-heat-treated products, all precipitates dissolve during the solution-heat-treatment operation. Depending on quench rate and alloy, precipitates can form during the quench from the solution-heat-treatment temperature at grain and subgrain boundaries and at particle-matrix interfaces. These coarse precipitates do not contribute to age hardening and can serve to reduce properties such as ductility, fracture toughness, and resistance to intergranular corrosion. After the quench, G-P zones form at ambient temperature (natural aging). These are agglomerates of atoms of the major solute elements with a diffuse, coherent boundary between the G-P zone and the matrix. During elevated-temperature precipitation heat treatments (artificial aging) G-P zones may either nucleate metastable precipitates or they may dissolve, and metastable precipitates nucleate separately. Cold working subsequent to quenching introduces dislocations that may serve to nucleate metastable or equilibrium precipitates. With prolonged artificial aging, equilibrium precipitates may form. Coarse equilibrium precipitates form during annealing treatments of heat-treatable alloy products, O temper. They also form during most thermomechanical treatments prior to solution heat treatment.

Grain Structure. The grain size of aluminum alloy ingots and castings is typically controlled by the introduction of inoculants that form intermetallic compounds containing titanium and/or boron. During deformation processing, the grain structure becomes modified. Most aluminum alloy products undergo dynamic recovery during hot working as the dislocations form networks of subgrains. New dislocation-free grains may form between and following rolling passes (static recrystallization) or during deformation processing (dynamic recrystallization). During deformation, the crystal lattice of the aluminum matrix rotates at its interfaces between constituent and coarse precipitate particles. These high-

energy sites serve to nucleate recrystallization. This process is termed particle-stimulated nucleation and is an important mechanism in the recrystallization process of aluminum. The particle size that will serve as a nucleus decreases as deformation temperature decreases and strain and strain rate increase. Dispersoid particles retard the movement of high-angle grain boundaries. Consequently, hot-worked structures are resistant to recrystallization and often retain the dynamically recovered subgrain structure in the interiors of elongated cast grain boundaries. In heat-treated products containing a sufficient quantity of dispersoids--the unrecrystallized structure of hot-worked-plate--forgings and extrusions can be retained after solution heat treatment.

Degree of recrystallization of hot-worked products has an effect on fracture toughness. Unrecrystallized products develop higher toughness than do products that are either partially or completely recrystallized. This behavior is attributed to precipitation on the recrystallized high-angle grain boundaries during the quench. These particles increase the tendency for low-energy intergranular fracture. Products such as sheet, rods, and tubing that are cold rolled invariably recrystallize during solution heat treatment or annealing to O temper.

Decreasing the grain size can increase strength of 5*xxx* alloy products in the O temper by 7 to 28 MPa (1 to 4 ksi), but grain size is not a major factor in increasing strength of other aluminum alloy products. Several measures of formability are influenced by grain size, however, so grain size is controlled for this reason. One particular use of grain size control is to produce stable, fine grains, which are essential in developing superplastic behavior in aluminum alloy sheet.

Crystallographic Texture. Cast aluminum ingots and shapes generally have a random crystallographic texture; the orientation of the unit cells comprising each grain are not aligned. With deformation, however, certain preferred crystallographic orientations develop. Many of the grains rotate and assume certain orientations with respect to the direction of deformation. For flat-rolled products and extrusions having a high aspect ratio of width to thickness, the deformation texture is similar to that in pure fcc metals. These orientations are described by using the Miller indices of the planes {nnn} in the grains parallel to the plane of the worked product and directions [nnn] parallel to the working direction. The predominant textures are {110}[112], {123}[634], and {112}[111]. During recrystallization, a high concentration of grains in the {001}[100] or {011}[100] orientations may develop. Alternatively, if particle-stimulated nucleation is present to a large extent, the recrystallized texture will be random. Control of crystallographic texture is particularly important for non-heat-treatable sheet that will be drawn. If texture is not random, ears form during the drawing process. In extruded or drawn rod or bar, the texture is a dual-fiber texture in which almost all grains are aligned so that the grain directions are either [001] or [111]. In heat-treatable alloys, texture has the most potent effect on the properties of extrusions that have the dual-fiber texture. Strengthening by this process is so potent that the longitudinal yield strengths of extruded products exhibiting this texture are about 70 MPa (10 ksi) higher than strength in the transverse direction. If this dual-fiber texture is lost by recrystallization, strength in the longitudinal direction decreases to that in the transverse directions.

Effects of Composition, Processing, and Structure on Properties of Nonferrous Alloys

Ronald N. Caron, Olin Corporation; James T. Staley, Alcoa Technical Center

Copper and Copper Alloys

After iron and aluminum, copper is the third most-prominent commercial metal because of its availability and attractive properties: excellent malleability (or formability), good strength, excellent electrical and thermal conductivity, and superior corrosion resistance (Ref 18, 19, 20, 21, 22, 23, 24, 25). Copper offers the designer moderate levels of density (8.94 g/cm^3, or 0.323 lb/in.^{3}), elastic modulus (115 GPa, or 17 × 10^6 psi), and melting temperature (1083 °C, or 1981 °F). It forms many useful alloys to provide a wide variety of engineering property combinations and is not unduly sensitive to most impurity elements. The electrical conductivity of commercially available pure copper, about 101% IACS (International Annealed Copper Standard), is second only to that of commercially pure silver (about 103% IACS). Standard commercial copper is available with higher purity and, therefore, higher conductivity than what was available when its electrical resistivity value at 20 °C (70 °F) was picked to define the 100% level on the IACS scale in 1913. The thermal conductivity for copper is also high, 391 W/m · K (226 Btu/ft · h · °F), being directly related to the electrical conductivity through the Wiedemann-Franz relationship.

Copper and the majority of its alloys are highly workable hot or cold, making them readily commercially available in various wrought forms: forgings, bar, wire, tube, sheet, and foil. In 1995, copper used in wire and cable represented about 50% of U.S. production and in flat products of various thickness another 15%, rod and bar about 14%, tube about 14.5%, with foundries using about 5% for cast products, and metal powder manufacturers about 0.6%. Besides the more familiar copper wire, copper and its alloys are used in electrical and electronic connectors and components, heat-exchanger tubing, plumbing fixtures, hardware, bearings, and coinage.

As with other metal systems, copper is intentionally alloyed to improve its strength without unduly degrading ductility or workability. However, it should be recognized that additions of alloying elements also degrade electrical and thermal conductivity by various amounts depending on the alloying element, its concentration and location in the microstructure (solid solution or dispersoid). The choice of alloy and condition is most often based on the trade-off between strength and conductivity. Alloying also changes the color from reddish brown to yellow (with zinc, as in brasses) and to metallic white or "silver" (with nickel, as in U.S. cupronickel coinage).

Copper and its alloys are readily cast into cake, billet, rod, or plate--suitable for subsequent hot or cold processing into plate, sheet, rod, wire, or tube--via all the standard rolling, drawing, extrusion, forging, machining, and joining methods. Copper and copper alloy tubing can be made by the standard methods of piercing and tube drawing as well as by the continuous induction welding of strip. Copper is hot worked over the temperature range 750 to 875 °C (1400 to 1600 °F), annealed between cold working steps over the temperature range 375 to 650 °C (700 to 1200 °F), and is thermally stress relieved usually between 200 and 350 °C (390 and 660 °F). Copper and its alloys owe their excellent fabricability to the face-centered cubic crystal structure and its twelve available dislocation slip systems. Many of the applications of copper and its alloys take advantage of the work-hardening capability of the material, with the cold processing deformation of the

final forming steps providing the required strength/ductility for direct use or for subsequent forming of stamped components. Copper is easily processible to more than 95% reduction in area. The amount of cold deformation between softening anneals is usually restricted to 90% maximum to avoid excessive crystallographic texturing, especially in rolling of sheet and strip.

Although copper obeys the Hall-Petch relationship and grain size can be readily controlled by processing parameters, work hardening is the only strengthening mechanism used with pure copper. Whether applied by processing to shape and thickness, as a rolled strip or drawn wire, or by forming into the finish component, as an electrical connector, the amount of work hardening applied is limited by the amount of ductility required by the application. Worked copper can be recrystallized by annealing at temperatures as low as 250 °C (480 °F), depending on prior degree of cold work and time at temperature. While this facilitates processing, it also means that softening resistance during long-time exposures at moderately elevated temperatures can be a concern, especially in electrical and electronic applications where I^2R heating is a factor. For applications above room temperature, but at temperatures lower than those inducing recrystallization in commercial heat treatments, thermal softening can occur over extended periods and characteristics such as the half-softening temperature should be considered; that is, the temperature for which the worked metal softens to half its original hardness after a specific exposure time, usually 1 h.

A more useful engineering property for many electrical contact applications is stress-relaxation resistance, the property that characterizes the decrease in contact load supported by a mechanical contact over time at a given temperature, typically measured at room temperature between exposures to elevated temperature (Ref 20). Figure 3 illustrates the characteristics of the tensile-stress-relaxation property of drawn (worked) copper wire; the degree of relaxation increases with temperature and time. It also increases with the initial temper or degree of cold work in the material. The mechanism is the thermally activated and applied-stress directed motion of crystal lattice defects, such as point defects and dislocations. Consequently, the application of a thermal heat treatment (stabilization anneal) to induce recovery mechanisms to tie up mobile components of dislocations will improve the stress-relaxation resistance. Alloying elements also restrict dislocation motion and provide a more potent remedy for improving stress-relaxation resistance of cold-worked metal in service. For example, the improvement in stress-relaxation resistance obtainable by alloying copper with 5% Sn (alloy C51000) in combination with a low-temperature stabilization heat treatment and as a function of sheet orientation is illustrated by comparing the alloy data at 93 °C (200 °F) in Fig. 4 with those for copper in Fig. 3.

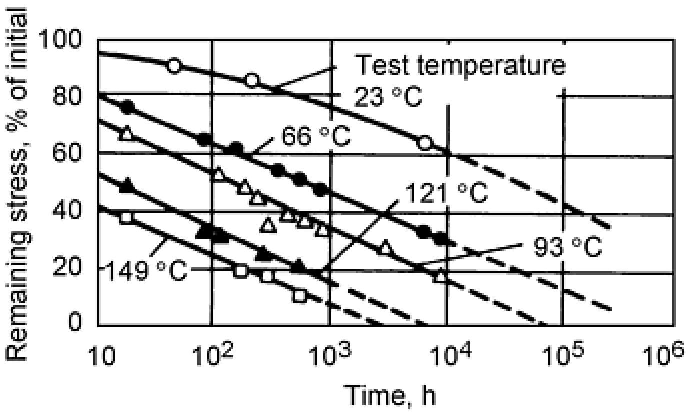

Fig. 3 Tensile-stress-relaxation characteristics of copper alloy C11000. Data are for tinned 30 AWG (0.25 mm diam) annealed ETP copper wire; initial elastic stress, 89 MPa (13 ksi).

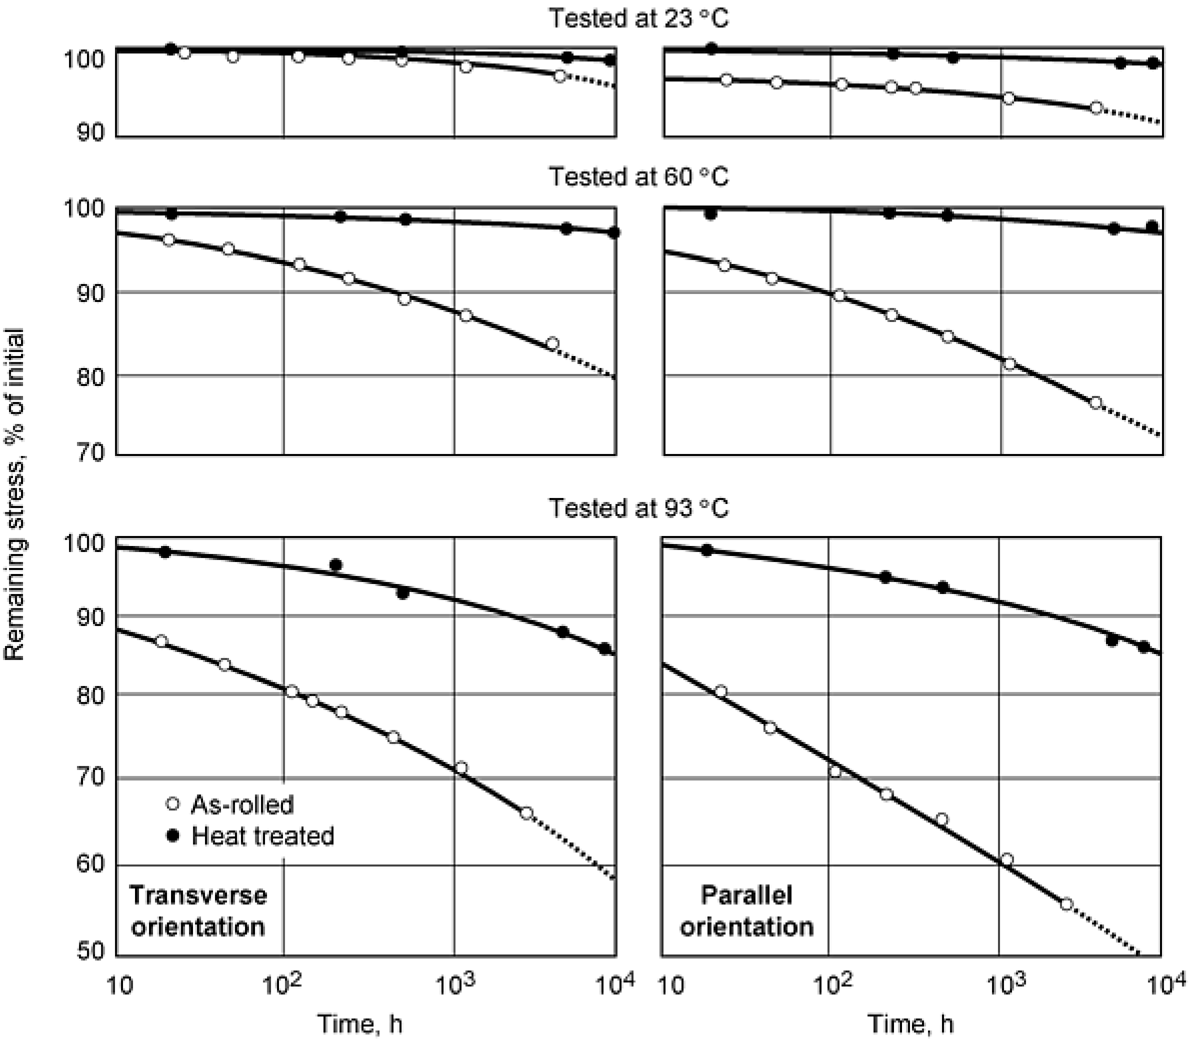

Fig. 4 Anisotropic stress-relaxation behavior in bending for highly cold-worked C51000 copper alloy strip. Data are for 5% Sn phosphor bronze cold rolled 93% (reduction in area) to 0.25 mm (0.01 in.) and heat treated 2 h at 260 °C (500 °F). Graphs at left are for stress relaxation transverse to the rolling direction; graphs at right, for stress relaxation parallel to the rolling direction. Initial stresses: as rolled, parallel orientation, 607 MPa (88 ksi); as rolled, transverse orientation, 634 MPa (92 ksi); heat treated, parallel orientation, 641 MPa (93 ksi); heat treated, transverse orientation, 738 MPa (107 ksi)

Wrought Copper Alloys

The purpose of adding alloying elements to copper is to optimize the strength, ductility (formability), and thermal stability, without inducing unacceptable loss in fabricability, electrical/thermal conductivity, or corrosion resistance. A list of selected wrought copper alloy compositions and their properties is given in Table 10. In this table, the alloys are arranged in their common alloy group: the coppers (99.3% min Cu), the high-coppers (94% min Cu), brasses (copper-zinc), bronzes (copper-tin, or copper-aluminum, or copper-silicon), copper-nickels, and the nickel silvers (Cu-Ni-Zn). Composition and property data are given by the Copper Development Association (CDA) and are incorporated in the ASTM numbering system, wherein alloys numbered by the designations (now UNS) C10100 to C79900 cover wrought alloys and C80100 to C99900 apply to cast alloys. Copper alloys show excellent hot and cold ductility, although usually not to the same degree as the unalloyed parent metal. Even alloys with large amounts of solution-hardening elements--zinc, aluminum, tin, silicon--that show rapid work hardening are readily commercially processed beyond 50% cold work before a softening anneal is required to permit additional processing. The amount of cold working and the annealing parameters must be balanced to control grain size and crystallographic texturing. These two parameters are controlled to provide annealed strip products at finish gage that have the formability needed in the severe forming and deep drawing commonly done in commercial production of copper, brass, and other copper alloy hardware and cylindrical tubular products.

Table 10 Compositions and properties of selected wrought copper alloys

Alloy	UNS No.	Nominal composition	Treatment	Tensile strength		Yield strength		Elongation, %	Rockwell hardness
				MPa	**ksi**	**MPa**	**ksi**

The pure copper alloys, also called the coppers (C10100 to C15900), are melted and cast in inert atmosphere from the highest-purity copper in order to maintain high electrical conductivity (oxygen-free, or OF, copper, C10200). Copper is more commonly cast with a controlled oxygen content (0.04% O as in electrolytic tough pitch, or ETP, copper, C11000) to refine out impurity elements from solution by oxidation. Included in this group are the alloys that are deoxidized with small addition of various elements such as phosphorus (C12200, Cu-0.03P) and the alloys that use minor amounts of alloy additions to greatly improve softening resistance, such as the silver-bearing copper alloys (C10500, Cu-0.034 min Ag) and the zirconium-bearing alloys (C15000 and C15100, Cu-0.1Zr).

High-copper alloys (C16000 to C19900) are designed to maintain high conductivity while using dispersions and precipitates to increase strength and softening resistance: iron dispersions in Cu-(1.0-2.5)Fe alloys (C19200, C19400), chromium precipitates in Cu-1Cr (C18200), and the coherent precipitates in the Cu-(0.3-2.0)Be-Co,Ni age-hardening alloys (C17200, C17410, and C17500).

Brass alloys are a rather large family of copper-zinc alloys. A significant number of these are binary copper-zinc alloys (C20500 to C28000), utilizing the extensive region of solid solution up to 35% Zn, offering excellent formability with good work-hardening strength at reasonable cost. The alloys below 15% Zn have good corrosion and stress-corrosion resistance. Alloys above 15% Zn need a stress-relieving heat treatment to avoid stress corrosion and, under certain conditions, can be susceptible to dezincification. Alloys at the higher zinc levels of 35 to 40% Zn contain the bcc beta phase, especially at elevated temperatures, making them hot extrudeable and forgeable (alloy C28000 with Cu-40Zn, for example). The beta alloys are also capable of being hot worked while containing additions of 1 to 4% Pb, or more recently bismuth, elements added to provide the dispersion of coarse particles that promote excellent machinability characteristics available with various commercial Cu-Zn-Pb alloys (C31200 to C38500). The tin-brasses (C40400 to C49000) contain various tin additions from 0.3 to 3.0% to enhance corrosion resistance and strength in brass alloys. Besides improving corrosion-resistance properties in copper-zinc tube alloys, such as C44300 (Cu-30Zn-1Sn), the tin addition also provides for good combinations of strength, formability, and electrical conductivity required by various electrical connectors, such as C42500 (Cu-10Zn-2Sn). A set of miscellaneous copper-zinc alloys (C66400 to C69900) provide improved strength and corrosion resistance through solution hardening with aluminum, silicon, and manganese, as well as dispersion hardening with iron additions.

Bronze alloys consist of several families named for the principal solid-solution alloying element. The familiar tin-bronzes (C50100 to C54400) comprise a set of good work-hardening, solid-solution alloys containing from nominally 0.8% Sn (C50100) to 10% Sn (C52400), usually with a small addition of phosphorus for deoxidation. These alloys provide an excellent combination of strength, formability, softening resistance, electrical conductivity, and corrosion resistance. The aluminum-bronze alloys contain 2 to 15% Al (C60800 to C64200), an element adding good solid-solution strengthening and work hardening, as well as corrosion resistance. The aluminum-bronzes usually contain 1 to 5% Fe, providing elemental dispersions to promote dispersion strengthening and grain size control. The silicon-bronze alloys (C64700 to C66100) generally offer good strength through solution- and work-hardening characteristics, enhanced in some cases with a tin addition, as well as excellent resistance to stress corrosion and general corrosion.

Cupronickels are copper-nickel alloys (C70100 to C72900) that utilize the complete solid solubility that copper has for nickel to provide a range of single-phase alloys (C70600 with Cu-10Ni-1.5Fe, and C71500 with Cu-30Ni-0.8Fe, for example) that offer excellent corrosion resistance and strength. The family of copper-nickel alloys also includes various dispersion- and precipitation-hardening alloys due to the formation of hardening phases with third elements, such as Ni_2Si in C70250 (Cu-3Ni-0.7Si-0.15Mg) and the spinodal hardening obtainable in the Cu-Ni-Sn alloys (C72700 with Cu-10Ni-8Sn, for example).

Copper-nickel-zinc alloys, also called nickel-silvers, are a family of solid-solution-strengthening and work-hardening alloys with various nickel-zinc levels in the Cu-(4-26)Ni-(3-30)Zn ternary alloy system valued for their strength, formability, and corrosion and tarnish resistance, and, for some applications, metallic white color.

Strengthening Mechanisms for Wrought Copper Alloys

Solution Hardening. Copper can be hardened by the various common methods without unduly impairing ductility or electrical conductivity. The metallurgy of copper alloys is suited for using, singly or in combination, the various common strengthening mechanisms: solid solution and work hardening, as well as dispersed particle and precipitation hardening. The commonly used solid-solution hardening elements are zinc, nickel, manganese, aluminum, tin, and silicon, listed in approximate order of increasing effectiveness. Commercial alloys represent the entire range of available solid-solution compositions of each element: up to 35% Zn, and up to (and even beyond) 50% Ni, 50% Mn, 9% Al, 11% Sn, and 4% Si. The relative amount of solution strengthening obtained from each element or particular combination of elements is determined by the ability of the solute to interfere with dislocation motion and is reflected in the work-hardening rate starting with the annealed condition, as illustrated by the increase in tensile strength with cold work shown in Fig. 5 and also Table 10.

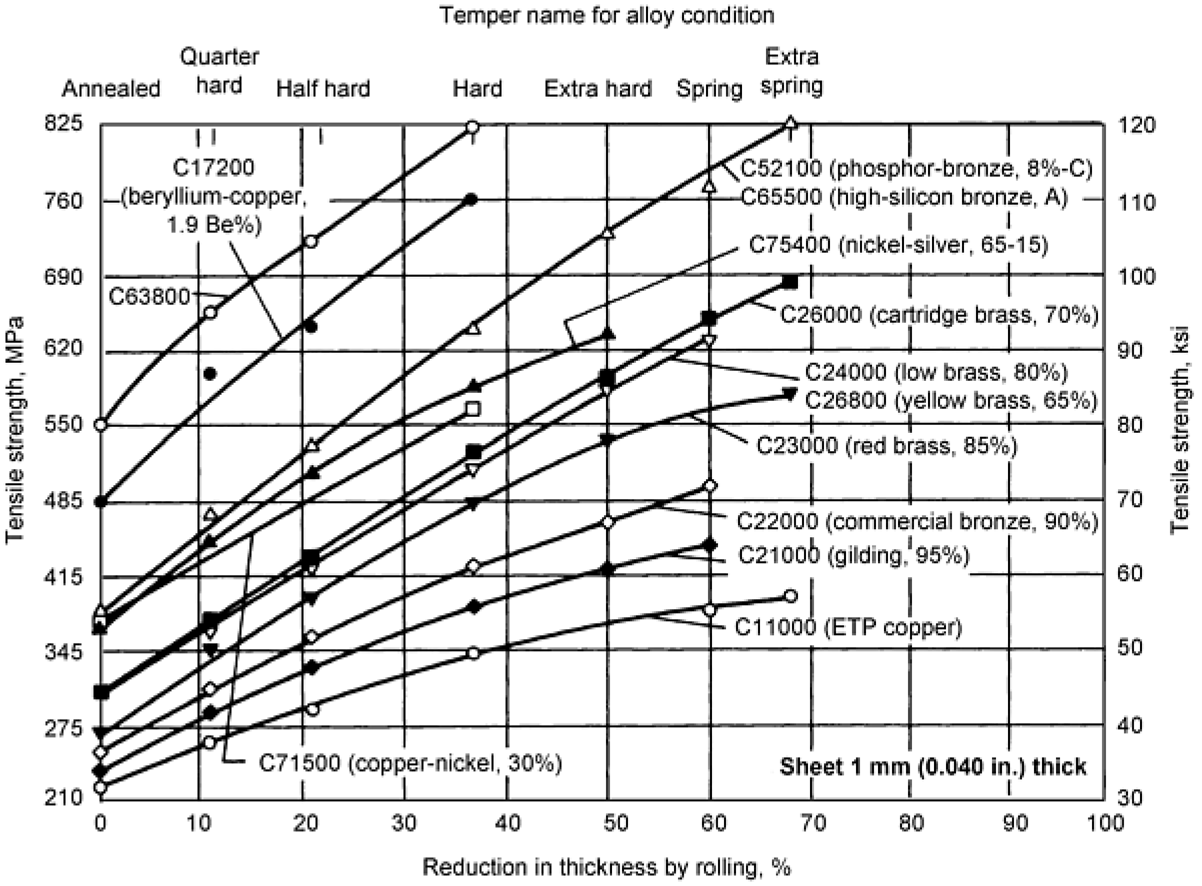

Fig. 5 Tensile strength of single-phase copper alloys as affected by percentage reduction in thickness by rolling (temper). Curves of lesser slope indicate a low rate of work hardening and a higher capacity for redrawing. ETP, electrolytic tough pitch

Work hardening is the principal hardening mechanism applied to most copper alloys, the degree of which depends on the type and amount of alloying element and whether the alloying element remains in solid solution or forms a dispersoid or precipitate phase. Even those alloys that are commercially age hardenable are often provided in the mill hardened tempers; that is, they have been processed with cold work preceding and/or following an age-hardening heat treatment. For the leaner alloys (below about 12% Zn, or about 3% Al, for example), processing generates dislocations that develop into entanglements and into cells, with some narrow shear band formation beyond about 65% cold reduction in thickness. After about 90% cold work, the distinct "copper" or "metal" deformation crystallographic texture begins to develop. With the richer solid-solution alloys that lower the stacking-fault energy, planar slip is the dominant dislocation mechanism, with associated higher work hardening. Beyond about 40% cold work in these richer alloys, stacking faults, shear banding, and deformation twinning become important deformation mechanisms that, beyond 90% cold work, lead to the "brass" or "alloy" type of crystallographic deformation texture and accompanying anisotropy of properties. The variation in tensile properties with cold working of an annealed Cu-30 Zn alloy (C26000) is shown in Fig. 6. The degree of work hardening seen with cold working several selected single-phase copper alloys is illustrated by the cold-rolling curves in

Fig. 5. Many copper alloys are used in wrought forms in a worked temper, chosen for the desired combination of work-hardened strength and formability, either for direct use in service or for subsequent component fabrication.

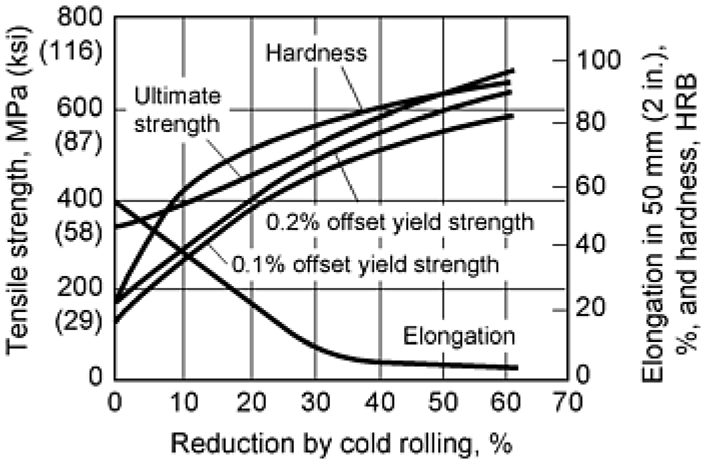

Fig. 6 The effect of cold rolling on the strength, hardness, and ductility of annealed copper alloy C26000 when it is cold rolled in varying amounts up to 62% reduction in thickness

Dispersion strengthening is used in copper alloys for hardening, controlling grain size, and providing softening resistance, as exemplified by iron particles in copper-iron alloys, C19200 or C19400, and in aluminum bronzes, C61300 or C63380. Cobalt silicide particles in alloy C63800 (Cu-2.8Al-1.8Si-0.4Co), for example, provide fine-grain control and dispersion hardening to give this alloy high strength with reasonably good formability. Alloy C63800 offers an annealed tensile strength of 570 MPa (82 ksi) and rolled temper tensile strengths of 660 to 900 MPa (96 to 130 ksi). Alloys offering exceptionally good thermal stability have been developed using powder metallurgy (P/M) techniques to incorporate dispersions of fine Al_2O_3 particles (3 to 12 nm in size) in a basically copper matrix, which is finish processed to rod, wire, or strip products. This family of alloys, C15715 to C15760, can resist softening up to and above 800 °C (1472 °F).

Precipitation Hardening. Age-hardening mechanisms are used in those few but important copper systems that offer a decreasing solubility for hardening phases. The beryllium-copper system offers a series of wrought and cast age-hardening alloys, UNS C17000 to C17530 and C82000 to C82800. The wrought alloys contain 0.2 to 2.0% Be and 0.3 to 2.7% Co (or up to 2.2% Ni). They are solution heat treated in the range 760 to 955 °C (1400 to 1750 °F) and age hardened to produce the beryllium-rich coherent precipitates when aged in the range 260 to 565 °C (500 to 1050 °F), the specific temperature being chosen for the particular alloy and desired property combination (Fig. 7). The precipitation sequence during aging consists of the formation of solute-rich G-P zones, followed in sequence by coherent platelets of the metastable intermediate phases γ' and γ''. Overaging is marked by the appearance of the B2 ordered equilibrium γ-BeCu phase as particles within grains and along grain boundaries, large enough to be seen in the light microscope. The cobalt and nickel additions form dispersoids of equilibrium (Cu, Co, or Ni)Be that restrict grain growth during solution annealing in the two-phase field at elevated temperatures (Fig. 7b). A cold-working step following solution annealing is often used to increase the age-hardening response. Alloy C17200 (Cu-1.8Be-0.4Co), for example, can be processed to reach high strength: that is, tensile strengths after solutionization (470 MPa, or 68 ksi), after cold rolling to the hard temper (755 MPa, or 110 ksi), and after aging (1415 MPa, or 205 ksi). While they are commercially available in the heat-treatble (solutionized) condition, the beryllium-copper alloys are commonly provided in the mill-hardened temper with the optimal strength/ductility/conductivity combination suitable for the application.

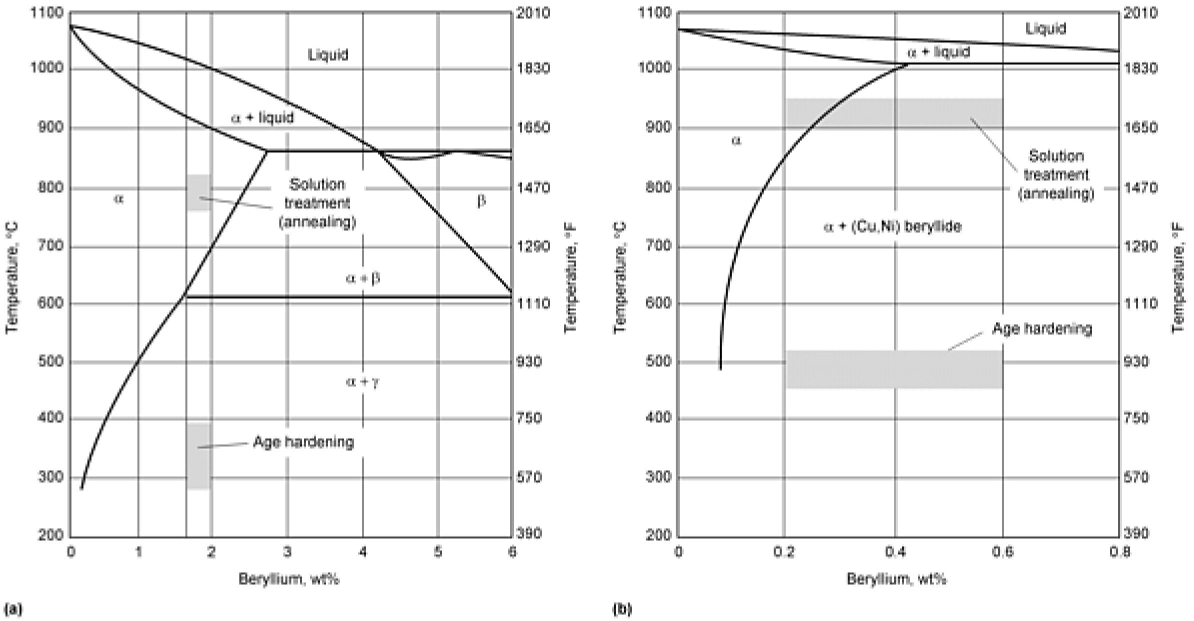

Fig. 7 Phase diagrams for beryllium-copper alloys. (a) Binary composition for high-strength alloys such as C17200. (b) Pseudobinary composition for C17510, a high-conductivity alloy containing Cu-1.8Ni-0.4Be

Other age-hardening copper alloys include the chromium-coppers, which contain 0.4 to 1.2% Cr (C18100, C18200, and C18400); these alloys produce arrays of pure chromium precipitates and dispersoid particles when aged. The Cu-Ni-Si alloys, C64700 and C70250, age harden by precipitating the Ni_2Si intermetallic phase (Fig. 8). Compositions in the Cu-Ni-Sn system, C71900 and C72700, are hardenable by spinodal decomposition, a mechanism that provides high strength and good ductility through the formation of a periodic array of coherent, fcc solid-solution phases that require the electron microscope to be seen. Each of these alloys, including the beryllium-coppers can be thermomechanically processed to provide unique combinations of strength, formability, electrical conductivity, softening resistance, and stress-relaxation resistance.

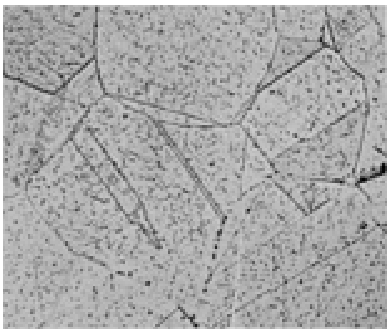

Fig. 8 Photomicrograph showing the dispersion of Ni_2Si precipitates in the quenched and aged condition of copper alloy C64700, Cu-2Ni-0.7Si. Magnification: 500×

Copper Casting Alloys

The copper casting alloys, numbered UNS C80100 to C99900, are available as sand, continuous, centrifugal, permanent mold, and some die castings (Ref 22, 23). They are generally similar to the wrought counterparts, but they do offer their own unique composition/property characteristics. For example, they do offer the opportunity to add lead to levels of 25% that could not be easily made by wrought techniques in order to provide compositions in which dispersions of lead particles are useful for preventing galling in bearing applications. The copper casting alloys are used for their corrosion resistance and their high thermal and electrical conductivity. The most common alloys are the general-purpose Cu-5Sn-5Pb-5Zn alloy (C83600), used for valves and plumbing hardware, and C84400, widely used for cast plumbing system

components. C83600 contains lead particles dispersed about the single-phase matrix and offers good machinability, with moderate levels of corrosion resistance, tensile strength (240 MPa, or 35 ksi), ductility, and conductivity (15% IACS).

While the Cu-Sn-Pb-(and/or Zn) casting alloys have only moderate strength, the cast manganese and aluminum bronzes offer higher tensile strengths, 450 to 900 MPa (65 to 130 ksi). As with the wrought alloys, the cast aluminum-bronze alloys commonly contain an iron addition (0.8 to 5.0%) to provide iron-rich particles for grain refinement and added strength. In addition, at aluminum levels in the range 9.5 to 10.5% (or 8.0 to 9.5% Al with nickel or manganese additions) the alloys are heat treatable for added strength. Depending on the section thickness and cooling rate of the casting, as well as the alloy composition and heat treatments, the microstructures can be rather complex. The aluminum-bronzes can be annealed completely or partially in the β field and quenched to form β martensite with α needles. Aging these alloys will temper the martensite by precipitation fine α needles. One of the aluminum-bronze alloys, Cu-10.5Al-5Fe-5Ni, for example, is used for its combination of high strength and good corrosion resistance. Through heat treatment, the intermetallic κ-phase, with its complex composition (Fe,Ni,Cu)Al and CsCl crystal structure, provides a strengthening component in any of its morphologies: as globular particles, fine precipitates, or as a component of cellular eutectoid colonies.

Copper Alloy Powders

Unique structural components are commercially made of copper and its alloys by P/M methods. Copper and prealloyed powders are made by reduction of oxides, or by atomization, wherein the solidification of liquid droplets from a pour stream is broken up by an impinging jet of a liquid or gas. Self-lubricating sintered bronze bearings are deliberately not pressed and sintered to 100% density in order to maintain an interconnected porosity to serve as an oil reservoir. The P/M technique is uniquely suited to permit the addition of up to about 1.5% graphite in these bearings. Likewise, various multiphase P/M copper alloys containing a mixture of hard and soft phases in a copper matrix (Cu-7Sn-3Fe-6Pb-6 graphite-3SiO_2, for example) are made for friction materials. The combination of thermal stability, wear resistance, and sliding friction properties make these materials suitable for use in clutch plates, and so forth. Various structural parts are made of bronze, brass, and nickel-silver alloys. In addition, P/M techniques are used to prepare the initial stages of the oxide-dispersion-strengthened (ODS) copper alloys, which are fabricated into finished forms by standard wrought methods to provide good softening resistance with excellent thermal or electrical conductivity. These ODS materials are prepared by internal oxidation of powder copper-aluminum alloy to form a dispersion of fine Al_2O_3 particles, about 3 to 12 nm in size.

Nickel and Nickel Alloys

Nickel and nickel alloys are used in the chemical processing, pollution control, power generation, electronic, and aerospace industries, taking advantage of their excellent corrosion, oxidation, and heat resistance (Ref 18, 26, 27, 28, 29, 30, 31, 32). Nickel is ductile and can be made by the conventional processing methods into cast, P/M, and various wrought products: bar/wire, plate/sheet, and tube. Commercially pure nickel has moderately high values of melting temperature (1453 °C, or 2647 °F), density (8.902 g/cm^3, or 0.322 lb/in.^{3}), and elastic modulus (204 GPa, or 30 × 10^6 psi). It is ferromagnetic, with a Curie temperature of 358 °C (676 °F) and good electrical (25% IACS) and thermal conductivity (82.9 W/m · K, or 48 Btu/ft · h · °F). Elemental nickel is used principally as an alloying element to increase the corrosion resistance of commercial iron and copper alloys; only about 13% of annual consumption is used in nickel-base alloys. Approximately 60% is used in stainless steel production, with another 10% in alloy steels and 2.5% in copper alloys. Nickel is also used in special-purpose alloys: controlled expansion, electrical resistance, magnetic, and shape memory alloys.

Effects of Alloying Elements in Nickel Alloys

Nickel has an fcc crystal structure, to which it owes its excellent ductility and toughness. Because nickel has extensive solid solubility for many alloying elements, the microstructure of nickel alloys consists of the fcc solid-solution austenite (γ) in which dispersoid and precipitate particles can form. Nickel forms a complete solid solution with copper and has nearly complete solubility with iron. It can dissolve about 35% Cr, about 20% each of molybdenum and tungsten, and about 5 to 10% each of aluminum, titanium, manganese, and vanadium. Thus, the tough, ductile fcc matrix can dissolve extensive amounts of elements in various combinations to provide solution hardening as well as improved corrosion and oxidation resistance. The degree of solution hardening has been related to the atomic size difference between nickel and the alloying element, and therefore the ability of the solute to interfere with dislocation motion. Tungsten, molybdenum, niobium, tantalum, and aluminum, when aluminum is left in solution, are strong solution hardeners, with tungsten, niobium, tantalum, and molybdenum also being effective at temperatures above 0.6 T_m (T_m = melting temperature), where diffusion-controlled creep strength is important. Iron, cobalt, titanium, chromium, and vanadium are weaker solution-hardening elements. Aluminum and titanium are usually added together to form the age-hardening precipitate, $Ni_3(Al,Ti)$.

Gamma Prime (γ') Precipitation. Gamma-prime (γ'), $Ni_3(Al,Ti)$, and the closely related γ'', Ni_3Nb, are the major precipitation-hardening phases in nickel alloys. These precipitates are based on the intermetallic compound, Ni_3Al, which has an fcc $L1_2$ ordered crystal structure with a lattice parameter differing from the nickel austenite (γ) matrix by $\leq$1%. This misfit allows the homogeneous nucleation and growth of rather stable arrays of coherent precipitates (Fig. 9). Strengthening is provided in part by the hindrance to dislocations moving across the γ-γ' interface and, more importantly, as they cut across the ordered precipitate, where they must split into partials to maintain the ordered crystal structure. Moreover, Ni_3Al is one of the unique phases that show a significant increase in flow stress with temperature. In particular, the yield strength increases over the range 300 °C (572 °F) to above 900 °C (1650 °F), showing a broad peak at about 600 °C (1110 °F).

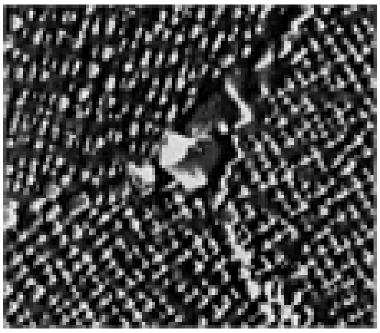

Fig. 9 Replica electron micrograph of the nickel alloy Udimet 700 (Ni-15Cr-17Co-5Mo-3.5Ti-4Al-0.06C) in the solution-annealed and aged condition, showing precipitation of carbide at grain boundaries and arrays of γ' within grains of the γ solid-solution matrix. 4500×

In addition, some alloying elements can partition to γ', affecting the interface mismatch and precipitate-coarsening kinetics as well as contributing a solution-hardening component to strength, with titanium being the most effective at room and elevated temperatures. However, titanium, niobium, and tantalum can influence mechanical properties still further by encouraging the formation of other similar types of precipitates. With higher titanium content, γ' will transform to the hexagonal close-packed (hcp) η-phase, Ni_3Ti, which has an acicular or cellular morphology. With increased amounts of niobium, γ' transforms to the commercially important metastable body-centered tetragonal (bct) phase γ'. A decrease in hardening will result if the equilibrium orthorhombic phase, Ni_3Nb, is allowed to form. The actual phases precipitated and their effectiveness in hardening the microstructure are dependent on the alloy composition, the applied heat treatments, the resulting precipitate volume fraction, and the service conditions.

Carbides. Although not a carbide former, nickel dissolves many elements that readily form the carbides seen in nickel alloys (MC, M_6C, M_7C_3, $M_{23}C_6$). The MC carbides (where M = W, Ta, Ti, Mo, Nb) are usually large, blocky, and undesirable. The M_6C carbides (M = Mo, W) can precipitate as small platelets in the grains or as blocky particles in boundaries useful for grain control, but deleterious for ductility and stress rupture properties. The M_7C_3 (M = Cr) can be useful when precipitated as discrete particles, but more so are grain boundary particles of $M_{23}C_6$ (M = Cr, Mo, W), where they can enhance creep rupture properties (Fig. 10). If carbides are allowed to agglomerate or form grain-boundary films during heat treatment or in service at elevated temperatures, they can seriously impair ductility and cause embrittlement. As in stainless steels, precipitation of chromium carbides at boundaries can lead to intergranular corrosion due to the chromium-depleted zone alongside the grain boundary becoming anodic to the rest of the grains. This grain-boundary sensitization is controlled in several ways: (1) by avoiding the chromium-carbide aging temperature range (425 to 760 °C, or 800 to 1400 °F) during processing, (2) with stabilization heat treatments to tie up carbon with more stable carbide formers (niobium, tantalum, titanium), and (3) by reducing the carbon level in the base alloy.

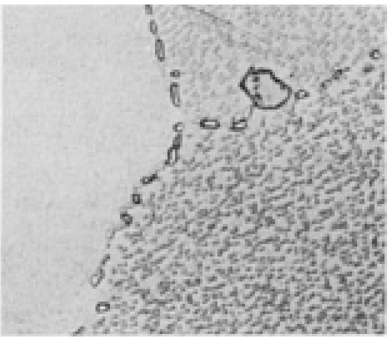

Fig. 10 Photomicrograph of the nickel alloy Udimet 700 (Ni-15Cr-17Co-5Mo-3.5Ti-4Al-0.06C) in the solution-annealed and aged condition, showing precipitation of $M_{23}C_6$ carbide at grain boundaries and arrays of γ' within

grains of the γ solid-solution matrix. 1000×

Nickel Alloys

Nickel is alloyed to extend the good corrosion resistance and good heat resistance of elemental nickel. Even with extensive amounts of alloying elements, the tough, ductile fcc austenitic matrix is preserved. It is convenient to describe nickel alloys by grouping them into their two broad application areas: corrosion resistance, especially in aqueous environments, and heat resistance. Naturally, this artificial separation should not be considered a rigid barrier as the corrosion-resistant alloys have good strength above room temperature and the heat-resistant alloys have good corrosion resistance. The unique, special-property alloys, many of which are also used for their good corrosion and heat resistance as well as high strength, are described separately.

Corrosion-Resistant Nickel Alloys. A list of selected corrosion-resistant nickel alloys with nominal values of mechanical properties is given in Table 11. The commercially pure nickel grades, Nickel 200 to 205, are highly resistant to many corrosive media, especially in reducing environments, but also in oxidizing environments where they can maintain the passive nickel oxide surface film. They are used in the chemical processing and electronics industries. They are hot worked at 650 to 1230 °C (1200 to 2250 °F), annealed at 700 to 925 °C (1300 to 1700 °F), and are hardened by cold working. For processed sheet, for example, the tensile properties in the annealed condition (460 MPa, or 67 ksi, tensile strength; 148 MPa, or 22 ksi, yield strength; and 47% elongation) can be increased by cold rolling up to 760 MPa (110 ksi) tensile strength, 635 MPa (92 ksi) yield strength, and 8% elongation. Because of its nominal 0.08% C content (0.15% max), Nickel alloy 200 (UNS No 2200) should not be used above 315 °C (600 °F), because embrittlement results from the precipitation of graphite in the temperature range 425 to 650 °C (800 to 1200 °F). The more widely used low-carbon alloy Nickel 201 (UNS No 2201), with 0.02% max C, can be used at temperatures above 290 °C (550 °F). Higher-purity nickel is commercially available for various electrical applications.

Table 11 Compositions and properties of selected corrosion-resistant nickel-base alloys

Alloy	Nominal composition, wt %	Ultimate tensile strength		Yield strength (0.2% offset)		Elongation in 50 mm (2 in.), %	Rockwell hardness

The low-alloy nickels contain 94% min Ni. The 5% Mn solid-solution addition in Nickel 211 protects against sulfur in service environments. As little as 0.005% S can cause liquid embrittlement at unalloyed nickel grain boundaries in the range between 640 and 740 °C (1185 and 1365 °F). Duranickel, alloy 301 (Ni-4.5Al-0.6Ti), offers the corrosion resistance of commercially pure nickel with the strengthening provided by the precipitation of γ'. There is sufficient alloying additions in alloy 301 to lower the Curie temperature, making the alloy weakly ferromagnetic at room temperature.

The nickel-copper alloys are strong and tough, offering corrosion resistance in various environments, including brine and sulfuric and other acids, and showing immunity to chloride-ion stress corrosion. They are used in chemical processing and pollution control equipment. Capable of precipitating γ', $Ni_3(Al,Ti)$, with its 2.7Al-0.6Ti alloy addition, alloy K-500 adds an age-hardening component to the good solution strengthening and work-hardening characteristics already available with the nominal 30% Cu in alloy 400. The composition of these alloys can be adjusted to decrease the Curie temperature to below room temperature.

The Ni-Cr-Fe(-Mo) alloys might simply be thought of as nickel-base analogs of the iron-base austenitic stainless steel alloys, with an interchange of the iron and nickel contents. In these commercially important alloys the chromium content in general ranges from 14 to 30% and iron from 3 to 20%. With a well-maintained Cr_2O_3 surface film, these alloys offer excellent corrosion resistance in many severe environments, showing immunity to chloride-ion stress-corrosion cracking. They also offer good oxidation and sulfidation resistance with good strength at elevated temperatures. These nickel-rich Ni-Cr-Fe alloys have maximum operating temperatures in the neighborhood of 1200 °C (2200 °F). Alloy 600 (UNS N06600, with Ni-15Cr-8Fe) is a single-phase alloy that can be used at temperatures from cryogenic to 1093 °C (2000 °F). The modest yield strength of strip in the annealed condition (207 to 310 MPa, or 30 to 45 ksi) can be readily work hardened by cold rolling to reach yield strengths of 827 to 1100 MPa (120 to 160 ksi) and can retain most of this strength up to about 540 °C (1000 °F).

The Ni-Cr-(Fe)-Mo alloys consist of a large family of alloys that are used in the chemical processing, pollution control, and waste treatment industries to utilize their excellent heat and corrosion resistance. Alloys in this commercially important family, such as C-276 and alloy 625, are made even more versatile by their excellent welding characteristics and the corrosion resistance of welded structures. The molybdenum additions to these alloys improve resistance to pitting and crevice corrosion. Aluminum improves the protective surface oxide film, and the carbide formers titanium and niobium are used to stabilize the alloys against chromium-carbide sensitization. Even with the low-level additions of aluminum and titanium to alloy 800, for example, small amounts of γ' can form in service during exposure to elevated temperatures. The high molybdenum and silicon additions in Hastelloy B and D promote good corrosion resistance in the presence of hydrochloric and sulfuric acids.

Heat-Resistant Nickel Alloys. Chemical compositions of selected heat-resistant superalloys are given in Table 12. A glance at this list reveals that these nickel-containing materials include nickel-, iron-nickel-, or cobalt-base alloys. They can be made by wrought and P/M methods, and also with castings produced with carefully controlled conditions to provide the desired polycrystal, or elongated (directionally solidified), or single-crystal grain structure for improved elevated-temperature mechanical properties. The majority of the nickel-base superalloys utilize the combined strengthening of a solution-hardened austenite matrix with γ' precipitation. The niobium-rich, age-hardening precipitate, γ'', offers the ease of heat treatment and weldability that has made alloy 718 the most important nickel-base superalloy for aerospace and nuclear structural applications. Alloy 718 is a high-strength, corrosion-resistant alloy that is used at temperatures from -250 to 700 °C (-423 to 1300 °F). Some of the alloys, Hastelloy X for example, obtain additional strengthening from carbide precipitation instead of γ'. Others, MA 754 for example, utilize P/M techniques involving mechanical alloying (Ref 27) to achieve a dispersion of about 1 vol% of very fine (25 nm) inert oxide particles, such as Y_2O_3, to promote higher elevated-temperature tensile and stress-rupture strength.

The iron-base Fe-Ni-Cr heat-resistant alloys are extensions of the iron-base stainless steels with higher nickel and additions of other alloying elements. Retaining the fcc iron-nickel austenite matrix, these alloys (alloys A-286 and 901, for example) are workable into various wrought forms and are capable of precipitation hardening with γ'. Alloys 903 and 909 are controlled thermal expansion Fe-Ni-Co-base alloys that are capable of age hardening with Ni_3(Nb,Ti) precipitation and are designed to have high strength and low coefficient of thermal expansion for applications in gas turbine rings and seals up to 650 °C (1200 °F) (Ref 26). These alloys are hot worked at about 870 to 1120 °C (1600 to 2050 °F) and solution heat treated at 815 to 980 °C (1500 to 1800 °F). The standard aging treatment consists of 720 °C (1325 °F) for 8 h, furnace cool at 55 °C (100 °F)/h to 620 °C (1150 °F) for 8 h, followed by air cooling. Alloy 909 in the as-hardened condition, for example, retains much of its room-temperature yield strength (1070 MPa, or 155 ksi) at 540 °C (1000 °F), namely, 895 MPa (130 ksi) (Ref 30).

Specialty Nickel Alloys. Unique combinations of properties are available with other nickel-base alloys for special applications. While some of these properties are also available to some extent with alloys described above, the alloys described below were developed to promote their rather unique properties.

There are many electrical resistance alloys used for resistance heating elements. They can contain 35 to 95% Ni, but invariably contain greater than 15% Cr to form an adherent surface oxide to protect against oxidation and carburization at temperatures up to 1000 to 1200 °C (1850 to 2200 °F) in air. Examples are Ni-20Cr (UNS N06003), Ni-15Cr-25Fe (UNS N06004), and Ni-20Cr-3Al-3Fe. These alloys are single-phase austenite and have the needed properties for heating elements: desirably high, reproducible electrical resistance; low thermal expansion to minimize thermal fatigue and shock; good creep strength; strong and ductile for fabrication (Ref 27, 28).

The ferromagnetic characteristics of nickel allow formulation of nickel-base alloys for corrosion-resistant soft magnets for a variety of applications, typified by Ni-5Mo-16Fe. Low thermal expansion characteristics are shown by Fe-(36-52)Ni-(0-17)Co alloys, making these materials useful for glass-to-metal sealing and containment equipment for liquefied natural gas, for example. The controlled thermal expansion alloys, typified by alloy 903 (Ni-42Fe-15Co + Nb,Al,Ti), are also γ'-precipitation hardenable, offering high strength and low, relatively constant thermal expansion coefficient for applications up to about 650 °C (1200 °F). With nearly 50-50 at.%, nickel forms a shape memory intermetallic alloy with titanium, which offers 8% of reversible strain via a thermoelastic martensitic transformation, along with good ductility and corrosion resistance.

The $L1_2$ intermetallic compound, Ni_3Al, has been the focus of development work to create a strong, corrosion-resistant material for elevated-temperature applications. Wrought and cast beryllium-nickel alloys are commercially available (UNS N03360 with Ni-2Be-0.5Ti, for example) and respond to processing and age-hardening heat treatments as readily as the beryllium-copper alloys, but offer higher strength with better resistance to thermal softening and stress relaxation (Ref 25, 29, 30, 31, 32).

Cobalt and Cobalt Alloys

Falling between iron and nickel in the periodic table, cobalt has many similar properties as these other two more familiar transition metals (Ref 18, 33). Its melting temperature (1493 °C, or 2719 °F), density (8.85 g/cm^3, or 0.322 lb/in.^{3}), thermal expansion coefficient (13.8/K, or 7.66/°F), thermal conductivity (69.0 W/m · K), and elastic modulus (210 GPa, or 30 × 10^6 psi) are all rather similar to the respective values of iron and nickel. All three are ferromagnetic, but the Curie temperature of cobalt, 1123 °C (2050 °F), is significantly higher than that of iron (770 °C, or 1418 °F) or nickel (358 °C, or 676 °F). The crystal structure and chemical and mechanical properties differ enough to give cobalt a viable commercial life of its own.

Cobalt is not as readily geologically available as its two companion metals are, making cobalt about 100 times more costly than iron and about 8 times more costly than nickel. Cobalt is heavily used as an alloying element in nickel-base heat-resistant alloys and as the ductile binder phase (3 to 25%) for tungsten carbide particles in cemented carbides. Nonetheless, the excellent wear resistance, elevated-temperature hardness, and corrosion resistance of cobalt alloys have been commercially utilized in gas turbine engines, earthmoving equipment, and as bearing materials. Cobalt alloys are most often used for their wear resistance either in solid forms or as welded or thermally sprayed overlays to hardface other structural materials. They are also available as P/M products and in wrought sheet, bar, and tube forms.

Elemental cobalt has an hcp crystal structure (ε-Co) at room temperature, transforming to fcc (α-Co) at 417 °C (783 °F). Although the principal alloying elements affect the temperature of this transition (chromium, tungsten, and molybdenum stabilize the hcp phase, and iron and nickel stabilize the fcc structure), the fcc-to-hcp transformation is notably sluggish especially in alloyed cobalt. The alloys usually go into service at room temperature in the metastable fcc form. The α-to-ε transformation usually occurs by the strain-induced martensitic (or shear) reaction, which also contributes to the high work-hardening rates generally seen with cobalt alloys. Carbon, one of the principal alloying elements, has a profound influence on hardness, elevated-temperature strength, and creep resistance, as well as resistance to abrasive wear through formation of carbide phases.

Effects of Alloying Elements in Cobalt Alloys

The traditional cobalt alloys are known as Stellite alloys and were originally formulated around 1900 for their wear and hardness properties. They are composed of significant amounts of chromium, tungsten, molybdenum, iron, nickel, and carbon. The ferromagnetism of cobalt is suppressed by the heavy additions of chromium and retained as expected by

additions of iron and nickel. Chromium is restricted to less than 25% to avoid precipitation of the chromium-rich σ-phase. The microstructures consist of hard complex alloy carbides (M_7C_3, M_6C, and $M_{23}C_6$) in a tough solid-solution alloy matrix. The morphology and volume fraction of the carbide phase are a function of alloy composition and fabrication method. Cobalt-base alloys can be grouped into their three major property application areas: wear resistance, elevated-temperature strength, and corrosion resistance. A representative sampling of the many commercially available cobalt-base alloys is listed in Table 13. In most applications, the cobalt alloy must also exhibit good properties in all three general property areas.

Wear-Resistant Cobalt Alloys

Cobalt alloys are used mostly for their excellent wear resistance (Ref 33, 34). The Co-Cr-W-C Stellite wear-resistant alloys contain generous amounts of carbide-forming elements chromium, tungsten, and molybdenum, with carbon varying from 0.1 to 3.3% to encourage the formation of hard carbide particles. The microstructures generally consist of chromium-rich M_7C_3 carbides and, in the higher tungsten alloys, the tungsten-rich M_6C type of carbide, with enough chromium and tungsten alloying element left in solid solution to provide a tough, solution-hardened matrix. Stellite 6, for example, was reported (Ref 34) to contain about 12% Cr_7C_3 in a solid-solution matrix of about 58Co-18Cr-4W. The somewhat richer alloy Stellite 1 contains about 27% M_7C_3 and 1.5% W_6C, in a matrix of 45Co-11Cr-10W-0.3C. In general, alloys with more than about 1.3% C can be made only by casting because of limited ductility. These higher-carbon alloys are applied as hardfacings onto other structural metals using weld overlays or spray coatings. The solidification microstructures (Fig. 11), resulting from multipass weld overlays using the gas tungsten arc welding (GTAW) process, for example, contain arrays of eutectic carbides (dark etching phases) between alloy-rich dendrites (white etching phases in Fig. 11a to d).

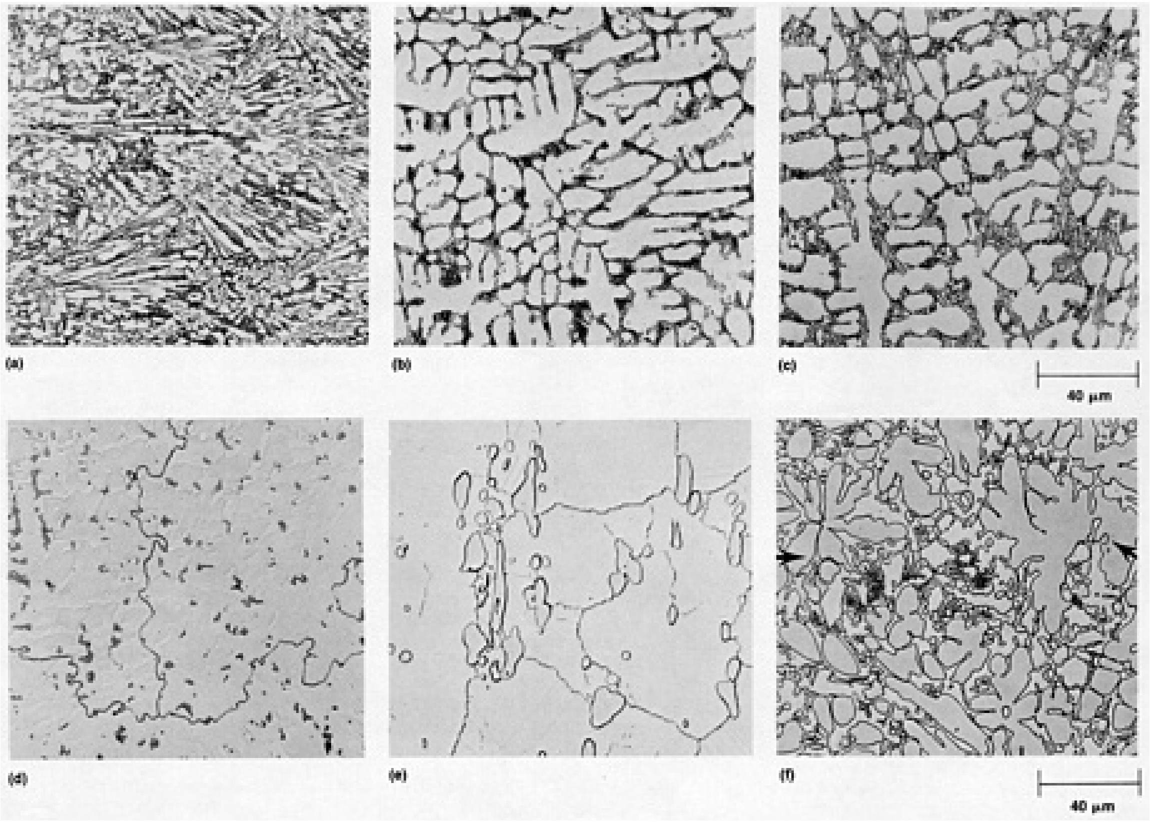

Fig. 11 Microstructures of various cobalt-base wear-resistant alloys. (a) Stellite 1, two-layer GTAW deposit. (b) Stellite 6, two-layer GTAW deposit. (c) Stellite 12, two-layer GTAW deposit. (d) Stellite 21, two-layer GTAW deposit. (e) Haynes alloy 6B, 13 mm (0.5 in.) plate. (f) Tribaloy alloy (T-800) showing the Laves precipitates (the largest continuous precipitate, some of which are indicated with arrows). All 500×

Haynes alloy 6B is available in plate, sheet, and bar wrought forms, with a more homogeneous microstructure, containing globular carbides in a worked or an annealed matrix (Fig. 11e). In wrought form, alloy 6B offers tensile properties of 619 MPa (90 ksi) yield strength, 998 MPa (145 ksi) tensile strength, and 11% elongation. On the other hand, the commercial alloy Tribaloy T-800 contains large additions of molybdenum and silicon to produce a large volume fraction (about 50%) of a hard, corrosion-resistant Laves phase, an intermetallic compound of the type $MgZn_2$ (Fig. 11f). Depending on the cobalt alloy, this phase can have a complex composition beyond a simple AB_2 stoichiometry (CoSiMo, or Co_2W). Although the massive amounts of hard second-phase particles limit room-temperature ductility in the Tribaloy alloys, they are readily formed as thermally sprayed or as P/M components to provide exceptionally good wear resistance.

Abrasion Resistance. The characteristics of both the carbide and the matrix give cobalt alloys their good resistance to the various types of wear encountered in service. The hard second-phase carbide particles in cobalt alloys provide the resistance to abrasive wear whether of the high-stress type, where the abrasive medium is crushed after entrapment between metallic surfaces, or of the low-stress type, where the moving surfaces come into contact with packed abrasive particles such as soil and sand. The resistance to the cutting/plowing abrasive wear mechanisms shown by cobalt-base alloys generally depends on the hardness of the solid-solution matrix as well as the hardness, volume fraction, and distribution of the carbide or Laves phases.

Sliding Wear Resistance. Sliding wear, where two surfaces are forced together and move relative to one another especially without lubricant, consists of a complex set of mechanisms that can occur singly or in combination. The three mechanisms involve, first, generation of localized high temperatures (at low contact forces) to form adherent oxide glazes that can reduce wear rates or, by spalling of the oxide glaze, create oxide debris that combines abrasion with sliding wear, called fretting. The second type is related to high stress metal-to-metal contact (at high contact forces) resulting in cold welding and fracture of small surface pieces, transferring them from one surface to another (called galling). The third mechanism is subsurface initiation and growth of fatigue cracks. The solid-solution matrix of cobalt-base alloys gives the good resistance to sliding wear through control of the oxidation behavior, the inherent resistance to deformation, fatigue, and fracture at elevated temperatures, independent of the presence of hard second-phase particles.

Erosion Resistance. Cobalt alloys are resistant to the several types of erosive wear. The ductility and toughness of the solid-solution matrix are important in resisting the cutting/plowing action of solid-particle erosion, that is, impingement of small, solid particles carried by a gas or by a liquid in a slurry against the metal surface. Resistance to liquid-droplet erosion and cavitation erosion, however, requires the ability to absorb shock (stress) waves without microstructural fracture. While liquid-droplet and cavitation erosion have the same effect on the surface, they are caused by different mechanisms. Both result in a succession of shock (or stress) waves induced by liquid drops hitting the surface. In cavitation erosion the metal surface is in contact with a liquid undergoing pressure changes. The collapse of bubbles, momentarily formed by localized low-pressure areas or by evaporated pockets of the liquid, causes surface damage by the impact of liquid jets from the bubble implosion. The good resistance to cavitation erosion shown by cobalt alloys is attributable to its tough matrix having the ability to absorb the shock waves through work hardening and the energy-absorbing, strain-induced $\alpha$to εmartensitic phase transformation. The important role that the strain-induced phase transformation plays in the good erosion wear resistance shown by cobalt alloys is indicated by the detection of an increase in ε-cobalt on the alloy surface and the identification of this phase in the wear debris in wear test experiments with Stellite alloy 6.

Heat-Resistant Cobalt Alloys

The high-temperature resistance of cobalt alloys is due to the stability of both the arrays of carbide particles and the matrix. The hardness and creep rupture strengths are stable to about 800 °C (1472 °F). The carbide particles pin grain boundaries to suppress grain growth (hardness) and grain-boundary sliding (creep resistance). Moreover, the room-temperature hardness is essentially unchanged after exposure to relatively high elevated temperatures. Cobalt alloys are used in aircraft gas turbines because they show good elevated-temperature strength, and resistance to thermal fatigue and thermal shock as well as good oxidation resistance. The alloys also have the good resistance to sulfidation needed in land-base turbines that use lower-quality fuels.

Both Haynes alloy 25 (L605) and alloy 188 are available in wrought forms as sheet, plate, bar, or pipe. In either alloy, the chromium and tungsten provide solution hardening and nickel stabilizes the α-phase for improved ductility. Both alloys work harden rapidly and offer a small aging response, with good ductility shown after the aging/stabilization heat treatment. For example, the strength of alloy 25 in the annealed condition--476 MPa (69 ksi) yield strength, 917 MPa (133 ksi) tensile strength, 41% elongation--will increase after a 30% cold-working step to 1000 MPa (145 ksi) yield strength, 1345 MPa (195 ksi) tensile strength, 16% elongation. When quenched from its annealing temperature (1175 to 1230 °C, or 2150 to 2250 °F), the alloy shows a small increase in hardness accompanied by a small decrease in ductility when aged or exposed to 480 to 650 °C (900 to 1200 °F). Alloy 25 retains good strength at elevated temperatures. At 982 °C (1800 °F), for example, the annealed temper offers 165 MPa (24 ksi) yield strength, 255 MPa (37 ksi) tensile strength, and 72% elongation. In Haynes 188, the carbides are precipitated during the aging treatment in the range 650 to 1175 °C (1200 to 2150 °F), with M_6C forming at the higher aging temperature and $M_{23}C_6$ at the lower end of the range. A small lanthanum addition gives this alloy its excellent oxidation resistance by its making the oxide scale more adherent and more impermeable to diffusion and further growth.

MAR-M Alloy 509 is capable of being cast into complex shapes as an investment casting alloy that offers high strength, high creep strength, as well as good resistance to oxidation, sulfidation, and thermal shock. This alloy is used in the cast condition at temperatures up to about 955 °C (1750 °F). In this type of alloy, chromium and tungsten are the main solid solution strengthening elements, nickel stabilizes the fcc phase to improve ductility, and the tantalum, titanium, zirconium additions form MC type carbides. Its room-temperature tensile properties are typically 586 MPa (85 ksi) yield strength, 780 MPa (113 ksi) tensile strength, and 4% elongation. Good strength is retained even at temperatures as high as 982 °C (1800 °F), where typical tensile properties are 190 MPa (28 ksi) yield strength, 248 MPa (36 ksi) tensile strength, and 26% elongation.

Corrosion-Resistant Cobalt Alloys

Several cobalt-chromium-nickel-molybdenum alloys have been developed for providing excellent corrosion resistance along with high strength and toughness. In these alloys, the carbon is minimized to avoid carbide precipitation along grain boundaries, maximizing corrosion resistance. The presence of chromium in cobalt alloys permits them to passivate by forming adherent films of Cr_2O_3 as do stainless steels. These alloys are provided in various wrought forms, in the work-hardened or work-plus-age-hardened condition.The alloys work harden rapidly due to the strain-induced transformation that provides a dispersion of fine hcp platelets. The tensile strength of the annealed condition (937 MPa, or 130 ksi) can be increased to 1585 MPa (230 ksi), with about 50% cold reduction and raised still further (2000 MPa, or 290 ksi) after a subsequent aging treatment at about 530 to 593 °C (1000 to 1100 °F) for 4 h. In this aged condition the alloy retains

favorable levels of ductility and toughness, showing around 10% elongation and 46% reduction in area. Good strength and ductility are available at elevated temperatures as well.

Because of their biocompatibility, nonmagnetic cobalt-chromium-molybdenum alloys, such as Co-28.5Cr-6Mo (ASTM F 75 and F 799), have been used for orthopedic implants. When made by investment casting, the alloys are strengthened by carbide particles. When made by forging or hot isostatic pressing, the alloys are hardened by a combination of nitrogen and carbide strengthening mechanisms. In addition to the excellent corrosion resistance for these applications, these alloys also have the required high-cycle fatigue resistance as well as strength, ductility, and wear resistance.

Titanium and Titanium Alloys

The good strength, low density (4.5 g/cm^3, or 0.16 lb/$in.^3$), relatively high melting point (1668 °C, or 3034 °F), excellent corrosion resistance, and good heat-transfer properties of titanium and its alloys have made them attractive to structural designers for use primarily in aerospace and chemical industries where the combination of unique properties can justify the cost (Ref 18, 35, 36, 37, 38, 39). Titanium is also seeing increased use for sporting goods, such as golf clubs. The alloys are available as castings, P/M products, and in basically all wrought plate, sheet, tube, forging, bar, and wire forms. Titanium exists in two crystallographic forms: the room-temperature hcp α-phase transforms to the bcc β-phase at 883 °C (1620 °F). Manipulating the morphology of these two allotropic phases through alloy additions and thermomechanical processing is commonly done to provide a wide range of useful mechanical property combinations. The coefficient of thermal expansion, 8.41 μm/m · K, is lower than that of steel or aluminum, while its elastic modulus (110 GPa, or 16.2 × 10^6 psi), falls between the values of steel and aluminum. Titanium can be used for cryogenic applications because it has no debilitating ductile-brittle transition temperature (DBTT), although decreases in toughness below room temperature can be seen in β alloys. The maximum useful temperature range for structural applications is 425 to 580 °C (800 to 1100 °F), depending on the alloy and condition.

Titanium readily forms a stable adherent oxide layer, TiO_2, that passivates the metal and provides resistance to attack by most mineral acids and chlorides. Titanium is nontoxic and resists human body fluids, making it biocompatible for use in the biomaterials field. In an anhydrous or nonoxygen environment, however, the oxide film will not re-form if damaged, making titanium susceptible to crevice corrosion. Titanium is also susceptible to hydrogen embrittlement, through its ability to form hydride by absorbing hydrogen in pickling solutions at room temperature or from reducing atmospheres at elevated temperatures. Because of its excellent corrosion resistance and good heat-transfer characteristics, unalloyed (commercially pure) titanium is used in heat exchangers, condensers, jet engine shrouds, submarine components, reactor vessels, and storage tanks.

Titanium is made by double, or triple melting in vacuum electric arc furnaces, with the ingots from the first melt used as consumable electrodes for subsequent melts. In addition to homogenization, the purpose of this melt practice is to reduce the number of hard, embrittling oxygen or nitrogen-rich inclusions and to remove volatile elements especially hydrogen. The impurity elements carbon, nitrogen, silicon, iron, and oxygen raise strength and lower ductility. In particular, the iron and oxygen impurity content control the strength of unalloyed titanium, while the carbon and nitrogen impurities must be kept to a minimum to avoid embrittlement. Extra-low-interstitial (ELI) grades are commercially available that maximize ductility and toughness.

Effects of Alloying Elements in Titanium Alloys

The relatively low strength of the commercially pure grades of titanium are readily improved with the addition of alloying elements in conjunction with the application of thermomechanical processing during fabrication into final products (Table 14). The alloying elements used in titanium are classified by their individual effects on the phase diagram: whether they stabilize the α- or the β-titanium phase (Table 15). Titanium and its alloys are processed at temperatures both above and below the β transus, the temperature above which the alloy is 100% β, in order to manipulate the amount and morphology of the α and β phases during processing as well as the relative amounts retained in the final product. The base composition and the processing temperatures dictate the microstructural constitution of the alloys, which are classified according to the dominant phase in the alloy. Alpha alloys are predominately α, usually with minor amounts of β present. Alpha-beta alloys will obviously contain both phases, with more β than the α-alloys. The β content at room temperature may be as low as 5 to 10%, and greater. Beta alloys have sufficient β stabilizer content that the alloys can be solution treated above the β transus, water quenched, and retain 100% β. The commercial alloys are normally metastable and are aged to precipitate α to increase strength. The microstructure will thus consist of α in a β matrix.

(a) Mechanical properties given for annealed condition; may be solution treated and aged to increase strength.

(b) Mechanical properties given for solution treated and aged condition; alloy not normally applied in annealed condition. Properties may be sensitive to section size and processing.

(c) Primarily a tubing alloy; may be cold drawn to increase strength

Table 15 Ranges and effects of some alloying elements used in titanium

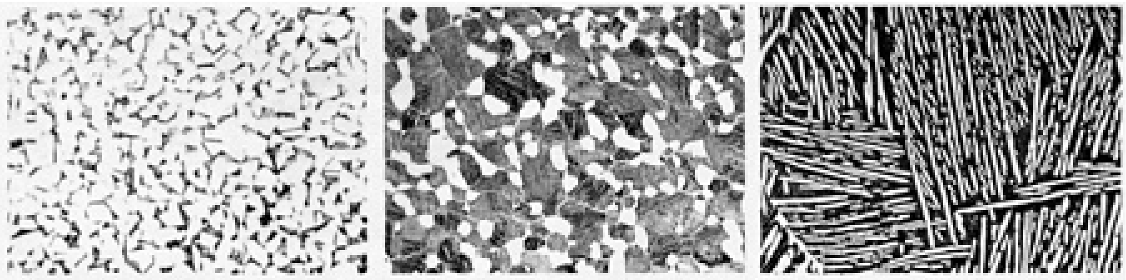
Alloying element	Range, (approx), wt %	Effect on structure
Aluminum	3-8	α stabilizer
Tin	2-4	α stabilizer
Vanadium	2-15	β stabilizer
Molybdenum	2-15	β stabilizer
Chromium	2-12	β stabilizer
Copper	~2	β stabilizer
Zirconium	2-5	α and β strengthener
Silicon	0.05-0.5	Improves creep resistance

Aluminum in solution hardens the α phase, but at levels >6 wt% it can form the embrittling intermetallic phase Ti_3Al. Zirconium and tin solution harden both the α and the β phases, and both elements retard the rates of phase transformation, permitting greater control of microstructures during heat treatment. Niobium is added to titanium to improve oxidation resistance at elevated temperatures. Chromium additions enhance corrosion resistance.

Titanium Alloy Microstructure/Property Relationships

Alpha Phase. The α and near-α titanium alloys are processed in the β or α/β phase fields at elevated temperatures to take advantage of the greater processibility of the bcc β phase than the α phase. Beta is strain-rate sensitive and is processed at low strain rates to reduce the resistance to deformation. Beta phase responds well to solutionizing (hardenability) and age hardening treatments. The alloys are processed in the β or the α/β two-phase field, cooled to room temperature, and heat treated to form controlled amounts and morphology of β-to-α phase transformation products. For example, when the near-α alloy, Ti-8Al-1Mo-1V, is forged at the appropriate elevated temperature within the α/β-two-phase field, the resulting microstructure (Fig. 12b), consists of relatively fine equiaxed α grains retained from their equilibrium presence at the processing temperature (primary α) in a matrix comprising acicular α grains that

transformed from the β grains that existed at the elevated temperature. It is this microstructure (Fig. 12b), that provides the best combination of strength and ductility for this alloy. When this alloy is hot forged at a temperature much lower in the α/β two-phase field, the microstructure at room temperature consists of nearly all α grains (Fig. 12a), resulting in lower strength than the alloy is capable of providing. This microstructure could also be achieved by processing at the same temperature as in Fig. 12(b), but with slow cooling from the processing (or solution-treatment) temperature. This microstructure in Fig. 12(a) has better toughness than that in Fig. 12(b). In contrast, hot forging of this alloy at a temperature in the all-β regime will result in the relatively coarse array of acicular α transformation products produced from a coarse grain β parent, Fig. 12(c). This structure provides the maximum fracture toughness, with a notable reduction in ductility and fatigue strength.



(a) Forged with a starting temperature of 900 °C (1650 °F), which is below the normal temperature range for forging Ti-8Al-1Mo-1V

(b) Forged with a starting temperature of 1005 °C (1840 °F), which is within the normal range, and air cooled

(c) Forged with a starting temperature of 1093 °C (2000 °F), which is above the beta transus temperature, and rapidly air cooled after finish forging

(b) Equiaxed grains of primary α (light) in a matrix of transformed β (dark) containing fine acicular α. (c) Transformed β containing coarse and fine acicular α (light). Etchant: Kroll's reagent (192). All micrographs at 250×

Alpha-Beta Structures. The α-β titanium alloys offer similar microstructures as the α alloys, but with a greater amount of retained β, which affects the properties. For example, when the commercially important α-β alloy, Ti-6Al-4V, is cooled from an elevated-temperature processing operation or heat treatment, the β phase can transform to the coarse acicular structure seen in Fig. 12(c) or to a fine acicular α structure via a diffusion-controlled nucleation and growth mechanism, or to needlelike α' via a martensitic reaction as it cools below the martensite start temperature, M_s (Fig. 13). The coarseness of the transformed structure is controlled by cooling rate. The martensite reaction produces the α' phase from the β by a diffusionless or shear movement of the product grain boundary, mechanistically similar to what occurs during the quenching of steels. The martensitic product has an hcp crystal structure and is in a supersaturated state with respect to the alloy content because it inherits the composition of the parent β. A second type of martensitic transformation product, the orthorhombic α", can occur either upon cooling (athermal) or during cold working (strain induced). When aged, both metastable martensites precipitate equilibrium amounts of α+ β.

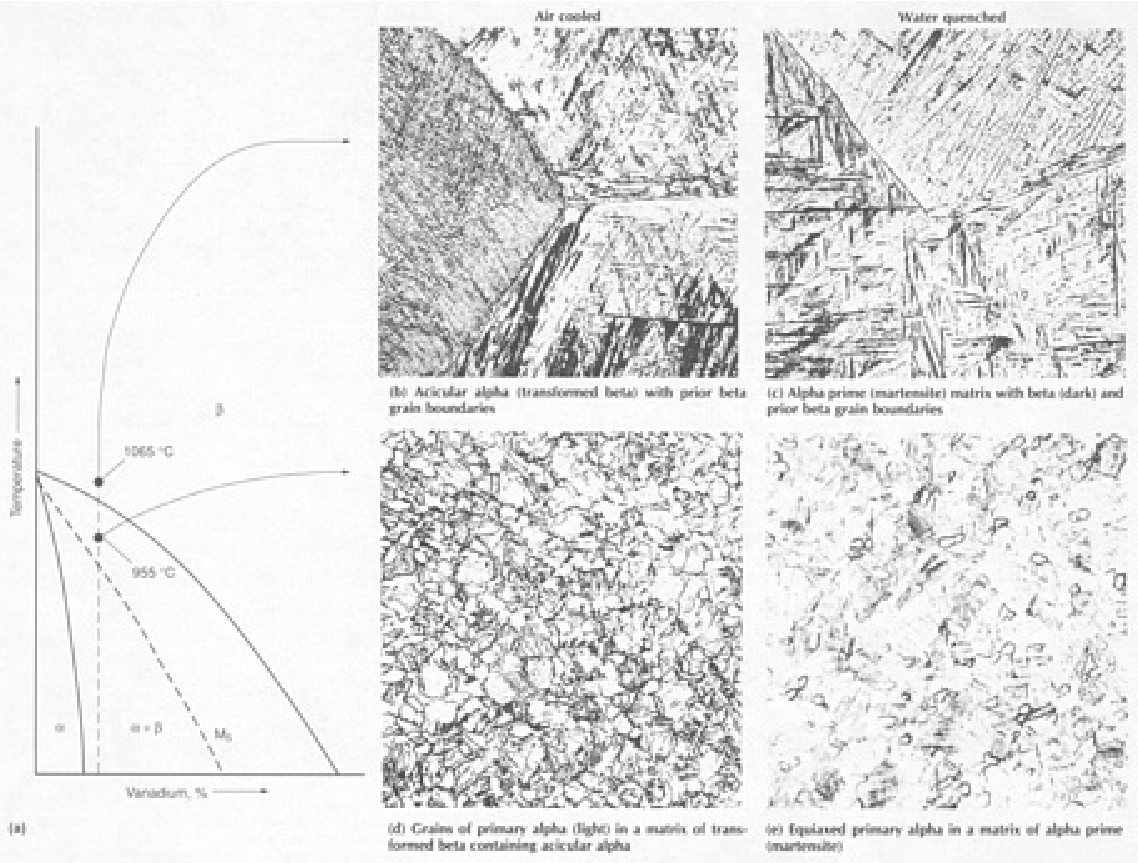


Fig. 13 Microstructures of alloy Ti-6Al-4V after cooling from different areas of the phase field shown in (a). The specimens represented in micrograph (e) provided the best combination of strength and ductility after aging. Etchant: 10 HF, 5 HNO_3, 85 H_2O. All micrographs at 250×

The fine acicular α may be difficult to distinguish from the martensite as illustrated in Fig. 13. In general, acicular (or lamellar) α improves creep resistance, fracture toughness, and crack growth resistance, but at a sacrifice in ductility and fatigue (with a slight drop in strength). The coarser the transformed-β structure, the greater the improvement in toughness and crack-growth resistance, and the greater the loss in ductility and fatigue strength.

Typical microstructures representative of those most commonly used for α/β alloys are shown in Fig. 14. Proceeding from Fig. 14(a) to (d) will generally result in progressively decreased tensile and fatigue strengths, with increasing improvements in damage tolerance type properties. The difference in microstructure between Fig. 14(a) and (b) is due to the differences in processing history. The temperature during sheet rolling decreases as rolling proceeds, and the final rolling temperature is significantly lower than the final forging temperature. Thus, there is less retained β at the final working temperature for the sheet, and a predominantly "globular"-type α microstructure (the black features in Fig. 14a are retained or transformed β). The final forging temperature is significantly higher, with more retained β, accounting for the higher amount of lamellar transformed β microstructure. The slow cooling of the recrystallized annealed structure permits the primary α to grow during cooling, consuming most of the β. Retained β is observed at some α-α boundaries and triple points. The solution-treated and aged condition is not commonly used for Ti-6Al-4V, but it is the standard heat treatment for aerospace fasteners.

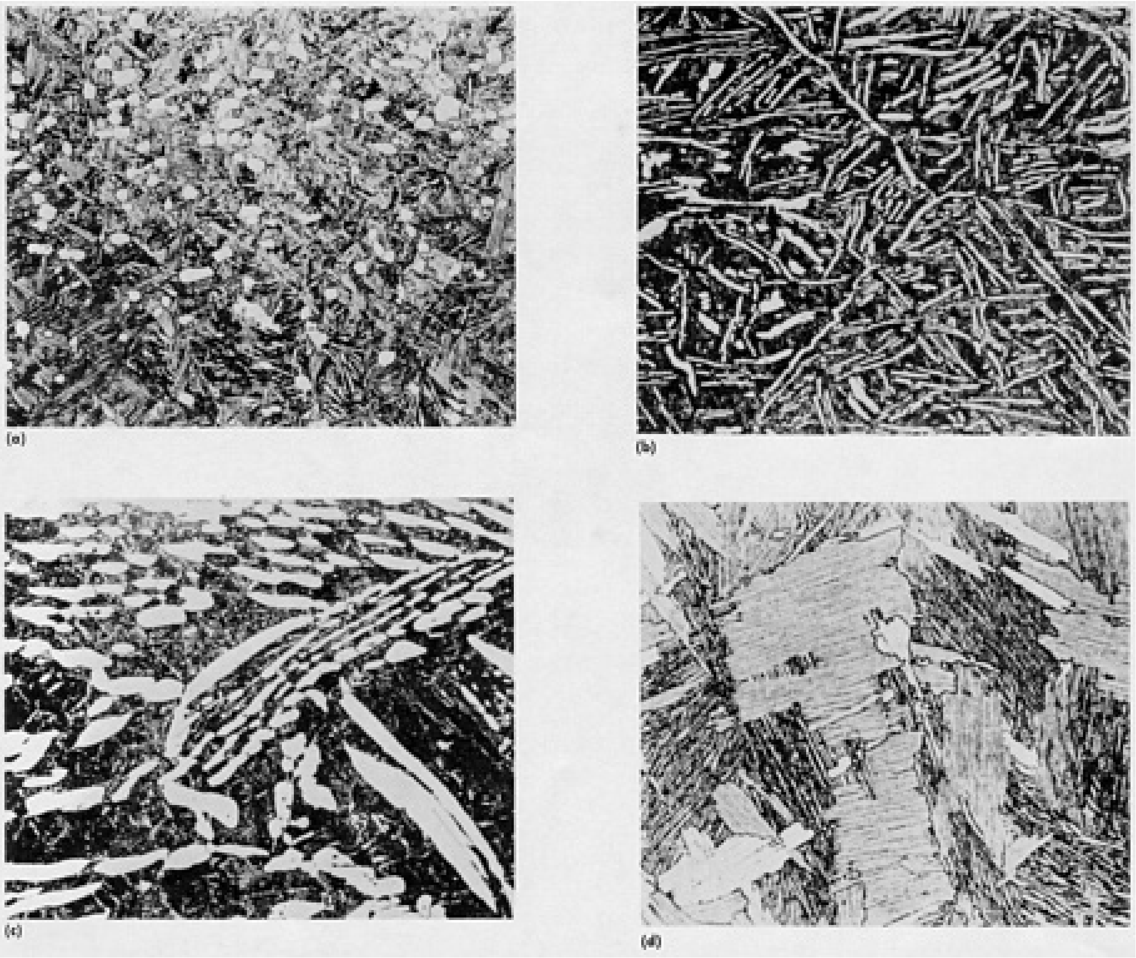

Fig. 14 Microstructures corresponding to different combinations of properties in Ti-6Al-4V forgings. (a) 6% equiaxed primary α plus fine platelet α in Ti-6Al-4V α-β forged, then annealed 2 h at 705 °C (1300 °F) and air cooled. (b) 23% elongated, partly broken up α plus grain-boundary α in Ti-6Al-4V, forged and water quenched, then annealed 2 h at 705 °C and air cooled. (c) 25% blocky (spaghetti) α plates plus very fine platelet α in Ti-6Al-4V forged from spaghetti-α starting structure, then solution treated 1 h at 955 °C (1750 °F) and reannealed 2 h at 705 °C. (d) 92% α basketweave structure in Ti-6Al-4V β forged and slow cooled, then annealed 2 h at 705 °C. Structures in (a) and (b) produced excellent combinations of tensile properties, fatigue strengths and fracture toughness. Structure in (c) produced very poor combinations of mechanical properties. Structure in (d) produced good fracture toughness, but poor tensile properties and fatigue resistance.

Beta Phase. The β alloys are rich enough in β-stabilizing elements (Tables 14 and 15) that the beta phase can be retained at room temperature with appropriate cooling rates. The martensite reaction does not occur because the M_s is below room temperature. In this metastable condition, the retained β is hardenable by precipitation of α given the proper aging heat treatment. The family of β alloys are classified as "lean" and "rich" β alloys, a useful oversimplification in spite of the continuum of phase changes that occur with increasing alloy content (Fig. 15). The lean β alloys are prone to form the embrittling, metastable ω phase during cooling or aging, while the rich β alloys are stable enough to avoid formation of ω phase during processing. In practice, this is not a problem as these alloys are normally aged at a temperature above the ω solvus so α and β are the only phases present. However, this would preclude using β alloys in the solution-treated condition for elevated-temperature application below about 425 °C (800 °F) where ω precipitation will occur. Using aged β alloys below this temperature should not be a problem as the aging stabilizes the β sufficiently to prevent ω formation. The formation of ω phase can also be effectively suppressed by cold working the parent β phase before aging to encourage extensive heterogeneous nucleation of the desired equilibrium α phase.

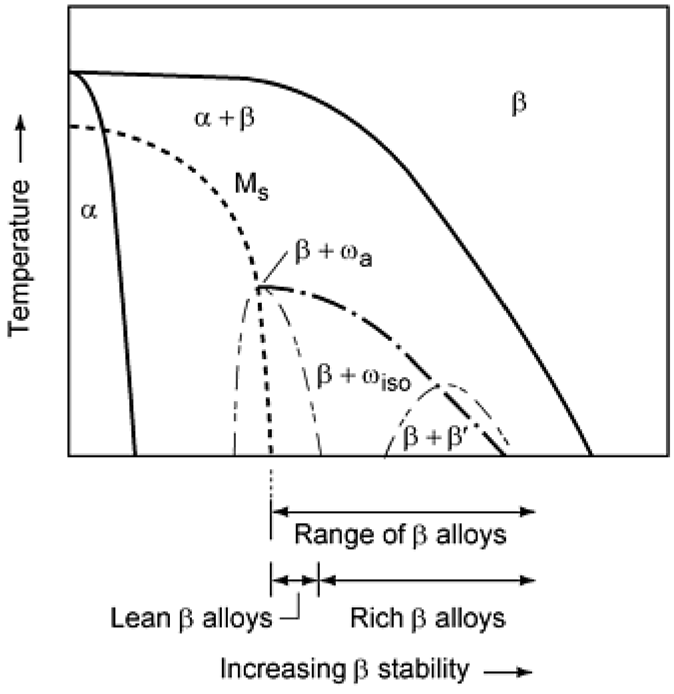

Fig. 15 Schematic phase diagram of a β-stabilized titanium system, indicating the compositional range that would be considered β alloys and the subdivision of this range into the lean and rich β alloys

Besides shaping the alloy, the thermomechanical working is designed to provide the microstructure for the optimal combination of properties required by the application. The morphology (shape/size/volume fraction) of the α phase determines structural properties. For the near-α and the α-β alloys, in general, the equiaxed α morphology promotes higher ductility and formability, higher strength, better low-cycle fatigue, and higher threshold stress for hot-salt stress corrosion compared to the acicular α morphology. However, when processed with a predominately acicular morphology, the alloy has superior creep resistance, higher fracture toughness, superior stress-corrosion resistance, and lower crack-propagation rates. A general comparison of the structural property combinations available with either the β or the α-β processing mode applied to the α-β alloys are qualitatively described in Table 16.

Table 16 The effect of processing mode on the properties of α-β titanium alloys

Property	β processed	α/β processed
Tensile strength	Moderate	Good
Creep strength	Good	Poor
Fatigue strength	Moderate	Good
Fracture toughness	Good	Poor
Crack growth rate	Good	Moderate

Grain size	Large	Small

Wrought Titanium Alloys

Unalloyed titanium is all α phase at room temperature. The acicular form is readily obtained as the principal β transformation product, but the equiaxed α morphology is obtainable only by applying a recrystallizing heat treatment to a cold-worked condition. The commercially pure grades have relatively low strength (Table 14), but with good control of impurities it has good toughness, offering impact toughness values equivalent to quenched-and-tempered steels. There is good creep resistance up to about 315 °C (600 °F). Because of the good corrosion resistance and the ability to maintain a clean surface in service, the base titanium metal/oxide system offers good heat-transfer properties making commercially pure grades particularly useful for heat-exchanger applications. Commercially pure grades are also available with minor alloy elements. For example, a small solid-solution addition of 0.2 Pd improves corrosion resistance still further. The alloy Ti-0.3Mo-0.8Ni (UNS R53400) offers higher strength with corrosion resistance between that of the unalloyed and the titanium-palladium grades.

Titanium and its alloys are processed at elevated temperatures to take advantage of the better forgeability of the bcc β phase. It also results in less crystallographic texturing and more uniform properties than does processing the hcp α phase. In the initial ingot breakdown operations, the metal is forged in the β field just above the β transus. However, as the metal is taken down through the secondary processing steps, such as rolling, it is processed high in the α/β field just below the β transus to avoid excessive β grain growth.

Many titanium alloys are placed in service in heat-treated conditions. After being shaped into final form or before machining, the alloys are commonly given softening, stress-relieving, or solutionizing and aging thermal treatments. The alloys are commonly given stress-relief anneals without adversely affecting strength or ductility in order to relieve the stresses induced by prior thermomechanical processing and forming operations. However, care is taken to choose temperatures that are high enough to accomplish the stress relieving and low enough to avoid overaging (for the solution treated and aged condition) or strain aging, or to avoid recrystallizing of a cold-worked condition. Cooling rates from stress relieving or aging treatments must be sufficiently slow and uniform to avoid reintroducing thermal stresses. Aging treatments are carried out at a temperature in the range 425 to 650 °C (800 to 1200 °F) as appropriate for the specific alloy and desired properties.

Heating rates to the aging temperature of β alloys must be rapid enough to avoid precipitation of the ω phase. The α and α-β alloys are solution treated just below the β transus for optimal ductility, toughness, and creep strength of the aged condition. On the other hand, annealing or processing is done well below the β transus to encourage a fine equiaxed α in the final product for high strength, good ductility, and resistance to fatigue crack initiation.

The annealing treatments need to be carried out in inert atmosphere or in vacuum to avoid excessive oxidation of the surface. When an oxygen-enriched layer is formed it is called "α case", and it must be chemically or mechanically removed before being put into service. Titanium should not be heat treated in a hydrogen atmosphere; the hydrogen content is limited to a maximum of 125 to 150 ppm to avoid embrittlement, which manifests itself as reduced impact strength, low notched tensile strength, and delayed cracking.

Titanium alloys in general can be made to exhibit superplasticity under the right conditions, but the α-β alloys show the highest degree of this phenomenon. Superplasticity is exceptionally high ductility when processed or tensile tested with very fine α-β structures, with a primary α grain size of about 10 μm (400 μin.) at very high temperature and with controlled, (slow) strain rates. The α-β alloy, Ti-6Al-4V, for example, has been superplastically formed commercially into complex parts at 870 to 925 °C (1600 to 1700 °F), under an argon atmosphere, and at strain rates in the range 1.3×10^{-4} to 1.0×10^{-3}/s.

Alpha Alloys. The α-titanium alloys are slightly less corrosion resistant but offer higher strength than unalloyed titanium. The α alloy Ti-5Al-2.5Sn (UNS R54520), for example, shows good ductility at a tensile strength level of 790 MPa (115 ksi) (Table 14). However, outside of grain size control of strength, it cannot be strengthened by heat treatment. Its primary use is for cryogenic applications.

The near-α titanium alloys utilize a small amount of β-stabilizer elements to retain some β for additional microstructural and property control. These alloys, Ti-8Al-1Mo-1V (UNS R54810) and Ti-6Al-2Sn-4Zr-2Mo, for example, are processed high in the α/β field to restrict β grain growth. The microstructures can range from equiaxed to acicular α (Fig. 12a to c). The latter alloy is used primarily for elevated-temperature applications, up to 540 °C (1000 °F).

Alpha-Beta Alloys. The α-β titanium alloys contain one or more α with one or more β-stabilizing elements, offering increased strength and a wider range of properties, with the usual trade-off in strength versus ductility. These alloys can be strengthened by heat treatment or by thermomechanical processing to produce the wide variety of microstructures described above (Fig. 13 and 14). These alloys can be aged, with better aging response shown when the β is more rapidly cooled to room temperature. The most commonly used alloy in this family, Ti-6Al-4V (UNS R56400), can be processed to provide a wide range of tensile properties. The alloy exhibits yield strengths in the range of 830 to 970 MPa (120 to 140 ksi), tensile strengths of 900 to 1070 MPa (130 to 155 ksi), and elongations of about 10 to 15% in the annealed condition. In the solution treated and aged condition the properties range from 1000 to 1100 MPa (145 to 160 ksi) yield strength, 1070 to 1170 MPa (155 to 170 ksi) tensile strength, and elongations of 5 to 8%. The aged properties are strongly dependent on section thickness.

Beta Alloys. With the β titanium alloys, it is difficult to obtain a great variety of useful property combinations by processing, but they do offer better fracture toughness and better room-temperature forming characteristics than the α-β alloys. The β alloys also provide high strength where yield strength instead of creep strength is important. The beta alloys are more hardenable and better able to retain the desired as-quenched condition in heavier sections than the α-β alloys. Aging treatments are done at 450 to 650 °C (850 to 1200 °F) producing dispersions of fine alpha particles in the retained beta matrix. Yield strengths approaching 1380 MPa (200 ksi) are available with β alloys in the solution treated and aged condition. The β alloy Ti-3Al-8V-6Cr-4Mo-4Zr (UNS R58640) exhibits cold-drawn and aged tensile strengths of 1310 to 1450 MPa (190 to 210 ksi) with a minimum of 10% elongation for wire.

Titanium Casting Alloys

The titanium casting alloys comprise less than 2% of total mill products and have been based on traditional wrought alloy compositions, with Ti-6Al-4V being used for about 85% of the total. Casting permits the manufacture of increasingly complex parts and have been used primarily in pumps and valves for marine and chemical plant applications as well as for air frames, gas turbine engine components, and surgical implant prostheses. The cast microstructure invariably consists of β-transformation products formed during cooling of the casting: α platelets, grain boundary α, and α colonies. The inevitable shrinkage porosity seen in the as-cast microstructure has been successfully eliminated in commercial practice by applying subsequent hot isostatic pressing (HIP) operations. With the application of pressure under argon of 103 MPa (15 psi) at temperatures of 815 to 980 °C (1500 to 1800 °F), the shrinkage porosity collapses and the interfaces diffusion bond to provide a high-quality product. Stress-relief annealing is done at lower temperatures (730 to 845 °C, or 1350 to 1550 °F) and in vacuum to remove hydrogen and protect surfaces from oxidation.

Industrial and marine applications for the cast alloys are mostly for corrosion resistance. The α-β alloy Ti-6Al-4V is used in the annealed condition with tensile properties of 855 MPa (124 ksi) yield strength, 930 MPa (135 ksi) tensile strength, and 12% elongation. The α-β alloy Ti-6Al-2Sn-4Zr-2Mo, making up of about 6% of casting products, is employed at higher operating temperature where its good creep resistance up to 500 to 600 °C (930 to 1110 °F) is needed. The β alloy Ti-15V-3Al-3Cr-3Sn, developed as a cold-formable, age-hardenable sheet alloy, is also heat treatable as a casting alloy, where it has tensile strengths of 1200 MPa (175 ksi).

The inherently large β grains resulting from casting (0.5 to 5 mm, or 0.02 to 0.2 in.) are beneficial for fracture toughness, creep resistance, and fatigue crack propagation resistance, but they are harmful to fatigue strength and tensile elongation. Heat treatments are applied to minimize the amount of large boundary α for improved fatigue strength.

Titanium Alloy Powders

Titanium and its alloys, particularly the α-β alloy Ti-6Al-4V, have been fabricated by P/M techniques to take advantage of the net-shape manufacture and of the complex configurations that are possible with these methods. Blended elemental powder components are cold pressed and sintered to achieve densities on the order of 95 to 99% of theoretical and can be

hot isostatically pressed to higher densities. Full densities are not achieved unless low Cl^- powder is used. Prealloyed powder is directly hot isostatically pressed to the desired shape. Unlike the P/M products of some other metals, titanium cannot tolerate the least amount of porosity lest it degrade fatigue and fracture properties. For this reason, contamination in the original powder must be avoided and hot isostatic pressing (or other hot processing) steps are used after sintering to ensure high-integrity P/M products.

When powdered fines from the sponge manufacturing method are used, the sintering is done in the β field at temperatures in the range 1150 to 1315 °C (2100 to 2400 °F). The resulting P/M product usually comprises relatively coarse α platelets in colonies of similar orientations. Prealloyed powder products are used for more demanding applications and processing to achieve 100% density is a requirement. Post-sintering thermal or thermomechanical treatments are applied to the compacts, and powder with a low Cl^- content must be used to ensure 100% density and to refine the α microstructure for improved strength and fatigue resistance.

Ti-6Al-4V products made by the prealloyed powder route offer respectable tensile properties for the pressed-and-sintered condition, nominally 847 MPa (123 ksi) yield strength, 930 MPa (135 ksi) tensile strength, and 14% elongation. When the sintered product is forged, the tensile properties are 951 MPa (138 ksi) yield strength, 1027 MPa (149 ksi) tensile strength, and 9% elongation, with improved fatigue properties. These properties are comparable with what is available with wrought products of similar microstructures. Beta alloys are also successfully made by P/M methods. After thermal treatment, the alloy Ti-8V-1.3Al-5Fe has shown yield and tensile strengths as high as 1461 MPa (212 ksi) and 1516 MPa (220 ksi), respectively, with 8% elongation. An additional benefit of P/M is its inherent effectiveness at providing a homogeneous composition; castings of a composition with such a high iron content as the latter alloy would have segregation problems that would degrade properties if made in cast or wrought products.

Zinc and Zinc Alloys

Zinc is the fourth most used industrial metal (after iron, aluminum, and copper). It is principally used in galvanized coatings and anodes for corrosion protection of iron and steels, zinc casting alloys (die, permanent, sand mold), copper (brasses), aluminum, and magnesium alloys, wrought zinc alloys, and zinc chemicals (zinc oxide) (Ref 18, 40, 41). In the United States during 1994, zinc usage was about 54% in galvanizing, 21% in zinc-base alloys, 15% in brass and bronze, and 10% in other uses. As a structural material zinc offers good strength at a moderate density (7.133 g/cm^3, or 0.258 lb/in.^{3}), and good electrical conductivity (28% IACS) and thermal conductivity (113 W/m · K). Its relatively low boiling point (906 °C, or 1663 °F) and its relatively low melting point (420 °C, or 788 °F), make it easy to purify by distillation

and to cast into useful products. The high fluidity of the liquid contributes to its good castability, permitting the casting of thin-wall components. Wrought zinc and zinc alloys are available in flat-rolled, wire-drawn, and extruded and forged shapes. Zinc and its alloys are widely used in the automotive, hardware, home appliance, and electrical components industries.

Zinc and its alloys show excellent bearing and wear properties because of its self-lubricative surface characteristics resulting in a low coefficient of sliding friction and resistance to galling. Zinc also offers good spark resistance and good machining characteristics. Its excellent sound and vibration-damping properties, that increase with temperature, are similar to those of cast irons. Zinc can be soldered, but solder alloys based on lead, cadmium, or tin cannot be used, because these elements promote intergranular corrosion. In addition to its attractive physical and mechanical properties, zinc and its alloys have a relatively low cost and are environmentally friendly.

Because of its highly anodic position (second to magnesium) in the electromotive series of metals, zinc is widely used as a sacrificial anode for protection of iron and steels as galvanized coatings. Zinc structural components have good corrosion resistance provided impurity limits are not exceeded and provided that the component is a stand-alone or is otherwise designed properly to avoid galvanic corrosion by contact with other metals. The thin adherent surface film, zinc "patina" ($ZnCO_3 \cdot 3Zn(OH)_2$) readily forms in air, giving zinc alloys their resistance to atmospheric corrosion. However, this film is attacked by acids and does not stand up well in continuous contact with moisture. Zinc responds well to a wide variety of finishing and coating treatments, such as buffing, plating, chromating, painting, anodizing, plastic coating, and phosphating. Chromating and anodizing treatments also provide good corrosion protection.

Although adequate for its many room-temperature applications, commercially pure zinc has poor creep resistance at modestly elevated temperatures, which can be improved upon somewhat by alloying. With such a low melting temperature (420 °C, or 788 °F), one would expect high diffusion rates, natural aging reactions, and active creep mechanisms leading to microstructural and dimensional instability at and just above room temperature (homologous temperature of 0.43 T_m). The modulus of elasticity of zinc is listed as a range (70 to 140 GPa, or 10 to 20 × 10^6 psi) because there is no region of strict proportionality in the tensile stress-strain curve in polycrystalline zinc. For this reason, yield strength values are not listed for zinc or its leaner alloys. Alloying beyond 4% Al adds stiffening second phases to allow yield strength and the elastic modulus to be measured in standard tensile tests. But even so, tensile and other mechanical properties are affected by operating temperature and time. For hardness data, the test duration, usually 30 s, should also be specified along with test load and penetrator shape. The mechanical property and dimensional changes shown by a rapidly cooled alloy casting can be countered by a post solidification stabilization anneal, typically 100 °C (212 °F) for 3 to 6 h followed by air cooling. At 100 °C (212 °F), tensile strengths are about 65 to 75% of the room-temperature values.

Unalloyed zinc is available in three basic grades differing by impurity content: special high grade, high grade, and prime western. Impurities, especially lead, cadmium, and tin, must be tightly controlled to avoid intergranular and subsurface corrosion. The use of high-purity zinc with minute amounts of a specific element, such as 0.02% Mg or 0.01% Ni, that counteract impurities via mechanisms that are not yet clear, greatly reduces the corrosion susceptibility. A "steam test" consisting of exposure to saturated water vapor at 95 °C (203 °F) for 10 days correlates well with the corrosion behavior of zinc-aluminum alloys in humid atmospheres. Iron and silicon impurities are also controlled to minimize the formation of hard particles that harm machinability.

The poor room-temperature working characteristics and directional properties of zinc are a direct consequence of its hcp crystal structure. Of the twenty-two elements with an hcp structure, only zinc and cadmium exhibit a c/a ratio greater than the ideal close-packed value of 1.633. Not only is slip difficult because of the limited number of available slip systems, but cleavage readily occurs along the basal plane. Zinc has a ductile-brittle transition temperature (DBTT) just below room temperature and sharp radii must be avoided to reduce its notch sensitivity. Much of the useful deformation strain in processing is by twinning. In a single crystal, the interatomic bonds in the hexagonal layer, or basal plane, are significantly stronger than those between the layers, or normal to the basal plane. This anisotropy in atom-bonding strength leads to significantly larger values of compressibility and coefficient of thermal expansion along the direction of the c-axis. For example, in the basal plane along the distance of closest atomic approach, the thermal expansion coefficient is 15 ppm/°C (8.3 ppm/°F), while normal to the basal plane it is as high as 62 ppm/°C (34 ppm/°F). This anisotropy is inherent in wrought products that have crystallographic texture due to processing.

Effects of Alloying Elements in Zinc Alloys

Of the eleven elements exhibiting a reasonable level of solubility in zinc, silver and gold are too costly, while cadmium, mercury, and as little as 0.08% Mg lead to hot shortness. It is aluminum and copper, with minute amounts of magnesium

(<0.08%), and more recently titanium, that are mainly added to casting and wrought zinc alloys. The principal role of the alloy elements is, in general, to provide second-phase particles or precipitates to increase mechanical strength, while restraining recrystallization, grain growth, and creep processes. The compositions of the various casting alloys are distinguishable from wrought, as seen from the selected examples listed in Table 17. The rationale for these differences is discussed below.

Table 17 Composition and properties of selected zinc alloys

UNS No.	Common name	Nominal composition, %	Tensile strength		Elongation, %	Hardness, HB[(a)]
			MPa	**ksi**		
Die-casting alloys

(a) Test duration, 30 s

Zinc forms a eutectic with aluminum at 5% Al and at 382 °C (720 °F). The maximum solid solubility of aluminum in zinc is about 1% which decreases to 0.05% at room temperature. Consequently, the microstructure of zinc-aluminum alloys consists of a mixture of aluminum-rich and zinc-rich phases. The aluminum phase is solution hardened by zinc in solution and by precipitation of zinc particles; the zinc-rich phase is hardened by precipitation of the aluminum phase particle, with little aluminum in solution at equilibrium at room temperature (Fig. 16). The precipitation of the less dense aluminum phase contributes to the dimensional changes with time after zinc is rapidly cooled after casting or heat treatment. It is the primary function of the stabilization anneal to provide a more equilibrium volume fraction of the aluminum phase to stabilize the microstructure.

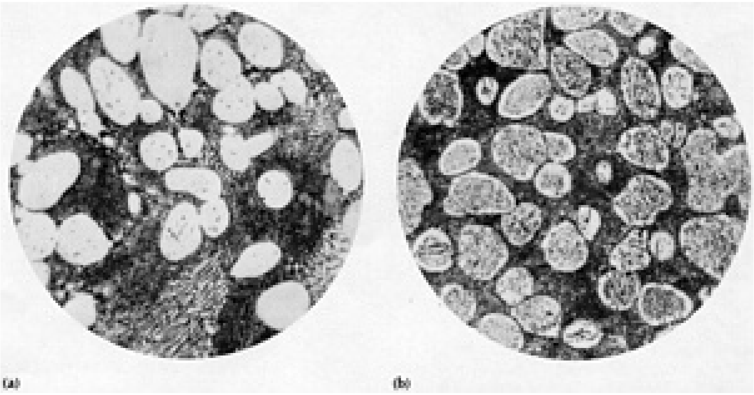

Fig. 16 Photomicrographs of zinc die-casting alloy No. 5 (UNS Z35531), Zn-4Al-1Cu-0.05Mg, showing (a) the zinc solid solution surrounded by eutectic in the as-die-cast microstructure and (b) the precipitation of aluminum-rich precipitates in the zinc phase after aging 10 days at 95 °C (205 °F). 1000×

Zinc Casting Alloys

Pure zinc is coarse grained, attacks iron when molten, and exhibits property anisotropy when cast and processed. Because molten zinc does not dissolve hydrogen, there is no need to flux and cast products are generally sound. The addition of aluminum greatly reduces the iron dissolution rate, permitting the use of ferrous die-casting equipment. Thus, aluminum is the principal alloying element in the cast zinc alloys, providing good castability and increased cast strength. The casting alloys can be divided into two principal classes based on aluminum content: the hypoeutectic alloy with about 4% Al for optimal mechanical properties and those with much greater levels of aluminum, as seen in Table 17. The cast microstructure of the 4% Al alloys consists of zinc-rich dendrites, with interdendritic eutectic arrays of zinc and aluminum (Fig. 16). Alloys with >5% Al are hypereutectic and have aluminum-rich dendrites, with interdendritic aluminum/zinc eutectic structures. Aluminum additions above 4% add strength, hardness, and stiffness, but at the price of lower ductility. Because the electrical conductivity of aluminum (higher than zinc) is lowered by dissolved zinc and alloying elements have little solubility in the zinc phase, electrical and thermal conductivity values are rather constant across the range of alloys.

Copper, magnesium, and titanium are the other common alloying elements. Copper is added for strength, hardness, and creep resistance. However, with increasing amounts of copper, ductility decreases and the degree of dimensional growth with time increases. Where it is an important design criterion, dimensional stability can be a problem especially if moderately elevated temperatures are expected in service. For example, after die casting, Zn-4Al shows an initial shrinkage that decreases with time. The effect of copper in this alloy was quantified in a laboratory experiment where after the initial shrinkage after casting, exposure for 1 year in dry air at 95 °C (205 °F) resulted in dimensional growth of 0.0002 in./in. at 0% Cu and 0.002 in./in. for a Zn-4Al-1.5Cu alloy. The amount of growth seen at the 1.25% Cu level is considered tolerable for many applications. Originally, copper was also added to counteract the harmful effects of impurity elements, a role taken over by very low, but deliberate additions of magnesium. It is still unclear how the impurities causing intragranular corrosion are neutralized by copper or magnesium. Nickel works as magnesium, but it is harder to control. Magnesium also has the added benefit of lowering the DBTT or embrittlement temperature. However, exceeding about 0.08% Mg leads to hot shortness during cooling of the casting. Exceeding the strict impurity limits in general will lead to intragranular corrosive attack and warping and cracking with time after casting.

The die-casting alloys (No. 2 to 7 in Table 17) are basically a family of Zn-4Al alloys because this composition provides excellent casting characteristics and optimal strength and ductility. The copper addition provides strength, hardness, and creep resistance, but it is limited by the expansion or swelling with time it induces. The expansion with time shown by alloy No. 2 (2.5% Cu) might be too excessive for some applications. On the other hand, alloy No. 3 (0% Cu) has low creep resistance and should not be exposed to temperature above 50 °C (120 °F) under load.

The gravity-fed castings (sand and permanent mold) are made of higher aluminum-containing alloys, ZA-8, ZA-12, and ZA-27, to take advantage of the higher strength and creep and fatigue resistance than the 4% Al alloys. The improved creep resistance is directly related to the coarser cast grain structure. These alloys are also more dimensionally stable and have lower densities than the 4% Al alloys. ZA-27 is the lowest density (5.00 g/cm^3, or 0.181 lb/in.^{3}), the strongest, and the hardest zinc-casting alloy, but it suffers from low ductility and impact strength.

Wrought Zinc Alloys

The wrought zinc alloys are fabricated as flat-rolled, wire-drawn, and extruded and forged products. The flat-rolled products are processed from cast slabs 25 to 100 mm (1 to 4 in.) thick to gages as thin as foil, 0.025 mm (0.001 in.). Zinc alloys are hot worked at 120 to 150 °C (250 to 300 °F), but even at room temperature, the heat generated during an individual processing or forming step is generally sufficient to cause recrystallization, precluding the need for annealing.

The wrought alloys are relatively lean in alloy content and the strict impurity control noted for the casting alloys also applies to the wrought alloys. Owing to the crystallographic texture derived from working of this hcp material, the mechanical and thermal expansion properties are anisotropic (directional) in the rolled product, with the orientation transverse to the rolling direction showing higher tensile strength and lower thermal expansion than the longitudinal orientation (rolling direction), as illustrated by the properties for one of the rolled zinc alloys (Zn-0.06Pb-0.06Cd), listed in Table 18.

Table 18 Property directionality in the rolled zinc alloy Zn-0.06Pb-0.06Cd

Property	Direction of measurement	
	Longitudinal (rolling direction)	**Transverse to the rolling direction**
Tensile strength, MPa (ksi)	150 (22)	170 (25)
Coefficient of thermal expansion, μm/m · K (μin./in. · °F)	32.5 (18.1)	23.0 (12.7)

In addition to pure zinc, there are three commercial rolled zinc alloys: Zn-0.08Pb (UNS Z21210), Zn-0.06Pb-0.06Cd (UNS Z21220), and Zn-0.3Pb-0.03Cd (UNS Z21540) that are deep drawn into battery cans, eyelets, and grommets. They are readily formable provided that the temperature is kept above 21 °C (70 °F) and are generally hot worked at 120 to 275 °C (250 to 525 °F). Higher strength and creep resistance are obtainable with the alloys in which copper is used as a hardening agent, through the precipitation of the ε-copper-zinc phase: Zn-1.0Cu (UNS Z44330), Zn-0.8Cu-0.010Mg (UNS 45330), and Zn-0.8Cu-0.15Ti (UNS Z41320). The last named alloy offers higher room-temperature tensile strength (200 to 262 MPa, or 29 to 38 ksi) and creep resistance than the other wrought alloys provided that the alloy is heat treated after rolling (typically at 250 °C, or 480 °F, for 45 min) to precipitate the intermetallic compounds that zinc forms with copper and titanium. In this latter alloy, the precipitation of $TiZn_{15}$ at grain boundaries restrains grain growth (Fig. 17).

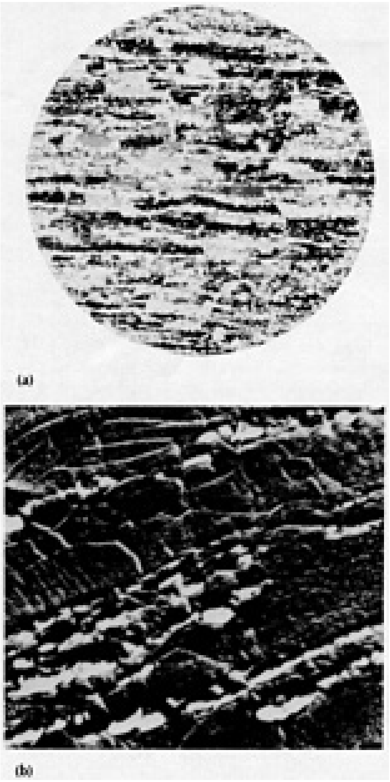

Fig. 17 Photomicrographs of hot-rolled zinc alloy Zn-0.6Cu-0.14Ti. (a) Photographed under polarized light to show the elongated grains (parallel to the direction of rolling) restrained by stringers of the $TiZn_{15}$ particles. 250×. (b) Replica electron micrograph showing the morphology and distribution of the $TiZn_{15}$ particles (white) along the grain boundaries. 4400×

One of the most-studied superplastic materials is the Zn-22Al eutectoid alloy, to which 0.5% Cu and 0.02% Mg can be added for enhanced creep strength. When solutionized, quenched, and annealed, this alloy forms a microstructure comprising small equiaxed grains of zinc and aluminum terminal solid solution phases (Fig. 18). It is this fine-grain structure that exhibits a tensile elongation in excess of 2500% when tensile tested in the superplastic regime at 250 °C (480 °F) and is easily formed into complex shapes at 250 to 270 °C (480 to 520 °F). When heated above 275 °C (527 °F) and slowly cooled to room temperature, it loses its superplastic properties. The alloy has the directionality in properties of a wrought product, with tensile properties in the rolling direction of 255 MPa (37 ksi) yield strength, 310 MPa (45 ksi) tensile strength, and 27% elongation; in the orientation transverse to the rolling direction, 295 MPa (43 ksi) yield strength, 380 MPa (55 ksi) tensile strength, and 25% elongation. Forgings and extruded products are made primarily of either the zinc-aluminum alloy, Zn-14.5Al-0.75Cu-0.02Mg, or the zinc-titanium alloy, Zn-1.0Cu-0.01Ti, with the former showing good tensile strength with higher impact strength at low temperatures.

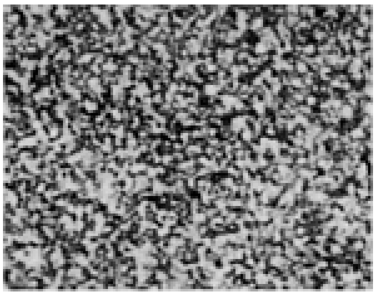

Fig. 18 Photomicrograph of Zn-22Al alloy (eutectoid composition) showing superplastic, fine-grained structure obtained by annealing at 350 °C (660 °F) and water quenching. 2500×

Magnesium and Magnesium Alloys

Magnesium and its alloys have been employed in a wide variety of structural applications because of their favorable combination of tensile strength (140 to 365 MPa, or 20 to 53 ksi), elastic modulus (45 GPa, or 6.5 × 10^6 psi), and low density (1.74 g/cm^3, or 0.0628 lb/$in.^3$). Magnesium alloys have high strength-to-weight ratios (tensile strength/density), comparable to those of other structural metals (Ref 18, 42, 43). Approximately 15% of annual production is used in structural applications, primarily as die castings (11%), gravity-fed castings (1%), and wrought mill products (3%). The bulk of the remainder is used as alloying additions to aluminum alloys (54%), to desulfurize steel (11%), and to nodularize cast iron (4%). The wrought products start out as cast ingots and are processed into extruded bars, billets, wire, plate, sheet, or general forged shapes. Its rather low melting point (650 °C, or (1202 °F), facilitates its use in die casting, permanent-die, and gravity-feed sand-casting operations, provided the melt is protected from oxidation with inert atmospheres. Magnesium has relatively good electrical (38% IACS) and thermal conductivity (418 Wm · K, or 240 Btu/ft · h · °F) values. It also has a remarkably high damping capacity, that is, the ability to absorb elastic vibrations.

Magnesium falls at the highest anodic position in the galvanic series of metals, making it ideally suited as a sacrificial anode material to protect underwater or underground structures, such as piping, ship hulls, and ballast tanks. On the other hand, this position in the galvanic series also requires proper design of structural applications of this metal to avoid unwanted galvanic corrosion in service. Proper design may involve nothing more than ensuring that the magnesium component be insulated from other metals lower in the galvanic series or be protected from the environment with a well-maintained chromate coating among others.

Magnesium and its alloys are used in a wide variety of structural applications in automotive, industrial, materials-handling, commercial, and aerospace equipment. They are used in support brackets, various types of automotive housings, grain shovels, hand-held tools, luggage frames, computer housings, and ladders. Magnesium and its alloys are quite easily machined, permitting dry cutting at high speeds and great cutting depths, requiring caution to prevent fine machining chips from heating to near the melting point and catching fire. Magnesium alloys can be welded by gas metal arc and by resistance spot welding, but it is also often joined by adhesive bonding.

The primary grade of unalloyed magnesium commercially available is grade 9980A (ASTM B 92) with a nominal purity of 99.8%, which is adequate for most uses. The available higher-purity grades must be specified when improved corrosion resistance is needed. The elements nickel, iron, and copper, in particular, must be kept below restricted limits (typically, 0.005% Ni, 0.005% Fe, 0.05% Cu for some alloys) or corrosion resistance rapidly degrades due to the formation of second-phase particles that are cathodic to magnesium: Mg_2Ni, $FeAl_3$, Mg_2Cu, $MgCu_2$, Fe. A minimum level of manganese is sometimes specified to ensure a critical iron/manganese ratio for tying up iron. One important consequence of the low melting point (650 °C, or 1202 °F) of magnesium is its susceptibility to creep under load at moderately elevated temperatures. Magnesium is alloyed to improve its creep performance to acceptable levels by controlling grain-boundary sliding and migration, the primary creep mechanism in this metal.

Magnesium has poor ductility at room temperature and below. This hcp metal is more easily worked at temperatures above 225 °C (440 °F), usually in the range 345 to 510 °C (650 to 950 °F), where additional hcp slip systems (mainly pyramidal) and twinning become active, augmenting the primary basal slip and twinning deformation modes available at

lower temperature. Another consequence of the predominant basal plane slip at room temperature is the mechanical property anisotropy (or directionality) in cold-rolled sheet due to crystallographic texture. For example, a mildly rolled sheet has a tensile strength and tensile elongation in the rolling direction (241 MPa, or 35 ksi, and 2% elongation) that differ from those transverse to the rolling direction (262 MPa, or 38 ksi, and 8% elongation). Moreover, the hcp crystal structure combined with coarse solidification grain structure also leads to tensile properties that vary with location and direction, especially in large castings. The mechanical property anisotropy in wrought products is also manifested by the observation that the 0.2% offset yield strength in compression is equal to about 40 to 70% of the corresponding yield strength in tension. In the case of cast products, however, the yield strength in compression is roughly equal to the tensile yield strength.

Magnesium Alloys

There are two basic families of magnesium alloys: alloys with 2 to 10% Al with additions of zinc and manganese, and alloys containing zinc with additions of rare earth (RE) metals, thorium, silver, zirconium for strength, creep resistance, and grain refinement. Because the rare earth metals behave similarly, they are alloyed in a group by adding mischmetal, which naturally contains about 50% Ce. The maximum solid solubility of aluminum in magnesium is 12.7% at the eutectic temperature, 437 °C (819 °F), which drops to about 1% at 100 °C (212 °F). The maximum solubility of zinc in magnesium is 6.2% at its eutectic temperature (340 °C, or 644 °F), which drops to 2.0% at 100 °C (212 °F). Thus, alloys containing aluminum and/or zinc are capable of age hardening to combine particle strengthening with solution hardening by aging to form metastable precipitates or the equilibrium phases, $Mg_{17}Al_{12}$ or MgZn. An alloy containing 9Al-1Zn, for example, is precipitation hardenable either naturally or artificially in a furnace. After a solutionizing treatment above 370 °C (700 °F), aging above 205 °C (400 °F) will precipitate $Mg_{17}Al_{12}$ in a continuous array of Widmanstätten particles, whereas aging at lower temperatures will form this phase in a discontinuous cellular morphology. The other alloying elements commonly used in magnesium--zirconium, manganese, thorium, and cerium--have <1.0% maximum solubility. The magnesium alloy designation code identifies the main alloying elements and the amount added. For example, alloy AZ31B contains 3Al-1Zn and is the second alloy (B) in the family sequence. Each of the standard alloying elements are indicated by code, the most important of which are: A (Al), C (copper), E (rare earth), H (thorium), K (zirconium), L (lithium), M (manganese), Q (silver), S (silicon), T (tin), Z (zinc). Magnesium and its alloys are available in the as-cast or the as-fabricated (F), the annealed (O), or the worked (H24, H26) tempers.

The properties of a group of selected commercially available magnesium alloys are given in Table 19. The tensile properties available with magnesium alloys generally range from 70 to 340 MPa (10 to 49 ksi) yield strength, 140 to 365 MPa (20 to 53 ksi) tensile strength, and 1 to 15% elongation. The principal magnesium die-casting alloys are used directly in the as-cast (F) condition and contain Al-Zn-Mn, Al-Mn, or Al-Si-Mn. As aluminum is added to magnesium, the strength continuously rises to 10% Al, but with tensile elongation peaking at about 3% Al. Even though alloys with ≥4% Al are age hardening, aluminum is generally not effective at improving creep resistance. Magnesium alloys with 3% Al have optimal ductility, those with 9% Al offer the best strength, but those with about 6% provide the best combination of strength and ductility. Zinc as an alloying element can be viewed similarly; that is, ductility is optimum for a 3% addition and a good combination of strength and ductility is available with 5% Zn.

Table 19 Compositions and properties of selected cast and wrought magnesium alloys

Alloy and temper	Nominal composition, wt %	Tensile strength		Yield strength		Elongation in 50 mm (2 in.), %	Hardness, HRB

(a) RE, rare earth addition

The remarkable effectiveness of zirconium in grain-refining cast magnesium has been explained by the similarities in crystal structure and lattice parameters of the two elements. The respective distance of closest atomic approach between them differs by about 0.75%, allowing magnesium grains to nucleate epitaxially on the (0001) basal planes of hcp α-zirconium phase crystals, which are first to separate during cooling of the casting. The zirconium addition is usually kept below 0.8%. It readily forms compounds with iron, aluminum, silicon, carbon, oxygen, and nitrogen, and it reacts with hydrogen to form a hydride that is insoluble in magnesium. Additions of thorium and the rare earth metals reduce microporosity and hot cracking, while improving strength and creep resistance. Manganese is added for corrosion stability in Mg-Al-Zn alloys, and yttrium is added for the same purpose in the aluminum-free and the zinc-free magnesium alloys. Manganese forms elemental manganese particles in aluminum-free magnesium alloys, but forms $MnAl_n$ (n = 1, 4, or 6) in aluminum-containing alloys. Magnesium alloys are not susceptible to stress corrosion, except for alloys containing aluminum above 1.5%, which may require a stress-relief anneal, especially after welding, before being placed in service to help reduce susceptibility to stress corrosion.

Besides being readily die cast directly from a liquid melt, magnesium alloys are also formed from semisolid slugs. The most common die-casting alloy for applications at room temperature is AZ91D, containing Mg-9Al-1Zn-0.13 min Mn. The alloy shows excellent castability from melt temperatures in the range 625 to 700 °C (1157 to 1292 °F). It is prone to hot shortness at 400 °C (752 °F), even though its solidus and liquidus occur at 470 and 595 °C (878 and 1103 °F), respectively. The alloy shows a good combination of mechanical properties. The higher-purity version AZ91E also offers good resistance to saltwater corrosion, as long as good control of iron, nickel, and copper impurities is maintained. A good dispersion of $Mg_{17}Al_{12}$ particles obtainable in die-cast AZ91D is illustrated by Fig. 19. As described above, this phase can be solutionized and precipitated throughout the microstructure with appropriate heat treatments. The higher-

purity alloy AM60B, containing Mg-6Al-0.1Mn, shows greater ductility and toughness and is used for automobile wheels and for sports equipment. Alloys with silicon, such as AS41A (Mg-4.3Al-0.35Mn-1.0Si) are more resistant to creep at temperatures up to 175 °C (347 °F). The sand-casting alloy EZ33A, Mg-3RE-3Zn-0.6Zr, is used for its good strength and creep resistance at temperatures up to 260 °C (500 °F) and where there is a special need for pressure tightness (soundness) and good damping capacity. It is also readily welded via a gas shielded arc using welding rods of the same alloy.

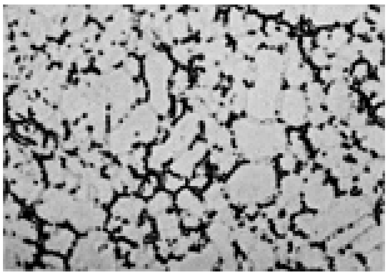

Fig. 19 Photomicrograph of the ZA91A-F die casting alloy, Mg-9Al-0.13Mn-0.7Zn, showing the particles of $Mg_{17}Al_{12}$ at the boundaries of small, cored grains. Segregation (coring) in the grains and absence of precipitated discontinuous $Mg_{17}Al_{12}$ are results of the rapid cooling rate of die castings. 500×

Increased creep resistance is available with the alloy HK31A (Mg-3Th-0.7Zr), which is available as either a casting or as a wrought alloy. The alloying elements provide particles to pin and restrict the sliding and migration of grain boundaries at elevated temperatures, which help retain usable strength up to 315 to 345 °C (600 to 650 °F). As a sheet and plate alloy, HK31A also has good formability and weldability. The alloy ZK60A, containing 5.5Zn-0.45Zr, offers still higher strength and good ductility. This alloy is hot worked at 315 to 400 °C (600 to 752 °F) and can be age hardened at 150 to 200 °C (302 to 392 °F). Although the solidus and liquidus for this alloy are 520 and 635 °C (968 and 1175 °F), respectively, the as-cast condition is susceptible to hot shortness as low as 315 °C (600 °F); the wrought product experiences hot shortness at 510 °C (950 °F).

AZ31B, containing Mg-3Al-1Zn, is a widely used sheet and plate alloy, which offers moderate strength with good ductility and formability. In the annealed (O) condition it offers a yield strength of 150 MPa (22 ksi), a tensile strength of 255 MPa (37 ksi), and 21% elongation. In the rolled/relief annealed temper (H24) this alloy shows tensile properties of 220 MPa (32 ksi) yield strength, 290 MPa (42 ksi) tensile strength, and 15% elongation. The fine, elongated grain morphology seen in the warm-worked microstructure is illustrated in Fig. 20. The alloy can be used up to 100 °C (212 °F) in either temper. The alloying additions lower electrical conductivity (18.6% IACS) and thermal conductivity (96 W/m · K) while providing solution hardening. The good formability is obtainable through hot working at 230 to 425 °C (450 to 800 °F). As little as 15% cold deformation will be recrystallized by a 1 h exposure to 205 °C (400 °F). As noted previously, still higher strength is available with higher aluminum content, such as in the wrought alloy AZ61A. This alloy is capable of being used up to 200 °C (392 °F) and is readily hot worked at 230 to 400 °C (446 to 752 °F). However, it is also hot short at 415 °C (780 °F), a temperature significantly below its solidus, 525 °C (977 °F). The strength level obtainable and the difference in tensile and compressive yield strength seen with this type of alloy are indicated by the tensile properties obtainable with processed sheet: 305 MPa (44 ksi) tensile strength, 220 MPa (32 ksi) tensile yield strength, 8% elongation, and 150 MPa (22 ksi) compressive yield strength.

Fig. 20 Photomicrograph of the longitudinal edge view of worked sheet of the magnesium alloy AZ31B-H24 (Mg-3Al-1Zn), showing fine, elongated grains resulting from warm working of this sheet material. 250×

Alloys with very low density and good formability have been made by adding lithium to magnesium. LA141A, for example, has sufficient levels of lithium (14%, or 36 at.%) to put the alloy into the bcc-lithium phase field. Experimental alloys containing Mg-37.6Li-5Al have been made with a density of 0.95 g/cm^3 (0.034 lb/in.^{3}), a value lower than that of water. This level of lithium in magnesium is well within the single bcc-lithium phase field and has a moderately low solidus, (340 °C, or 644 °F), and liquidus (425 °C, or 797 °F).

Effects of Composition, Processing, and Structure on Properties of Nonferrous Alloys

Ronald N. Caron, Olin Corporation; James T. Staley, Alcoa Technical Center

Beryllium and Beryllium Alloys

Because of its unusual combination of physical and chemical properties, beryllium finds its way into unique structural applications when its relatively high cost can be justified (Ref 18, 44, 45). It has a very low density (1.848 g/cm^3, or 0.067 lb/in.^{3}), a moderately high melting point (1290 °C, or 2341 °F), and a high elastic modulus (303 GPa, or 44 × 10^6 psi). It has good electrical conductivity (40% IACS) and thermal conductivity (190 W/m · K, or 109 Btu/ft · h · F). Beryllium is an important alloying element in copper and nickel to produce commercially important age-hardening alloys that are used in electrical contacts, springs, spot welding electrodes, and nonsparking tools. It is also added to aluminum and magnesium for grain refinement and oxidation resistance.

While it can be melted and cast, the resulting casting has coarse grains (>100 μm) that are difficult to process and attempts to refine them by alloying have been unsuccessful. The fine grain size is produced primarily by P/M techniques, from which it inherits the fine grain size (5 to 15 μm) from the powder processing. Powder consolidation is done by vacuum hot pressing and has also been done by the hot or cold isostatic pressing methods in argon atmosphere. It shows only modest ductility ($\leq$3% tensile elongation) at room temperature, which is attributed to a large covalent component in its atomic bonding in the *c*-axis direction and to its hcp crystal structure, which is limited at room temperature to only one slip direction on two crystal planes, basal and prism. This low ductility is not improved even when impurities are reduced to levels as low as $\approx$10 ppm. However, beryllium does show improved ductility at temperatures above 200 to 250 °C (392 to 482 °F), where more crystal deformation modes are available. At 400 °C (752 °F), for example, it shows a tensile elongation as high as 50%. Beryllium transforms to a bcc phase at 1270 °C (2318 °F), only 13 °C below the melting point.

Beryllium is flat rolled, extruded into shapes, and forged at elevated temperatures. It is worked warm; the handbooks suggest a temperature range 800 to 1100 °C (1470 to 2110 °F) for hot working. Beryllium is commercially available as tube shapes and as plate, sheet, and foil in thickness ranging from 0.013 to 15.2 mm (0.0005 to 0.6 in.). Recrystallization annealing is done at 725 to 900 °C (1340 to 1650 °F). As with other hcp metals, beryllium displays anisotropic mechanical properties in wrought forms because of crystallographic texture and grain morphology. The traditional ball-

milling method of making powder produces flat, crystallographically oriented powder particles that naturally leads to a crystallographic texture in the initial pressing stage. Newer powder preparation techniques, involving impact-grinding or atomization methods, produce a more equiaxed product, avoiding the oriented flat powders produced by ball milling and reducing the amount of crystallographic texture during the initial consolidation operation. Even so, care is taken to fabricate beryllium with a fine grain and as random a crystallographic orientation as possible. The room-temperature tensile properties of cross-rolled sheet are 345 to 414 MPa (50 to 60 ksi) yield strength, 483 to 621 MPa (70 to 90 ksi) tensile strength, 10 to 40% elongation. Both the tensile and the yield strength have been shown to obey the Hall-Petch relationship between yield strength and grain size.

Beryllium forms a thin protective oxide (BeO) coating that provides good corrosion resistance to the atmosphere at room temperature and giving it excellent resistance to pure water up to 300 °C (570 °F). However, corrosion resistance is impaired by impurities. The presence of carbides or chlorides, in particular, can cause a reaction with moist air at room temperature. Above 760 °C (1400 °F), beryllium reacts with oxygen and nitrogen, but not at all with hydrogen at any temperature. It is attacked by many dilute common acids at room temperature. It can be anodized or chromate coated for improved corrosion resistance. Beryllium shows the machining characteristics of cast iron when the required carbide tools are used. It is commonly brazed and adhesive bonded and with care can be welded.

Unalloyed beryllium is used in weapons, spacecraft, rocket nozzles, structural tubing, optical components, and precision instruments. The specific modulus, that is the ratio of elastic modulus to density, is higher than that of aluminum, magnesium, or titanium. The high specific modulus and the low thermal expansion translates into good physical stability and low distortion during inertial or thermal stressing, making beryllium useful for critical aerospace components. Its exceptionally good dimensional stability and its ability to reflect infrared radiation makes beryllium highly suited for mirrors, either as polished or as a plated substrate. The near transparency of beryllium to x-rays and other high-energy electromagnetic radiation is responsible for its widespread use in foil gage as windows in x-ray tubes and radiation-detection devices.

Beryllium Structural Materials

Commercially available grades of beryllium are distinguished by impurity levels and BeO content. The metal, in fact, normally contains 0.7 to 4.25% of BeO, which is unavoidable and increases with the fineness of the beryllium powder used in the consolidation process. It has extremely low solubility for oxygen and readily forms oxide particles that are situated at grain boundaries, which help to control grain growth without being harmful to ductility below 1.2% BeO. Of the structural grades, indicated by the S in the designation, S-65B, with 99.0% min Be and 0.7% BeO, offers the most ductility at room temperature: 207 MPa (30 ksi) yield strength, 290 MPa (42 ksi) tensile strength, and 3% min elongation. Grade S-200F, with 98.5% min Be and 1.5% BeO is stronger, but less ductile, at room temperature: 240 MPa (35 ksi) yield strength, 325 MPa (47 ksi) tensile strength, and 2.0% elongation. This grade has usable strength and modulus up to 600 to 650 °C (1110 to 1200 °F), at which temperature the tensile properties are: 100 MPa (15 ksi) yield strength, 130 MPa (19 ksi) tensile strength, and 10% elongation.

Beryllium is almost too reactive to accept alloying elements; it reacts to form stable compounds with most of the other common metals. While beryllium shows some solid solubility for copper, iron, nickel, cobalt, palladium, platinum, gold, and to a lesser extent, <1.0%, for chromium and cerium, compounds formed with these metals tend to cause embrittlement. For example, the inherent impurity levels of iron and aluminum in commercial beryllium have been singled out as being particularly harmful to ductility: iron either in solid solution or as $FeBe_{11}$ particles causes embrittlement, and aluminum segregated to grain boundaries leads to hot shortness. These two elements are controlled through the appropriate processing to form discrete grain-boundary precipitates of $AlFeBe_4$.

Beryllium is mutually insoluble with and forms binary eutectic phase diagrams with silicon and aluminum. Alloys in each of these systems have recently been developed to take advantage of the properties made available by creating intimate mixtures of the respective two metals. One of these alloys, for example, is cast at the eutectic composition, Be-46Si, and contains a mixture of beryllium and silicon grains to provide a material with thermal expansion characteristics that are useful for mirror substrate application. Be-(38-50)Al alloys can be made by rapid-solidification techniques, using liquid metastable miscibility gap to separate Al + Be liquid phases into a fine, interconnected morphology after solidification. The structural properties obtainable are determined by rule-of-mixtures of the two metals and combine the ductility of aluminum (and potential for age hardening) with the strength, stiffness, and low density of beryllium (Ref 46).

Inhalation of respirable beryllium and its compounds should be avoided. Users should comply with occupational safety and health standards applicable to beryllium in Title 29, Part 1910, Code of Federal Regulations.

Refractory Metals and Alloys

The refractory metals and their alloys have been so named for their heat resistance because of their characteristic high melting points, good elevated-temperature strength and mechanical stability, and good resistance to softening. They also have high densities, low vapor pressure, and relatively low thermal expansion coefficients compared to the other common structural metals and alloys (Ref 47). The unique physical properties available with the refractory metals are compared to those of iron, aluminum, and copper in Table 20. It is natural to find the refractory metals in elevated-temperature applications. While these metals generally have high chemical reactivity and oxidation tendencies, some of these metals (tantalum and niobium) show exceptionally good resistance to certain corrosion environments, making them uniquely suitable for containing and protecting against particular corrosive media in the petrochemical and aerospace industries.

Table 20 Properties of the refractory metals compared to those of iron, copper, and aluminum

Metal	Crystal structure	Specific gravity	Melting point		Elastic modulus		Thermal expansion coefficient at room temperature	
			°C	**°F**	**GPa**	**10^6 psi**	**ppm/°C**	**ppm/°F**
Refractory metals								
Niobium	bcc	8.57	2468	4474	102	15	7.3	4.1
Tantalum	bcc	16.6	2996	5425	186	27	6.5	3.6
Molybdenum	bcc	10.2	2610	4730	324	47	4.9	2.7

Rhenium	hcp	21.0	3180	5755	460	67	6.7	3.7

Metals for comparison								
Iron	bcc	7.87	1538	2798	208	30	11.8	6.5
Copper	fcc	8.93	1085	1981	115	17	16.5	9.2
Aluminum	fcc	2.70	660	1220	62	9	23.6	13.1

Compared to aluminum and copper, the refractory alloys are generally difficult to cast and to process at either room or elevated temperatures because of their high melting temperatures and sensitivity to impurities. Besides requiring high processing temperatures, the refractory metals generally require protection from oxygen. These bcc crystal structure alloys show DBTTs at and above room temperature. Moreover, ductility is sensitive to the presence of impurity elements segregated to recrystallized grain boundaries. However, these materials are being fabricated into useful forms by good control of composition and processing parameters.

Niobium and its Alloys

Niobium (Nb), formerly called columbium (Cb) in the United States, has a lower density (8.57 g/cm^3, or 0.310 lb/in.^{3}), a lower melting point (2468 °C, or 4474 °F) and a lower modulus of elasticity (102 GPa, or 15 × 10^6 psi) than the other refractory metals. Most of the production of niobium is used as an alloying element in steels and nickel alloys; only about 6% of its annual use is made into niobium and niobium alloy mill products. Niobium and its alloys can be made by P/M techniques, but are usually made by consumable electrode vacuum arc melting and electron beam melting ingot techniques.

After careful surface preparation to remove defects, the materials are hot worked at 800 to 1200 °C (1470 to 2190 °F) and cold worked and formed at 200 to 300 °C (390 to 570 °F). The alloys of niobium are recrystallized at 1000 to 1300 °C (1830 to 2370 °F) and stress relieved at 900 to 1000 °C (1650 to 1830 °F), in vacuum or inert atmospheres. With good control of impurity elements and processing variables, niobium can be hot worked and exhibits excellent cold-working characteristics at room temperature in either the stress relieved or the recrystallized conditions. Tight control of impurities must be maintained during manufacture of niobium and its alloys to guarantee processing capability. Contamination by interstitial impurity elements impairs room-temperature ductility. The DBTT of this bcc material is comfortably below room temperature (-125 °C, or -195 °F) for the pure metal, but the DBTT increases with higher impurity content. Because of its high fabricability, niobium is commercially available in plate, sheet, wire, and tube forms. Owing to its adherent oxide, niobium is highly resistant to corrosion in most aqueous media and to liquid metal systems (lithium and sodium-potassium alloys) up to 1000 °C (1830 °F). Niobium and its alloys are gas tungsten arc weldable provided that great care is taken to clean the surface before and after welding and to shield the metal from the atmosphere.

Niobium offers reasonably good strength at elevated temperatures, but must be protected against hydrogen, nitrogen, and oxygen pickup during manufacture and in service. The oxides, nitrides, and hydrides formed with niobium by these gaseous elements are detrimental to ductility. Niobium has a high solubility for oxygen and absorbs it internally from the surface oxide that readily forms at temperatures above about 400 °C (752 °F). It will absorb hydrogen in the temperature range 250 to 950 °C (480 to 1740 °F), and it readily forms an embrittling hydride at 500 to 600 °C (932 to 1110 °F). Formation of hydride precipitates is in fact deliberately used to embrittle niobium to facilitate the grinding steps used in commercial powder preparation. Niobium and its alloys are protected from these atmospheric gases by melting and casting in vacuum, or by processing in sacrificial metallic containers made of molybdenum. Low levels of zirconium and yttrium are added as alloying elements to tie up oxygen internally as oxide particles to promote better ductility. It is not uncommon to see ZrO_2 particles scattered about the microstructure. Before placing niobium products in service, they can be protectively coated with aluminide or silicide compounds, such as hafnium-silicide, or applied as a mixture of Si-20Cr-20Fe.

Unalloyed niobium is basically soft and malleable. It can withstand extremely high amounts of cold working between anneals (whether stress relieving or recrystallizing). Unalloyed niobium recrystallizes at 1090 °C (2000 °F) for 70 to 80% cold working, but it can recrystallize at temperatures as low as 815 °C (1500 °F). Obtaining a uniform, fine recrystallized grain requires the proper balance between the degree and type of work and the temperature/time parameters of the anneal.

The specification limits for the trouble-some impurity elements set for good commercial quality niobium are 100, 200, 100, and 15 ppm max for each of carbon, oxygen, nitrogen, and hydrogen, respectively. Carbon is kept low (below 0.072%) to avoid poor ductility caused by niobium carbide formation at grain boundaries and within grains. Niobium has usable strength at 1000 to 1200 °C (1830 to 2190 °F), but the environment and mechanical loading will dictate whether and how it can be designed into the application.

The alloy Nb-1Zr, one of the first commercially available, was developed for the nuclear industry to take advantage of its low thermal nuclear capture cross section and improved creep strength over unalloyed niobium. The alloy can be used over the temperature range 980 to 1200 °C (1800 to 2200 °F). It has excellent machinability (80% on a scale where free-machining brass is defined as 100%).

Niobium shares complete solid solubility with each of tantalum, tungsten, vanadium, and molybdenum, and it is capable of dissolving significant amounts of hafnium and titanium as well as zirconium. The solubility of zirconium in niobium is complete above 970 °C (1778 °F), but it drops with temperature from the 9% value at the monotectoid reaction at 620 °C (1148 °F). Higher strength and higher application temperatures are available with significant additions of these solution-hardening elements. Tantalum, vanadium, and titanium increase ductility along with the higher strength by tying up oxygen as dispersoids of oxide particles. Alloy C103 is one such solution-hardening composition containing Nb-10Hf-1Ti. It offers higher strength and higher application temperature range, making it useful for aerospace applications, especially in rocket propulsion systems, such as rocket nozzles. The microstructure utilizes oxide particles of the alloying elements for grain size control and dispersion strengthening in an otherwise solid-solution matrix. C103 alloy is easily fabricated into sheet and rod products, and it can be welded with the proper precautions. Its service temperature range is 980 to 1315 °C (1800 to 2400 °F).

The more heavily alloyed C129Y, which contains Nb-10W-10Hf-0.1Y, 0.5 Ta max, 0.5 Zr max and can be solution annealed (at 1850 °C, or 3362 °F) and aged (at about 1200 °C, or 2190 °F, for 1 h) to form dispersoids of hafnium, zirconium, or yttrium oxides. While this alloy is somewhat more difficult to fabricate and weld than unalloyed niobium and alloy C103, it offers higher strength and extends the service temperature range of niobium to 1650 °C (3000 °F) (Table 21).

Table 21 Typical tensile properties of selected niobium alloys in the annealed condition

Alloy	Test temperature	Tensile strength		Yield strength		Elongation, %
		MPa	**ksi**	**MPa**	**ksi**	
Unalloyed niobium	Room temperature	207	30	103	15	35
	1093 °C (2000 °F)	45	6	. . .	. . .	. . .
Nb-1Zr	Room temperature	240	35	138	20	20
	1093 °C (2000 °F)	138	20	69	10	40
C-103 (10Hf-1Ti)	Room temperature	414	60	310	45	25
	1093 °C (2000 °F)	207	30	138	20	40
C-129Y (10W-10Hf-0.1Y)	Room temperature	586	85	448	65	25

Alloy Cb-752, containing Nb-10W-2.5Zr, also offers higher strength and modulus of elasticity. It is given an aging treatment to precipitate compounds of zirconium with interstitial impurity elements. There are a number of other commercial niobium alloys available that combine a dispersion of ZrO_2 particles in a solution-hardened matrix, namely, FS-48 (Nb-15W-5Mo-1Zr), FS-82 (Nb-33Ta-1Zr), FS-85 (Nb-28Ta-10W-1Zr), and B-66 (Nb-5Mo-5V-1Zr). A series of niobium alloys that use carbide precipitation for increased strength and creep resistance include D43 (Nb-10W-1Zr-0.1C), D31 (Nb-10Mo-10Ti-0.1C), and C3015 (Nb-29Hf-14.5W-2Ta-1.5Zr-0.5Ti-0.2C). The processing temperatures are high. Alloy D43, for example, is solution treated at 1649 °C (3000 °F) and aged at 1316 °C (2400 °F). Still other alloys have been made with TiO_2 dispersoids in niobium using P/M techniques. The alloy Nb-(45-55)Ti is a metal superconductor at low temperatures. It is readily fabricated into fine wires, but it needs to be quenched from elevated temperatures to avoid the titanium β-α phase transformation.

Tantalum and Its Alloys

Tantalum melts at 2996 °C (5425 °F) and has a density of 16.6 g/cm^3 (0.60 lb/in.^{3}). Its excellent cold fabricability is unique among the refractory metals. Tantalum has an extremely low DBTT for a bcc metal, falling as low as -260 °C (-452 °F) for the fully annealed condition and not seen with the cold-worked temper. About 25% of annual production appears as mill products in the form of plate/sheet, rod/bar, and tube. Because of its relatively good thermal conductivity and its remarkably good corrosion resistance to many industrial chemicals and body fluids, tantalum mill products are used in the chemical process industry as heat exchangers and tank liners as well as for prosthetic devices. It is clad to copper, or aluminum, or steel to take advantage of the combination of properties available with a composite, including lower cost. In elevated-temperature service, tantalum and its alloys are used in various aerospace applications and in heating elements in vacuum furnaces to take advantage of the good forming and welding capability as well as its good elevated-temperature strength. Its high density and excellent formability are called upon for shape-charge liner components of armor penetrators. About 50% of annual tantalum production is used in the electronics industry as capacitors to take advantage of the uniquely high value and temperature stability (over the range -55 to 125 °C, or -67 to 257 °F) of the dielectric constant of its oxide.

The tough, impermeable nature of the natural oxide film on tantalum is responsible for its excellent corrosion resistance to nitric, hydrochloric, bromic, and sulfuric acids. It is also resistant to the liquid metals bismuth, lead, lithium, magnesium, mercury, potassium, sodium, and sodium-potassium alloys. However, when exposed to air or an oxidizing atmosphere above 260 °C (500 °F) tantalum readily oxidizes and must be protected during processing and while in service above this temperature. Moreover, as with the other refractory metals, the properties are sensitive to impurity levels of carbon, oxygen, nitrogen, and hydrogen. When these elements exceed specified minima (100 to 200 ppm O, 50 to 75 C, 50 to 75 N, and 10 H) oxides, carbides, nitrides, and hydrides are formed, raising the strength and lowering ductility.

Tantalum is consolidated and refined in electron beam furnaces and in vacuum arc remelting furnaces, with some products made using P/M methods. Its excellent ductility and low work-hardening coefficient make tantalum and its alloys readily cold processible, permitting cold reductions of 75% or higher between intermediate process annealing steps. Tantalum and its alloys are rolled at 260 to 370 °C (500 to 700 °F) to take advantage of the increased plasticity made manifest by the more rapid dropoff in yield strength relative to the tensile strength at temperatures above 50 °C (122 °F). Recrystallization annealing of tantalum is done at temperatures in the range 1200 to 1400 °C (2200 to 2550 °F), in vacuum or inert atmospheres. Tantalum is weldable by gas tungsten arc or metal arc methods as well as by resistance and electron beam techniques, provided that good protection from the atmosphere is used. It has been successfully brazed with silver, copper, and specially designed refractory metal alloys. Tantalum has good machining and stamping characteristics, matching that of copper, but tantalum tends to gall and to smear processing tools.

The high-purity, unalloyed tantalum products are made using electron beam melting (UNS R05200) or sintered P/M products (UNS R05400). Tantalum has mechanical properties and forming characteristics similar to low-carbon steel, with a lower elastic modulus (186 GPa, or 26×10^6 psi). The room-temperature annealed tensile strength of 210 to 390 MPa (30 to 55 ksi) can reach 1400 MPa (200 ksi) with work hardening. While it has good elevated-temperature stability, tantalum must be alloyed to improve its low strength at elevated temperatures.

The doped tantalum alloys contain small additions (<100 ppm) of yttria, thoria, silicon, or yttrium, that provide fine particles to resist grain growth at elevated temperature. They are used for capacitor lead wires, electronic filaments and supports, and furnace parts.

Tantalum shows complete solid solubility for tungsten, niobium, and molybdenum and rather extensive solubility for hafnium, zirconium, rhenium, and vanadium, giving a wide choice of alloying elements available for solution hardening of the base metal. Ta-2.5W (63 Metal), for example, is used in heat exchangers and in welded-tube applications requiring high formability. The tungsten addition adds solid-solution hardening, increasing the room-temperature tensile strength by about 25%, or by 35 to 70 MPa (5 to 10 ksi), but doubling the elevated-temperature yield strength at 200 °C (390 °F) over that of unalloyed tantalum. At 1000 °C (1830 °F), this alloy has tensile properties of 69 MPa (10 ksi) yield strength, 124 MPa (18 ksi) tensile strength, and 20% elongation. The alloy Ta-10W (UNS R05255) offers still higher room-temperature tensile strength (482 MPa, or 70 ksi, min) and a higher elastic modulus (207 GPa, or 30 × 10^6 psi) than unalloyed tantalum. This alloy is used in aerospace applications and can be used at temperatures up to 2480 °C (4500 °F).

Still other tantalum alloys are available that combine solution-hardening elements, such as alloy T-111, containing 8W-2Hf, and alloy T-222, containing 10W-2.5Hf-0.01C. In addition, the solid-solution alloy Ta-40Nb is regarded as an inexpensive substitute for alloys richer in tantalum. This solution-hardened alloy combines the tensile strength of Ta-2.5W with a lower density (12.1 g/cm^3, or 0.437 lb/$in.^3$) and elastic modulus (152 GPa, or 22 × 10^6 psi), falling proportionally between the values of the pure metals, as one would expect for a solid solution.

Molybdenum and Its Alloys

Molybdenum has a density of 10.22 g/cm^3 (0.369 lb/$in.^3$) and a melting point of 2610 °C (4730 °F). Much of its annual production is used as alloying additions in other metal systems. Less than 5% of annual production is in the form of molybdenum mill products. The element has a bcc crystal structure and has a rather inconvenient DBTT of 7 °C (45 °F) even for extremely high-purity material (1 at. ppm impurity level). Molybdenum offers a rather high strength at elevated temperatures, a high elastic modulus (324 GPa, or 47 × 10^6 psi), a low coefficient of thermal expansion, a low vapor pressure at elevated temperatures, and good fabricability above the DBTT. It has a reasonably good thermal and electrical conductivity at room temperature (31% IACS). A large market for molybdenum is electronics, where the material, in monolithic form or as clad with copper or nickel, is used as heat sinks for silicon devices and packaging components, taking advantage of its good thermal conductivity and close thermal expansion match to silicon.

Molybdenum is extremely sensitive to impurities at grain boundaries and exhibits intergranular fractures when in the fully recrystallized condition. It is processed as a P/M product or starting from arc-melting processes. Molybdenum is cold worked at elevated temperatures below the recrystallization temperature (about 1010 °C, or 1850 °F) and can be processed to foil gages (0.012 mm, or 0.0005 in.) with interpass process anneals done at stress-relieving (recovery) temperatures. Molybdenum is generally commercially available in the worked/stress-relief-annealed condition. The microstructure of wrought molybdenum products consists of elongated, interlocked cold-worked grains, a structure that exhibits a DBTT of -20 to 40 °C (-4 to 104 °F) and directional mechanical properties. For example, molybdenum sheet can be readily bent in the direction of rolling, but it is difficult to make a bend at 90° to the rolling direction because of the alignment of the worked, interlocked boundaries aligned in the rolling or process direction. Deep-drawing quality is cross rolled to reduce the sheet anisotropy. Should the wrought/stress-relief-annealed product be heated above its recrystallization temperature in service, the DBTT rises to 40 to 80 °C (100 to 175 °F), making the metal brittle when cooled to room temperature.

When heated in atmospheres containing oxygen above 425 °C (800 °F), molybdenum forms a volatile, external oxide, MoO_3, that appears as a white odorless smoke, necessitating the use of protective coatings for applications above 500 °C (932 °F) to avoid undesirable thinning of the metal. Because of the extremely low solubility of oxygen in molybdenum, oxygen does not diffuse into molybdenum as it does in niobium. Molybdenum is inert to hydrogen, carbon dioxide (below 1205 °C, or 2200 °F), and ammonia gases, but molybdenum will readily react with ceramics, carbon, hydrocarbons, graphite, and silicon carbide. Molybdenum does not react with Al_2O_3 up to 1705 °C (3100 °F), making the latter the refractory of choice where one is needed in proximity to molybdenum in vacuum and inert atmospheres. Molybdenum is resistant to mineral acids without oxidizing agents and is resistant to liquid lithium, sodium, potassium, sodium-potassium, magnesium, and bismuth, but it is not resistant to molten tin, aluminum, iron, or cobalt.

For structural applications, molybdenum is limited to about 1650 °C (3000 °F). The tensile strength of molybdenum at 1205 °C (2200 °F) is about 96 MPa (14 ksi). Its high thermal conductivity and low thermal-expansion characteristics make it resistive to cracking on quenching and less susceptible to distortion in service, making molybdenum suitable for use as furnace resistance elements and heat-treating baskets. Taking advantage of its ability to resist elevated-temperature corrosion and abrasive conditions, molybdenum and its alloys are used for tools and dies for elevated-temperature processing of other metals. The low vapor pressure and structural stability at elevated temperatures make molybdenum suitable for elevated-temperature structural components in vacuum applications up to 1200 to 1300 °C (2190 to 2370 °F).

Molybdenum is weldable, but success depends on recognizing the need for protection from the atmosphere and that the weld zone will be brittle because of its coarse grain.

Limited in number, the alloys of molybdenum deliver higher elevated-temperature strength and creep resistance than unalloyed molybdenum. They are typically made using P/M techniques. Because the recrystallization temperature effectively places the upper temperature limit of wrought molybdenum at about 1010 °C (1850 °F), the HT grade of molybdenum uses nonmetallic elements at dopant levels to stabilize the interlocked wrought microstructure to above 1480 °C (2700 °F). An additional benefit is that the DBTT is below room temperature (-70 to -40 °C, or -94 to -40 °F) for either the wrought annealed or the recrystallized condition. These doped alloys require highly worked structures (>95% reduction in area) with the work being done in a single direction to develop optimal properties. Also processed this way are several oxide-doped alloys, such as TEM (Mo-0.2La_2O_3), MLR (Mo-0.7La_2O_3), and Z-6 (Mo-0.2ZrO_2).

TZM, Mo-0.5Ti-0.1Zr-0.03C (UNS R03630, arc cast, and UNS R03640, P/M product) is the most common commercial alloy and offers high-temperature stability and strength owing to its high recrystallization temperature of 1370 °C (2500 °F). However, it too is embrittled when recrystallized in service. The higher strength and creep resistance make this alloy suitable for heat engines, heat exchangers, nuclear reactors, radiation shields, and extrusion dies.

The three commercial alloys--TZC (Mo-1Ti-0.3Zr-0.15C), MHC (Mo-1.2Hf-0.05C), and ZHM (Mo-0.4Zr-1.2Hf-0.12C)--are carbide-strengthened alloys like TZM, but with richer alloy additions to develop greater strength at temperature and increased resistance to recrystallization. The Mo-30W alloy, available in arc-cast and P/M grades, is used specifically for tooling and components handling molten zinc. Finally, there are several molybdenum-rhenium alloys available (25, 41, 47.5% Re) where rhenium is added to improve the DBTT behavior and as a potent strengthener, greatly increasing the work-hardening rate of molybdenum.

Tungsten and Its Alloys

The key characteristics and properties of tungsten are its high melting point (3410 °C, or 6170 °F), high stability (strength and softening resistance, low vapor pressure) at elevated temperatures, high elastic modulus (400 GPa, or 58×10^6 psi), good electrical and thermal conductivity, and a high density (19.2 g/cm^3, or 0.697 lb/in.^{3}). The metal suffers from brittleness and notch sensitivity, with a DBTT falling above room temperature (150 to 300 °C, or 302 to 572 °F, for annealed unalloyed tungsten). As seen with the other refractory metals, tungsten is sensitive to impurity elements segregated to recrystallized grain boundaries (especially the interstitial elements oxygen, carbon, and phosphorus). Tungsten alloys are used in radiation shields, as counterweights and inertial weights, kinetic energy penetrators, heavy-duty electrical contacts, and targets for x-ray tubes. Its low thermal expansion coefficient is compatible with glasses over a broader temperature range than seen with iron-nickel Invar alloys, for example, making tungsten suitable as a glass-sealing material. Tungsten can be used at temperatures as high as 2500 °C (4530 °F).

About 25% of the annual production of tungsten is made into mill products; another 60% is used in cutting tools in the form of tungsten carbide. Tungsten is manufactured primarily by P/M techniques using powders in sizes ranging 1 to 10 μm (39 to 390 μin.) made from hydrogen-reduced tungsten oxide. Relatively thick-walled products are made by chemical vapor deposition (CVD) techniques by reacting WF_6 with H_2. Proper control of the process can produce fine equiaxed grains instead of the coarse columnar grain structure that is naturally favored by CVD.

Basic commercial processing involves extrusion and forging with rolling and drawing used as follow-up for making the finish forms. The alloys are "warm" worked at about 1200 °C (2190 °F), that is, at temperatures above the DBTT (about 300 °C, or 572 °F, for unalloyed tungsten) and below the recrystallization temperature (about 1370 °C, or 2500 °F) in order to avoid embrittlement caused by the crack sensitivity of recrystallized grain boundaries. Processing sequences of warm working at temperatures above about 650 °C (1200 °F) with interpass softening anneals (recovered, not recrystallized) intentionally develops a microstructure with elongated, cold-worked grains, with interlocked boundaries and with a recovered dislocation substructure, providing alternate, less-embrittling sites for interstitial impurity segregation. In this condition the material can be further worked or can be used in applications requiring hardness and strength at moderate, subrecrystallization temperatures. Such a cold-worked structure exhibits property anisotropy in sheet form. For higher-temperature use, the more stable, recrystallized grain structure needed to provide creep resistance and mechanical stability is obtained by alloy-doping techniques.

Tungsten has a low resistance to oxidation at temperatures greater than 1120 °C (2050 °F), primarily because of cracking in the oxide layer allowing further oxide penetration; it must be protected against oxidation during fabrication and use. It is common to process within a protective container or cladding made of a sacrificial alloy (molybdenum, niobium,

stainless steel cans, etc.). Tungsten does not react with H_2, N_2, or NH_3; it will not form an embrittling hydride. Tungsten also resists attack from liquid metals:mercury, potassium, sodium-potassium, magnesium, bismuth, and zinc; however, it is attacked by aluminum. While tungsten is designed for use at elevated temperatures, care needs be taken to retain ductility at room temperature. Residual stresses must be avoided during manufacture, even while applying the frequently needed stress-relief annealing treatments. While tungsten is machinable, it must be kept cool during grinding operations to avoid cracking due to residual stresses.

In unalloyed tungsten, with low impurity content (99.95% pure), cold working lowers the DBTT to below room temperature. Notch sensitivity is lower with a retained cold-worked structure, with increasing grain size up to 1 mm (0.039 in.), with even lower impurity content, and with even very low porosity inherited from incomplete sintering. But, unalloyed tungsten can show progressive grain growth with heating in applications such as heating elements for vacuum furnaces. Worked sheet can show tensile strengths of 965 to 1720 MPa (140 to 250 ksi) at room temperature and 21 MPa (3 ksi) at 2000 °C (3630 °F). Drawn fine wire can reach tensile strengths as high as 5860 MPa (850 ksi).

The doped tungsten alloys, or AKS alloys, are made by adding aluminum, potassium, and silicon compounds at dopant levels to the tungsten powder before pressing. During the sintering treatment at about 3000 °C (5430 °F) in hydrogen, the oxides are reduced and the dopants volatilized. Potassium, in particular, at residual levels of about 85 wt ppm (400 at. ppm) is entrapped in stringers of nanometer size bubbles that become aligned along grain boundaries, creating jagged boundaries during grain growth during in-process recrystallization anneals (Fig. 21). The resulting interlocking of recrystallized grain boundaries promotes good creep resistance, providing a more stable structure that shows less deflection and distortion during repeated heating cycles at high temperatures, making them suitable for common electric lamp filaments that can reach temperatures as high as 2500 °C (4530 °F) in service.

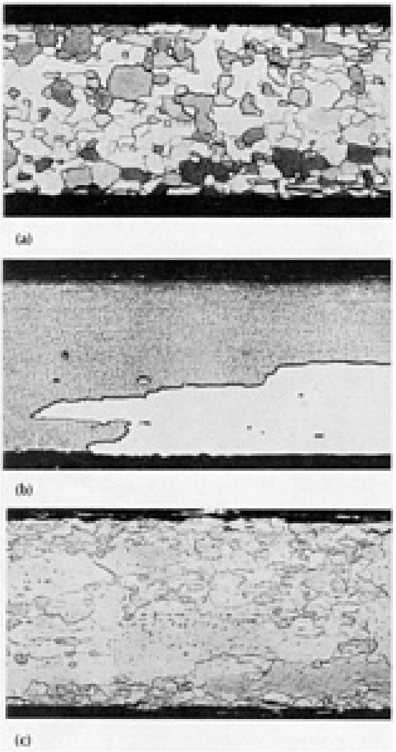

Fig. 21 Photomicrographs comparing (a) the fully recrystallized, equiaxed grains in undoped tungsten wire to (b) the "interlocked" recrystallized grain structure of doped tungsten wire and to (c) the recrystallized structure of mixed grain size due to ThO_2 particles (black dots) in thoriated tungsten wire. Wire diam., 0.2 mm (0.007 in.); annealed at 2700 °C (4890 °F) for 5 min. 200×

Thoriated or zirconiated tungsten alloys have been made by adding thorium or zirconium to form 1 or 2% of their respective oxide particles (ThO_2 and ZrO_2), which contribute dispersion hardening and grain-growth restraint at elevated temperatures (Fig. 21). These alloys are more machinable than unalloyed tungsten and are suitable for electronic filament and heater wire applications, as well as for gas tungsten arc welding electrodes. The alloy W-3.6Re-1ThO_2 combines

solution hardening (rhenium) with dispersion hardening (ThO_2) for imparting even higher strength at higher temperatures. Some manufacturers have replaced thoria with rare earth oxides such as lanthana, yttria, and so forth.

The tungsten-rhenium and tungsten-molybdenum alloys are important solid-solution alloys that provide more ductility and fabricability than unalloyed tungsten. They also exhibit higher recrystallization temperatures and low DBTT temperatures. While they work harden more rapidly, they also exhibit lower strength than unalloyed tungsten, explained by the phenomenon of "solution softening." Alloys commercially developed for optimal properties are W-25Re, and W-25Re(or 30Re)-30 at.% Mo.

The heavy-metal tungsten alloys, also called composite alloys, comprise a high volume fraction (about 85 vol%) of hard/strong, spheroidal tungsten grains in a continuous matrix of a ductile/tough nickel-base solid-solution alloy, nickel-copper, nickel-iron, or nickel-cobalt (Fig. 22). These alloys are made by powder metallurgy techniques starting with about 80 to 98% W powder and the remainder nickel alloy powder. These alloys are sintered at 1480 °C (2700 °F), that is, at temperatures above the melting point of the nickel alloy ("liquid metal sintering"), keeping to a minimum both residual porosity and any continuity of tungsten grains for improved ductility. Cracks can initiate at tungsten-tungsten grain interfaces with as little as 3 to 5% strain. During sintering, tungsten diffuses into the nickel phase where it provides added solution hardening. The strength and ductility are dependent on the strength of the nickel-alloy matrix. The alloys are annealed in vacuum or inert atmosphere, followed by rapid cooling to retain impurities in solution, to minimize impurity segregation to boundaries, and to minimize intermetallic phase precipitation. In the commercial W-Ni-Fe alloys the nickel/iron ratio is controlled to optimize mechanical properties by avoiding μ-phase (Fe_7W_6) seen with nickel/iron ratios less than 1 and Ni_4W precipitates seen with nickel/iron ratios greater than 4 to 1.

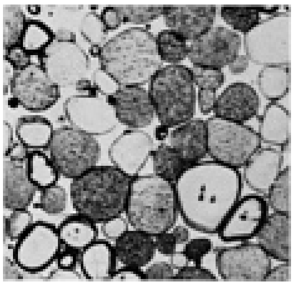

Fig. 22 Photomicrograph of the as-sintered condition of the tungsten heavy-metal alloy 90W-6Ni-4Cu, showing the spheroidal particles of tungsten (white and gray) embedded in a matrix of copper-nickel solid solution (white). 200×

These composite alloys continue to be developed for improved ductility and toughness of tungsten while preserving the desired combination of good strength and high density, for use in counterweights, electrical contacts, and kinetic-energy penetrators. Other alloying elements such as tantalum, molybdenum, and rhenium are added to solution harden the nickel phase and for either increasing (with rhenium) or decreasing (with molybdenum) the density. A similar microstructure is made when tungsten is alloyed with silver (W-25Ag) or copper (W-30Cu) using liquid metal sintering as above or using liquid copper or silver infiltration of a porous tungsten powder compact. These latter alloys are used as electrical contacts, offering high conductivity and high arc and welding resistance.

Other alloying elements, such as aluminum, yttrium, zirconium, and boron, are added to scavenge oxygen, nitrogen, and phosphorus impurity elements. During aging, the alloying elements niobium, tantalum, hafnium, and zirconium as well as tungsten can form carbide precipitates for dispersion hardening, such as is used in W-4Re-0.3HfC. Tungsten carbide precipitates, however, will coarsen with time at temperatures above 425 °C (800 °F); however, the other refractory metal carbides are resistant to coarsening at temperatures as high as 1650 °C (3000 °F).

Coatings of metal or refractory oxide or compound coatings are required in many applications to protect the base tungsten alloy against oxidation. Coatings protective against oxidation are applied in the form of metals, or oxides (zirconia), or as other compounds (carbides, nitrides, borides, and silicides). The metal coating systems include hafnium-tantalum, nickel-chromium (good to 1000 to 1400 °C, or 1830 to 2550 °F), platinum, and rhodium (good to 1650 °C, or 3000 °F), and usually are applied over a diffusion-barrier layer between the tungsten alloy and the coating.

Rhenium and Its Alloys

Rhenium is a strong, ductile, refractory metal with an hcp crystal structure. It has a very high density (21.0 g/cm^3, or 0.760 lb/in.^{3}) and melting point (3180 °C, or 5755 °F). It has good mechanical stability at elevated temperatures, offering good resistance to thermal shock and wear, and higher creep resistance and strength than the other refractory elements. The annealed condition, showing a room-temperature tensile strength of 1170 MPa (170 ksi), still has a tensile strength of about 48 MPa (7 ksi) at a temperature as high as 2710 °C (4910 °F). Rhenium is used for electrical contacts, thermocouples, filaments for electrical devices, including large-diameter lamp filaments. Because it is in short supply, it is costly and used mostly as an alloying addition to the other refractory alloys.

Rhenium is primarily made using P/M techniques with some also made by arc melting in an inert atmosphere. It has high cold ductility, but because of its very high work-hardening rate it requires the use of light deformation passes with frequent intermediate anneals, either stress relieving or recrystallizing at 1225 to 1625 °C (2237 to 2960 °F) in vacuum or dry H_2 or H_2-N_2 mixtures. Hot deformation must be carried out in vacuum or hydrogen to prevent hot cracking caused by formation of the low-melting-point oxide that penetrates grain boundaries during hot working in air. This is one case where the metal has a higher temperature stability than its oxide: the metal catastrophically oxidizes in air at moderately elevated temperatures, forming Re_2O_7, which melts at 297 °C (567 °F) and boils at 363 °C (685 °F), billowing off as a white cloud. Thus, the metal must be protected from oxidation during processing or while in service. A coating of iridium has been used. Because rhenium does not form a carbide, it is resistant to carbonaceous environments and is suitable for use in contact with graphite.

The high work-hardening rate of rhenium at room temperature translates into rapid increases in strength with cold work. For an annealed condition starting with a tensile strength of 1050 MPa (152 ksi), for example, cold working only 10% increases the tensile strength to 1900 MPa (276 ksi), and 20% to 2000 MPa (291 ksi), and with 40% cold work still further to 2670 MPa (388 ksi). The metal can be processed, but it must frequently be given interpass anneals. Crystallographic texturing of the hcp crystal structure and the high work-hardening rate lead to mechanical property anisotropy in processed sheet.

Rhenium is an important alloying element for tungsten and molybdenum, forming useful solid-solution alloys, W-(10-26)Re and Mo-(11-50)Re, with good combinations of strength and ductility over those of the unalloyed metals, reportedly by adding a twinning mode of crystal plastic deformation to the basic dislocation slip mechanism. The rhenium addition also lowers the DBTT and reduces the susceptibility to impurity embrittlement at recrystallized grain boundaries. This enhanced ductility with rhenium in solid solution has been called the "rhenium effect."

Effects of Composition, Processing, and Structure on Properties of Ceramics and Glasses

Victor A. Greenhut, Rutgers--The State University of New Jersey

Introduction

CERAMICS are most commonly defined as man-made, nonmetallic, inorganic materials. Common inorganic glasses should be considered a subcategory of ceramics. (Amorphous plastics and metals are technically also classed as glasses, but in this article the common understanding of "glass" is used; silicate glasses receive major emphasis because they represent the "ceramic" glasses most commonly used in consumer and engineering applications.) Ceramics are composed of crystals that have a long-range periodic atomic arrangement. Glasses have short-range order, but possess no long-range periodic crystal structure. Many ceramics can exist in both states, as for example silicon dioxide, which can be crystalline quartz or glassy, fused silica. Glass ceramics and vitrified bodies may be thought of as intermediate combinations of crystalline and glassy constituents (they are discussed later in this article).

Ceramics and glasses are usually composed of oxides, carbides, borides, or nitrides and show a number of common features attributable to their covalent/ionic bonding. Some ceramics are relatively more covalent in nature; these include silicon nitride and silicon carbide used for various high-temperature mechanical structures and wear parts. Other materials are almost purely ionic in bonding, including halides such as magnesium fluoride used for infrared transmitting windows and optical glass fibers. Most ceramics show some mix of covalent and ionic bonding, yielding a wide range of performance, but with common trends.

At all but extremely high temperatures, ceramics and glasses are mechanically hard and brittle with a potentially high strength limited chiefly by flaws and microstructure (see the article "Design with Brittle Materials" in this Volume). Most ceramics are quite refractory and allow application at quite high temperatures in many oxidizing and reducing environments. Ceramics are usually thermal and electrical insulators, but unlike metals these properties can often be varied independently with composition and microstructure control. Materials such as aluminum nitride and beryllia can show metallike thermal conductivity while functioning as good electrical insulators. Capacitive properties can be designed with appropriate additives and microstructure to vary greatly, either increasing or decreasing with temperature and applied voltage. Ceramics and glasses are generally transparent to light as individual crystals or particles, but can be made translucent or opaque by light scattering from interfaces of particle aggregates. These materials are also very resistant to reactive environments and thus are used for containment of chemicals and industrial reactants, including molten metals and glasses at elevated temperatures. This chemical resistance is called "durability"; the term is used, in particular, to describe resistance to water and relative inertness to aqueous solutions, both acid and basic. Because of the variety of properties that can be produced through appropriate processing of controlled chemistries and microstructures, the dollar value of ceramics used worldwide (based on total sales) is similar to that of metals.

Ceramics are commonly used as a polycrystalline aggregate most often processed at elevated temperature to yield a solid. Properties in the individual ceramic crystals are usually quite directional, and the random or preferred crystal orientation can lead to major differences in properties as a function of processing. Increased strength due to resistance to flaw propagation and directional piezoelectric properties are just two examples of how anisotropy in microstructure and properties can be manipulated to obtain desired performance. Many ceramics are multicomponent systems and are affected by the specific scale, shape, and microstructural arrangement of the various phases. In addition, most ceramics contain some level of porosity and the pore structure, whether continuous or isolated, can have profound effects on properties and performance. A great deal is understood about how chemical composition and the structure of starting materials can be manipulated by processing to yield microstructures with particular properties and performance. However, a full understanding of these relationships is still elusive. This article presents general principles and trends, but the selected references at the end of this article and the experience of experts should be used to reliably extend what is presented.

The various broad classes of ceramic materials are reviewed in this article, relating composition and structure to properties. General processing variables that can affect structure and compositional homogeneity are discussed and related to properties. Glasses are treated first because they play a role in other ceramic composition/structure-property relationships and are probably the most completely understood in terms of these relationships. This is followed by glass ceramics, which are usually derived from glass by thermal treatment. Traditional ceramics usually pertaining to clay-based systems follow. Technical ceramics, which include both oxide and nonoxide ceramics, conclude this article. Technical ceramics are often divided into engineering ceramics and advanced ceramics to distinguish more-developed materials from new, very high performance systems. It should be noted that the divisions and subdivisions used herein are those commonly followed by ceramists and that many materials may fall into two or several classifications depending on which compositional, microstructural, property, or performance features are being considered. The emphasis of this article is on mechanical and related properties; however, electrical, electronic, and magnetic properties are also very dependent on composition, processing, and structure.

Effects of Composition, Processing, and Structure on Properties of Ceramics and Glasses

Victor A. Greenhut, Rutgers--The State University of New Jersey

---

Glass

Glasses are amorphous materials that exhibit a glass transition, that is, a temperature at which the amorphous solid exhibits a sudden rate of change in thermodynamic quantities (discontinuous slope) with temperature (e.g., heat capacity and thermal expansion) without a first-order phase change. Glasses are usually products of fusion (liquids) that cool to a rigid state without crystallizing, yielding a rigid elastic mechanical solid. Some glasses such as sol-gel and vapor-derived glasses are made without melting of starting materials. Such materials, as well as nonoxide (ceramic) glasses, have growing commercial significance.

Traditional Glasses

Oxide glasses have as their chief component glass formers such as SiO_2, Pb_2O_5, and B_2O_3. Glass formers form the three-dimensional network of the glass structure. Glass modifiers enter the network structure at interstitial sites and modify the properties of formers. Alkaline oxides (Li_2O, Na_2O, K_2O, etc.) as modifiers tend to increase glass fluidity and lower the forming temperature of the "molten" glass. With such additions, glass that results has increasing thermal expansion and solubility in aqueous environments. The smaller the ionic radius (Li), the more effective are these modifier effects. The alkaline earth oxides (MgO, CaO, etc.) are sometimes termed stabilizers because they tend to restore durability while raising the working temperature of glasses containing substantial amounts of alkaline modifiers. Alkaline earth oxides also tend to promote crystallization of the glass as it is held at elevated temperature. The most commonly used glasses today are soda-lime-silica glasses (Table 1) based on the composition 74% SiO_2, 16% Na_2O, 10% CaO (wt%). These provide workability and glass fluidity over an extended range of moderate temperatures, with reasonable environmental durability. These glasses are the most inexpensive and are used for windows, containers, drinking glasses, plates, light bulbs, and so forth. Other modifiers (BaO, ZnO, etc.) may increase durability, workability, or some other property of the resulting glass. Glass intermediates such as Al_2O_3 and PbO can act as both glass formers and modifiers.

Trace additions are made to glass to provide color. Oxidized iron provides blue, green, amber or yellow depending on its oxidation state, while copper may yield green or blue and cadmium sulfide provides yellow, orange, or red. Other transition metal oxides yield such colors as blue (cobalt), green (chromium), and violet (nickel). Colloidal metals can also provide color; colloidal gold or copper can yield brilliant reds. Transparent colloidal silver halide particles incorporated in a glass decompose under ultraviolet light to yield opaque colloidal silver particles, which darken the glass. The effect is reversible (when the ultraviolet light is removed), producing photochromic glass. The ultraviolet absorption of glass is increased with additions of CeO_2, TiO_2, Fe_2O_3, V_2O_5, or CrO_3. Infrared absorption is increased by additions of FeO and CuO. Glass can be opacified with CaF_2, NaF, ZnS, or $Ca_2(PO_4)_3$, which can give an opalescent appearance to the glass. Trace iron in the raw materials is often masked with decolorizers such as MnO, Se^{2-}, NiO, or Co_3O_4.

The general attributes of the various major glass ingredients are shown in Fig. 1. Each ingredient can produce multiple effects so that the arrows indicate the tendency for each additive. Thus, PbO is most effective in increasing density while improving workability by extending and reducing the forming temperature range of a more fluid glass. Lead glasses also have a high index of refraction, making them useful for optical applications such as lenses. Their extended working range and brilliant light reflection makes them useful for such aesthetic applications as hand-crafted "crystal" and glazes for fine china. However, a high PbO addition particularly in the presence of alkaline oxide decreases the glass durability. Silica glasses are very viscous at their high working temperatures (over 2000 °C), which makes them costly to produce. Very high silica glasses are among the most chemically durable and lowest-expansion glasses, making them desirable for high-temperature chemical processing, ultraviolet lamps, optical fiber, and solid-state electronic processing. Borosilicate glasses (sold under the tradename Pyrex) provide a compromise of these properties with much lower forming temperatures and associated fabrication costs. Aluminosilicate glasses have relatively low expansion, high-temperature resistance, and chemical durability, but are less difficult to produce than high-silica glasses. They are used in fiberglass, electronics, and high-temperature laboratory equipment. Table 1 gives nominal compositions of many common commercial glasses.

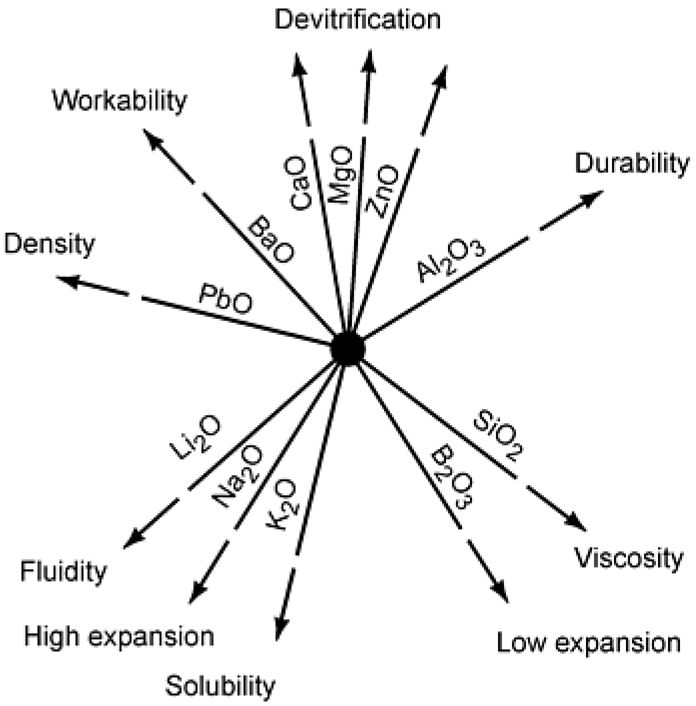

Fig. 1 Effect of glass composition on properties

A summary of properties for various commercial glasses is given in Table 2. The viscosity characteristics with temperature are defined in Fig. 2 (curve numbers refer to Table 2). The strain point is the temperature (viscosity) below which the glass acts like a perfectly elastic solid, for all practical purposes. That is, at any industrially practical strain rate the glass would not accumulate residual stresses, but would deform to accommodate the stress. Glass is held above the annealing point and slowly cooled below the strain point to remove any residual stresses introduced during production. As the temperature is raised, molecular mobility decreases the viscosity of the glass so that it flows more readily. The

working temperature defines the approximate temperature at which glass is formed or shaped. In the case of blow-molded glass, this may be from a small piece of glass, a "gob," sheared from a larger mass at a higher temperature.

Fig. 2 Relationship between temperature and viscosity of glass. The numbers refer to glasses listed in Table 2.

Below the glass transition temperature (T_g), glass behaves as a perfectly elastic, brittle solid. The strength of glass is limited by flaws such as scratches, inclusions, small bubbles (seeds), and small inclusions (stones). Optical fiber produced without flaws and immediately coated to prevent surface abrasion and water attack approaches theoretical strength levels of about 17 GPa (2.5 × 10^6 psi). Commercial fiber has a strength about an order of magnitude lower, while blown glass

has strengths up to 700 MPa (100 ksi). A typical strength for abraded glass is only about 10 MPa (5 ksi), but after exposure to atmospheric water this may decrease to a few ksi, particularly if a tensile stress is applied simultaneously. The nominal design strength is usually about 10 MPa (1 ksi).

Glass can be considerably strengthened by thermal tempering, rapidly cooling the glass from just above the softening point. The surface will be placed in a state of compression, typically about 70 to 200 MPa (10 to 30 ksi), which must be overcome to induce failure. As a result, abraded, tempered glass has an improved strength of about 100 to 250 MPa (15 to 35 ksi). Only simple shapes such as plate glass are amenable to thermal tempering. Tempered glass provides safety on failure as the release of balanced surface compression and interior tensile stresses will shatter the glass into many fine pieces less sharp than typical glass fragments.

An even higher surface compressive stress up to 700 MPa (100 psi) can be produced by "chemical tempering." The glass is immersed in a bath of molten alkali salt (usually KNO_3 for a sodium-modified glass) that "stuffs" the near-surface layers by ion exchange via the larger ion. This has the advantage of tempering the surface of complex shapes, but long treatment times are needed to produce a depth that will resist surface scratches.

Glass is often considered a very environmentally inert material, but even the most durable glasses are attacked by strongly acidic or basic solutions. Soda-lime-silica glass (and other high alkali-containing glasses) can be permanently damaged within the short period of a month if exposed to high humidity or if moisture is held on the surface by a dirt film. Moisture causes sodium ion exchange from the glass. The high-pH surface film that results causes accelerated attack of the glass. Mechanical strength can also be reduced by the attack of specific species in an aqueous environment. Glasses high in SiO_2, Al_2O_3, and CaO are usually most durable. Surface treatments with SnO_2, TiO_2, and SO_2 can also be used to increase durability.

Specialty Glasses

Solder (sealing) glasses are often based principally on PbO to give workability at low temperature. SiO_2 can also be used in these formulations. Such glasses have very low softening and working temperatures and are used in a variety of joining applications including glass joining of television picture tube plate/funnel assemblies. Other applications include electronic package sealing, hermetic feedthroughs, thick film materials, and component mounting material. The thermal-expansion characteristics are often adjusted by composition control for the specific glass/ceramic/metal assembly.

Chalcogenide glasses are based on the arsenic-selenium family and show controlled electrical conductivity and photoconductivity. A major application is the photosensitive coating of xerography drums, which is applied by vacuum deposition or reactive sputtering. Other applications include infrared transmitting fiber-optic waveguides and infrared lenses. Inability to achieve sufficient purity and homogeneity has limited fiber lengths, to date. These materials are also being studied for solar-cell applications.

Heavy metal fluoride glasses (HMFG) are candidates for repeaterless transoceanic communication links because of their low theoretical light attenuation (10^{-3} dB/km at 3.5 μm). Oxygen impurities and crystallization have limited realization of HMFG potential. Increased chemical durability to water is also required for practical application. Some of these glasses are commercially available for short transmission distance infrared applications.

Sol-gel glasses are chemically synthesized from a sol or solution using hydrolizable alkoxides. The final material is often chemically similar to materials produced by more conventional melt processes. In the case of a solution, the material converts to an alcogel, which may be dried by natural evaporation yielding an xerogel or by hypercritical extraction in a pressure vessel yielding an aerogel. A sol will form a hydrogel or precipitate resulting in turn in a cake or powder. Crystalline materials can also be produced by these routes. These techniques can lead to glasses of exceptional purity and homogeneity based on the purity of starting components. The product material typically has a very high nanoscale porosity that may be useful for high surface area applications such as catalyst substrates or where low density is required. The material can be consolidated at moderate temperatures. Chief applications are as films and coatings with some fibers and powders produced by this technology. Bulk shapes can be made, but the high cost of starting materials and material processing limit bulk applications.

Glass Ceramics

Glass ceramics are produced by melting a glass composition that is then formed into the desired shape by conventional high-speed glass manufacturing methods. The shape is then subjected to a multiple-temperature crystallization heat

treatment so that up to 99% of the final material is fine-grained crystals (about 1 μm) in a continuous glassy matrix with the original external shape maintained. The fine grain size, fully dense structure yields materials with mechanical properties and high-temperature resistance generally superior to the glasses from which they are derived. The glassy phase will usually limit performance at very high temperatures. These materials are often superior in strength to conventionally processed ceramics containing porosity and show superior toughness because crack fronts deflect around the fine crystals. If the index of the crystalline and glassy phases do not match, the glass ceramic will usually be white due to diffuse reflection of light. Matched index yields transparent glass ceramics.

Thermal expansion can be tailored by selection of the initial glass composition. The common compositions are based on low-expansion borosilicate glass chemistry. As with glasses generally, low modifier content yields low expansion. This low expansion, coupled with good strength and toughness, has led to applications in cookware and stove tops, which require thermal shock resistance. Near zero-thermal expansion coefficient can be designed over a temperature range useful for telescope mirrors and heat exchangers.

Machinable glass ceramics can be made by incorporating crack-arresting mica flakes in the structure, either by crystallization or by mechanical blending with frit. The resulting glass ceramics can be shaped economically in limited production by high-speed machine tools. Photomachinable glass ceramics include a photoactive element such as silver so that portions of the glass precursor exposed to light form crystals on heating. The crystallized portion is then etched away chemically. This allows complex shapes to be produced by techniques resembling photolithography. The photomachining process has been used to produce electronic and optical components as well as artware such as Christmas tree ornaments.

Glazes and Enamels

Glaze is a continuous adherent layer of glass applied to the surface of a ceramic body. It is applied to the surface of a ceramic as a suspension of ingredients (as indicated above for bulk glasses). After drying, the glaze is fired to yield a hard, nonabsorbent surface layer. The thermal expansion is usually selected by compositional control (by varying glass formers and modifiers as for bulk glass) to be slightly less than the ceramic body. Upon cooling, the slightly lower expansion results in a surface residual compression that increases the strength of the product. The flow temperature is adjusted by composition control to provide a firing maturation with the body, after bisque (partial) or full firing of a ware. Some glazes contain a crystalline constituent or partially devitrify upon cooling, providing opacity. Colorants are included for decoration. Properties of the glaze are similar to that of their bulk glass or glass ceramic composition.

Porcelain enamels are chemically durable and physically strong glasses, usually alkali-borosilicate glasses, applied to a metal either wet or nominally dry and fused to the surface at elevated temperature. As with glazes, they may contain crystalline phases for opacity and glass colorants. They are also tailored compositionally to yield favorable thermal expansion as well as to bond to the metal they coat. Properties can be inferred from bulk glass or glass ceramic behavior, as in the case of glazes.

Effects of Composition, Processing, and Structure on Properties of Ceramics and Glasses

Victor A. Greenhut, Rutgers--The State University of New Jersey

---

Traditional Ceramics

Traditional ceramics usually use clay as a major component of the batch. Most are clay-based bodies containing one or more clays such as kaolin (china) and ball clays combined with other minerals in the form of particulate powder. Some ingredients such as feldspar and nepheline syenite act as fluxes lowering the temperature at which glassy phase forms so that the ceramic can be fired at temperatures typically from 1000 to 1300 °C (1830 to 2370 °F). Fillers are added to assist in forming and firing and yield desired properties for the fired product. Silica is the most common filler and may melt partially into the glassy phase during firing. Alumina is used as a filler principally to impart strength to the final product.

The combination of clay, flux, and filler of controlled particle sizes together with added and/or native organic matter and water provide a plastic material termed a "green" ceramic. This can be formed into the object by various mechanical and slip-casting methods followed by the firing step. During firing, glass forms that binds the particulate material together during the process of vitrification, sometimes termed vitreous sintering. There is considerable shrinkage of the body during this process, and some of the glass may crystallize (devitrify) upon cooling.

A solid ceramic results with some features common to all traditional ceramics. Grains of filler and crystallized material are held together in a continuous glassy phase. Pores are a feature that may be regarded as a third phase. Pores may be isolated, interconnected, or a combination. The extent of these three general microstructural features--crystal grains, glass, and porosity--determines the classification and properties of traditional ceramics, as shown in Fig. 3. The size, shape orientation, composition, and distribution of these features determines the properties of the final product. A first major classification is into fine particle ware (particles less than 0.2 mm, or 8 mils) and coarse ware (chiefly larger particles, but less than 8 mm, or 0.3 in., for the coarsest structures). Further subdivision is based on the open porosity, as determined by water absorption. Color and application determine the further subdivisions shown in Fig. 3.

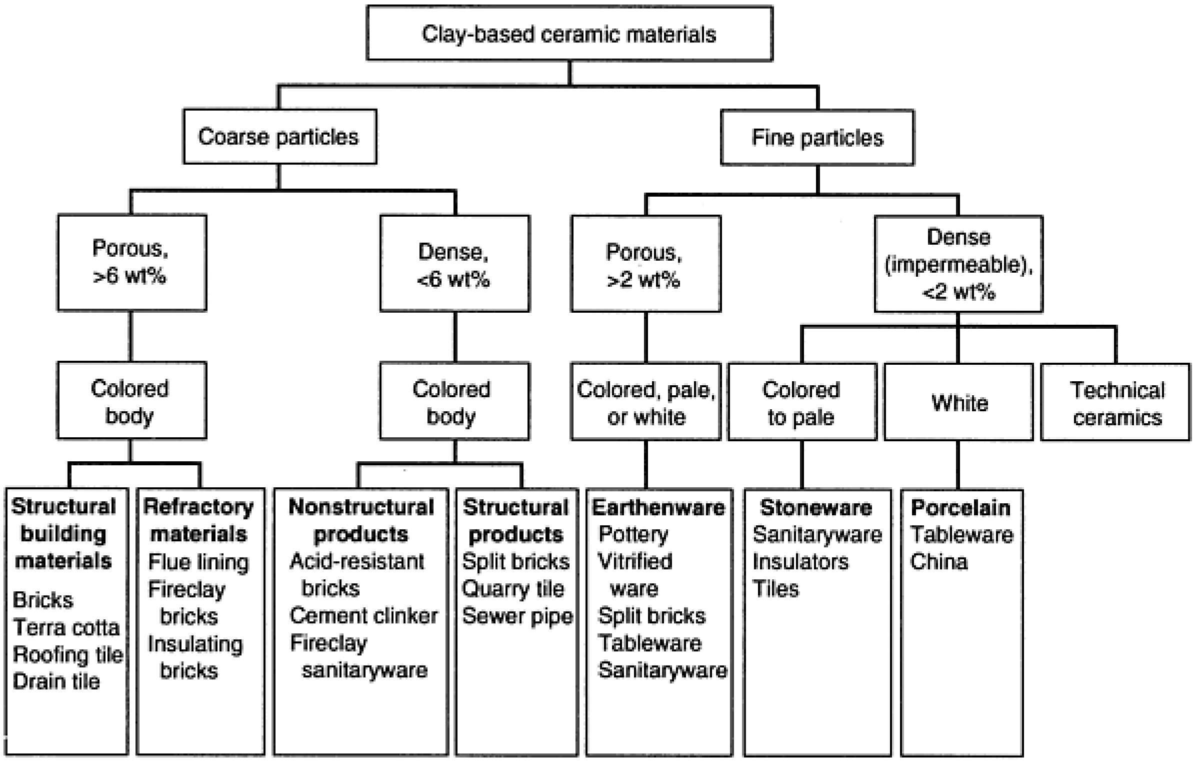

Fig. 3 Classification of clay-based ceramics. Weight percent values represent water absorptivity.

Compositions that contain more fluxing raw material tend to produce more glassy phase at lower temperatures, as does firing to higher temperature or for longer times. A higher glass content tends to vitreous sinter to a greater extent, yielding a body with higher density and lower porosity. A fully vitrified body may show no continuous porosity and zero water absorption. The extent of closed porosity depends on the specific composition and firing cycle selected. Usually, strength, environmental resistance, density, and translucency increase with vitrification because the greater amount of glass eliminates porosity and more fully binds together the crystalline particles of the microstructure. Glassy phases that form at higher temperatures tend to cause greater strength, lower thermal expansion, and improved resistance to water and chemical attack, if fired at higher temperature to achieve an equivalent structure to that of lower-firing body formulations. These whiteware properties follow the general behavior of glasses as discussed in the section "Glass" above. Fine-grained microstructures tend to show greater strength if other factors are held constant. Because of the wide combination of raw materials, particle sizes, and firing cycles it is difficult to establish a systematic description of resulting microstructures and related properties.

Several raw material and processing "errors" can result in undesirable structure. If, due to fast firing, the surface closes over, water and decomposing organic materials can cause bloating in which the body swells. There are limited

applications in which this is used to make a very open pore structure for lightweight material or thermal insulation. If the surface closes after water is removed the decomposition can lead to "black core," a discolored and often cracked, swollen center. Inhomogeneity, differential heating, or friction with the furnace setter (ware support material) can result in ware warping. A few included large grains can act as defects, as can large pores resulting from particle agglomerates, and inhomogeneous organic matter. These defects act as strength-limiting intrinsic defects. A thermal expansion mismatch between filler grains and glassy phase as well as the quartz inversion (transformation of high-temperature silicates back to quartz) can introduce internal cracks.

Whitewares (Fine Ceramics)

The fine particle branch of Fig. 3, fine ceramics, is often termed whitewares or whiteware ceramics. Most are made using triaxial (clay/feldspar/flint) bodies as the basis for formulation. Sometimes earthenware is distinguished as a separate group because of its greater water absorption (>2%) and range of color to browns and reds as distinct from the white, cream, ivory, or pale gray appearance often associated with the denser, more impermeable whitewares. Generally, proceeding from left to right among the fine ceramics in Fig. 3, the porosity and crystal grain size decrease while strength and durability (environmental resistance) increase. Aesthetic properties such as whiteness and translucency also improve. Definitions of whiteware bodies in terms of water absorption and typical applications are given in Table 3. The name of the subclass often helps to identify its source or microstructural characteristics. The typical formulations of a variety of whitewares are given in Table 4, and typical properties are listed in Tables 5 and 6. Vitreous bodies have no open porosity and are translucent in thin sections. With correct, defect-free manufacture, these are premier materials within each class, known both for their aesthetic beauty and performance in terms of strength and durability. Nonvitreous bodies have a relatively large water absorption due to open porosity and correspondingly poorer properties. The various classes and subclasses overlap significantly in structure and properties so that strict division and distinction by structure, chemistry, and/or properties may not be possible.

Table 3 Ceramic whiteware classes and products

Class and type	Absorption, %	Products
Earthenware		
Natural	+15	Tableware, artware, tiles
Fine	10-15	Tableware, artware, kitchenware, tiles

Earthenware is a low-temperature-fired nonvitreous clay-based body usually with relatively high porosity and water absorption (10-20%), except semivitreous earthenware, which is fired to medium porosity and water absorption (4-9%). The typical ware is opaque and generally has the lowest strength and resistance to water of whitewares because of its high porosity level. Semivitreous earthenware products have somewhat superior properties at higher firing cost. Other subclasses are natural earthenware, made from a single unbeneficiated clay; fine earthenware, made from a triaxial (clay/feldspar/flint) body with beneficiated clay and talc earthenware, formulated with a high talc level and showing greatest porosity levels. Typical bodies are red because of high iron oxide levels in the clays, but range to white for triaxial and talc formulations. Ware may be used glazed or unglazed.

Earthenware is used for a variety of household tableware, containers, and oven cookware. The water absorption of this red-colored pottery is often used to advantage in applications such as flower pots or other vessels that cool by evaporation. This type of ware is common in less-developed societies and is frequently used for aesthetic reasons in industrially developed countries.

Stoneware is intermediate in structure, properties, and firing between earthenware and porcelain ceramics (Fig. 3). Stoneware bodies are fine-textured, semivitreous, or vitreous bodies with moderate strength and environmental resistance attributable to an intermediate porosity level (water absorption of 0 to 5%). It is rather durable, but lacks the whiteness and translucency of china. Stoneware is also frequently colored as a result of impurities such as iron in the clay. Stoneware is used for tile and drain pipe as well as less demanding dinnerware and artware. Natural stoneware is made from a single unbeneficiated clay, while fine stoneware is made from beneficiated clay raw materials and nonplastic minerals. Basalt stoneware contains relatively high iron levels and is typically red or brown. Jasper stoneware is formulated with high barium levels. Basalt and jasper stoneware generally have improved strength and water absorption properties because their porosity is lower than that of natural and fine stoneware. Technical stoneware has the lowest porosity of this class of ceramics (0-0.2%) and superior properties. It is made from beneficiated materials fired to higher temperatures to achieve very low porosity suitable to application as chemical ware.

China is a term frequently used as synonymous with soft paste (tender) porcelain. The term porcelain is often used inclusively for china, porcelain tableware/artware, and technical porcelains. However, true porcelain is typically stronger but more brittle and more translucent than china, and it is blue-white in color, whereas china is cream-white. Microstructurally, porcelain contains more crystalline and less amorphous component than china. Typical high-fired china has very low continuous porosity and water absorption (0.1 - 0.5%) and may be used glazed or unglazed. While china bodies can be made from simple clay/flux/silica formulations, they frequently contain varying amounts of powders of alumina, bone, ash, frit (glass particulate), lithium minerals and/or cordierite (low thermal expansion). These additives alter the green and fired properties of the china as well as the appearance. China bodies and glaze are fired in a one-step process in which body and glaze mature at the same time, except when decoration is applied or very high luster is desired as in the case of tableware. Hotel china, for commercial food handling, and vitreous china, used for sanitary plumbing fixtures (sanitaryware), are developed with low porosity for low water absorption and superior impact resistance, high strength, and aqueous chemical durability. Fine china, usually considered the finest grade of china, is a relatively thin, translucent body made from bone (usually bovine), frit (Belleck, named for the famous Irish ware that uses crushed glass), or feldspar china. It is usually fired to mature the body and again to develop a very high gloss glaze. The term cookware is used across all whitewares, but most often for china. It refers to a body with a smooth glaze (produced in a single firing) that is resistant to contact by food acids, bases, and abrasives. Such ware is strong and resistant to chipping and thermal shock.

Porcelain is made from a triaxial composition (see the article, "Design for Ceramic Processing" in this Volume). Porcelains may have alumina or zircon substituted for silica in order to increase strength or be high in talc and low in alkali (steatite porcelain) for electrical and strength applications. Compositions based on magnesium aluminosilicates are often used for electronic applications (such as direct current power transmission) to avoid electrically mobile alkali ions. Porcelains have very low water absorption (less than 0.5%). Glaze may be applied after a partial firing (bisque fire) to allow volatiles to burn off. Hard porcelain is used for tableware and artware, while most other porcelain compositions are designed for specific application as technical ceramics.

Technical Ceramics. Whitewares, chiefly chinas and porcelains, are also used as technical ceramics for applications such as chemical ware, dental prostheses, electrical insulators, ball mills, refractories, and structural shapes. They are usually extremely low in porosity with near-zero water absorption. Strength, abrasion resistance, chemical durability, electrical properties, and/or high-temperature resistance are adjusted by compositional control of the glassy and crystalline phases(s). Other technical ceramics are made with little or no clay and are discussed in the section "Engineering Ceramics" in this article.

Structural Clay Products

Clay-based ceramic materials with relatively coarse particle sizes (left branch of Fig. 3) are used in various construction applications including brick, roofing and drain tile, terra cotta, and pipe. Tile is the sole exception, having a fine grain size that classifies it with other whiteware ceramics. Tile is classified by the American Standards Institute (ANSI A137.1) and European standards into categories such as ceramic mosaic tile, decorative wall tile, paver tile, porcelain tile, quarry tile, and wall tile. Various applications and their ASTM designations are given in Table 7. Raw materials are clays and/or shales with some fluxing agent and an amount of filler (usually silica) that depends on the application. Most compositions use 35 to 55% clay, 25 to 55% fluxing material, and the remainder filler material, usually silica. As with whitewares a portion of the constituents fuse and form a glassy bond on cooling. Structural clay ceramics show the existence of at least a minimal fired bond.

The most important properties of structural clay products are low density (which affects transportation cost), water absorption rate and water capacity (which depend chiefly on pore structure), and compressive strength (which depends on the fired bond and pore structure). Load bearing brick and tile (floor tile, paving brick, bearing wall brick) have strengths from about 17 to 140 MPa (2.5 to 20 ksi) with a relatively low porosity and higher fired bond. Decorative brick and tile are typically less dense, lowering bearing weight as well as shipping and material costs. Strength is lower, 3.5 to 70 MPa (0.5 to 10 ksi), due to the greater porosity. Drain tile for pipe are intermediate in strength (10 to 75 MPa, or 1.5 to 11 ksi). Thermal conductivity also depends on pore structure, with denser material being more thermally conductive. Frost damage and efflorescence can occur from porous structural clay products exposed to water, depending on the specific porosity and chemistry of the product.

The open pore structure is fundamental to the performance of structural clay products. A greater quantity of pores, as defined by the weight percent of water absorption, decreases strength, resistance to cyclic freezing of water-saturated material, insulating value, and corrosion resistance of product. Frost resistance and minimum capillarity is provided when

the preponderant size distribution of pores is substantially greater than 1 μm in size for the minimum pore dimension. Often, maximum damage occurs when the mean pore size is in the range 3 to 0.9 μm. Interconnection of pores and pore shape influences fluid permeability of the pores. The path between pores can be tortuous or sealed against fluid penetration, thereby restricting water flow. This would be desirable for water containment (pipe) or preventing water from entering a structure (brick, tile). Alternatively, high permeability is the engineered structure for drainage tile.

When increased compressive structural strength is desired, a material is fired at higher temperatures and/or longer times to achieve a greater fired bond. A body fired at higher temperatures contains more molten material, drawing particles together and furnishing a denser material. This yields fewer undesirable small pores from the standpoint of frost damage. The molten material solidifies on cooling, chiefly into glassy material. This binding phase provides mechanical strength, particularly in compression. As with whitewares, a large amount of "fused" (glassy) material is termed a vitreous product and those with a lesser amount semivitreous. A wide variation in classification and porosity exists specific to particular product type. Chemically resistant vitreous brick may have a porosity of about 0.5%, while vitreous sewer pipe may have a 6% porosity.

The range of properties that can be found within a structural clay product can be seen from the example of bearing-wall brick as given in Table 8. It can be seen that several mechanical properties such as compressive strength, bend strength (modulus of rupture), and elastic modulus can vary by several times. There is a parallel difference in pore structure shown in the table by the various water absorption characteristics. Differences in the fused bond can be inferred from the previous discussion.

Table 8 The general range of property values for commercial brick used in the United States

Property	Property value
Compressive strength	
Extruded brick, MPa (psi)	41-110 (6,000-16,000)
Molded brick, MPa (psi)	21-45 (3,000-6,500)
Modulus of rupture, MPa (psi)	4.8-27.6 (700-4,000)
Modulus of elasticity, GPa (10^6 psi)	9.7-34.5 (1.4-5.0)
Bulk density of solid volume, g/cm^3	1.65-2.08
Absorption for room-temperature water, %	0.5-10.0
Saturation coefficient	0.6-0.9
Initial rate of absorption, kg/m^2 · min (g/min · 30 in.^{2})	0.05-3.6 (1.70)
Coefficient of linear thermal expansion, μm/m · K (μin./in. · °F)	4.5-9.0 (2.5-4.5)
Moisture expansion, %	0.02-0.09

Shrinkage in service, %	0
Corrosion resistance	Can contain all acids hot or cold except hydrofluoric; resistant to all alkalies
Thermal conductivity, W/m · K (Btu · in./ft^2 · h · °F)	0.43-1.44 (3-10)

Refractories

Refractories are materials that maintain their structural strength and physical integrity at the elevated temperatures of a furnace environment. They must also resist thermal shock, thermal cycling, mechanical fatigue, and physical wear. Many are resistant to attack by aggressive environments of chemical processing, exhaust vapors, molten metals, cement clinker production, and fused glass (including slags) at extreme temperatures. The most demanding applications are containment refractories, which are nominally fully dense (near-zero porosity) and designed in terms of chemistry and phase structure to resist the particular environment and conditions of a manufacturing process. Chrome magnesite materials are used to resist molten iron and steel and their slags. Zirconia-base ceramics are employed for nonreactivity with cobalt- and nickel-base superalloys. Alumina and zirconia grain in an aluminosilicate matrix, AZS refractories, resist attack by molten soda lime silica glass and high alkali borosilicate glass used for fiberglass. Common refractories are made from natural materials, but high-performance refractories are often composed of more purely refined or chemically derived ceramics starting materials. Most refractories are metal oxide ceramics, silicon-carbide-base materials or graphite. Newer carbides, borides, nitrides, and silicides find use where their higher expense is justified.

A refractory usually has a designated upper-use temperature determined by the softening or melting point of constituent oxides. This temperature is usually a range because the refractory is a complex mixture of phases. A combination of temperature, time, load, and environment all interactively determine the actual utilization limits. Sometimes the pyrometric cone equivalent (PCE) is used to quantify refractoriness. This is a measure of the heat content that a refractory can withstand without softening as determined by slumping of the pyrometric cone (actually a tall, narrow-based, tilted tetrahedral pyramid). This can better reflect service because it combines temperature and time factors. Another approach is to determine the pyroplastic sag under its own weight of a narrow bar of refractory supported near its ends. The hot modulus of rupture (HMOR) is determined by bend testing at elevated temperature. The performance of a refractory depends on its phase distribution, particle size distribution, and porosity as determined by starting materials, processing, and firing conditions. The oxidizing or reducing nature of firing and use atmosphere can affect structure and properties. This is sometimes determined with a carbon monoxide resistance test, which evaluates the change in HMOR and other properties as well as microstructural alteration with prolonged high-temperature exposure to a carbon monoxide atmosphere. Refractories are termed low, medium, or high duty depending on their relative refractoriness within or between refractory types.

Refractories must also resist *spalling,* cracking or flaking that results from thermal cycling and thermal shock, differential expansion of microstructural constituents, temperature-dependent phase changes, and thermal gradients. The ability to insulate or conduct heat depends on thermal conductivity (Fig. 4). Glass tends to lower thermal conductivity, but conductivity cannot be predicted based only on glass and crystalline content. Phase distribution, particle size, and porosity are also very significant factors. Dimensional stability is also important. Reversible expansion during heating and cooling (Fig. 5) must either be accommodated in design or minimized. If a refractory is not fully dense, further densification can occur during use, resulting in unacceptable dimensional change. Under load (including self-load) this dimensional change (often called "subsidence") can lead to system failure. Minimization of open and closed porosity can avoid this effect. Porosity is closely controlled in refractory manufacture because it leads to a loss of mechanical strength and allows for penetrating chemical attack by gases and liquids. Internal pores do decrease thermal conductivity and can modestly improve fracture toughness (mechanical and thermal shock resistance). Improved strength, strength retention with thermal cycling, and blunting of cracks have all been observed in well-designed porous refractories.

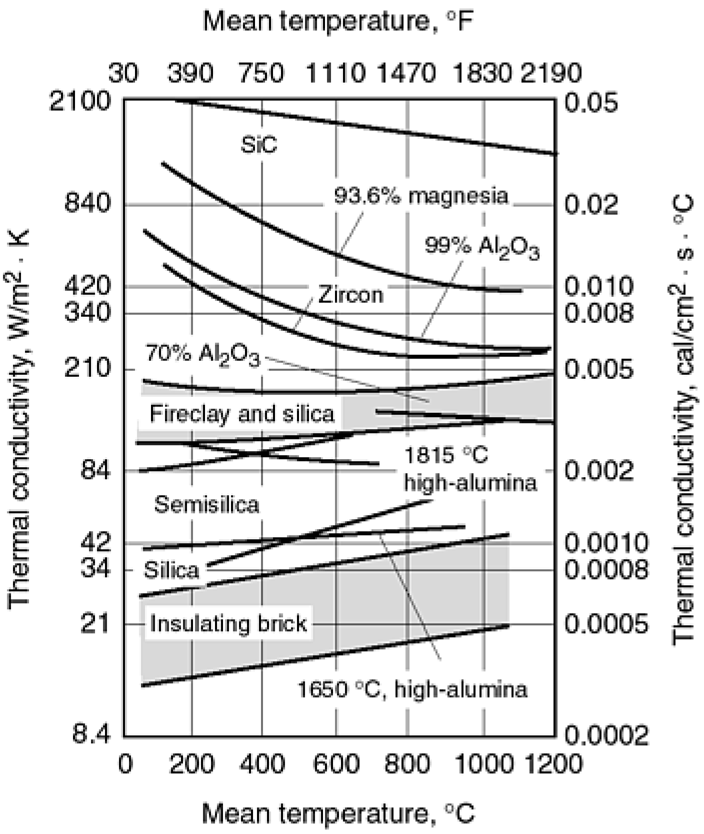

Fig. 4 Thermal conductivity of various types of refractory brick

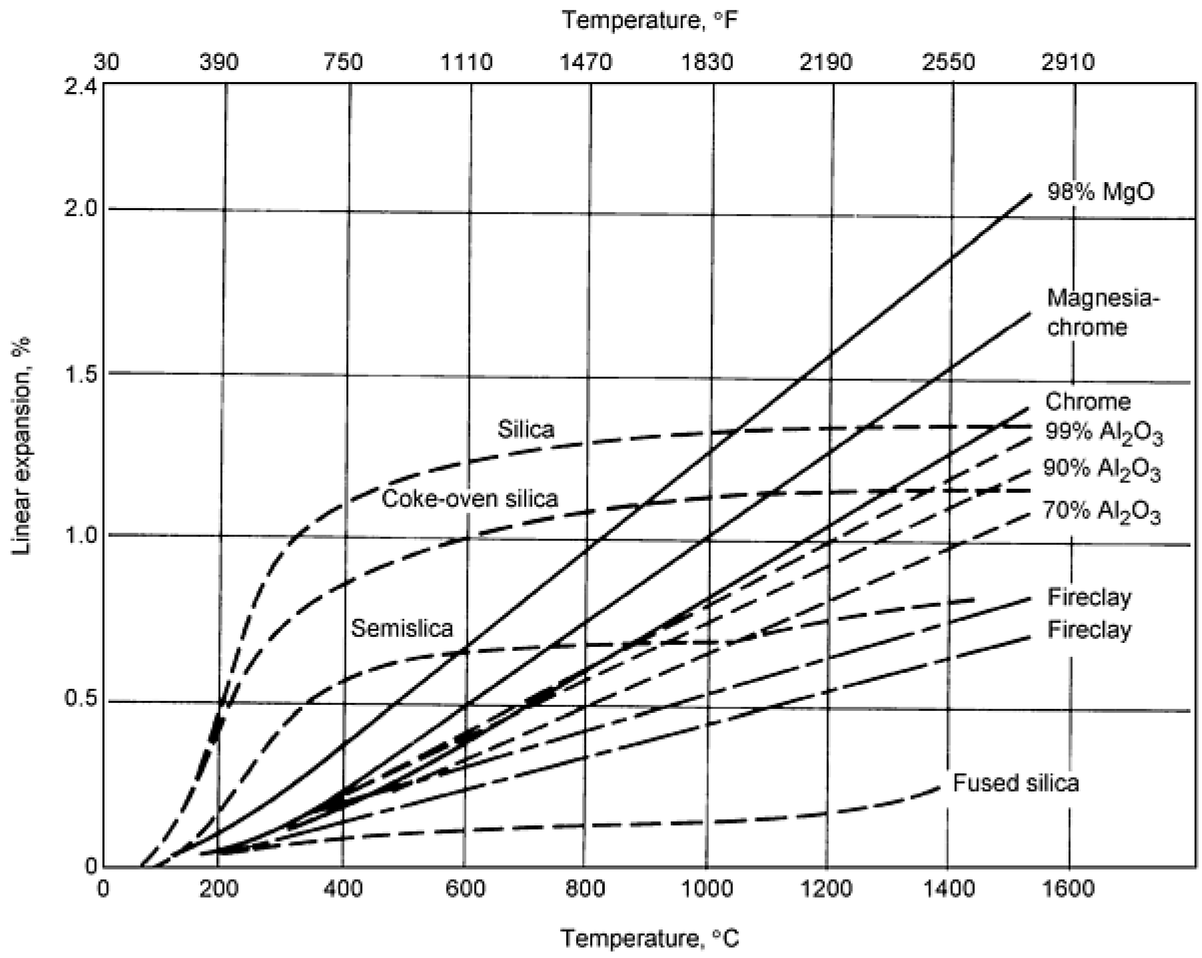

Fig. 5 Linear thermal expansion of magnesia and chrome brick (solid lines) and silica-alumina brick ranging in composition from 96% to 99% alumina (dashed lines)

The most common refractories are based on oxides of SiO_2, Al_2O_3, MgO, CaO, Cr_2O_3, and ZrO_2. All are considered "basic" except for SiO_2 and ZrO_2, which are considered "acidic." This distinction is based on historical concepts of the chemistry and chemical interaction of refractories with molten slags or fundamental chemical relationships. While these concepts have not proved fully accurate, the division is nonetheless useful. Oxide refractories are also divided into clay and nonclay materials. The composition and properties of selected basic refractories and high-duty refractories are given in Tables 8 and 9. The properties of selected refractory brick are given in Table 10, thermal conductivity with temperature in Fig. 4, and thermal expansion with temperature in Fig. 5.

Table 9 Composition and selected properties of basic refractory materials

Type	Composition	Maximum use temperature in oxygen		Thermal conductivity, kcal/min. · °C			Refractoriness under load of 197 kPa (28.5 psi)

The majority (about two-thirds) of refractories are used in the form of bricks, but a wide variety of other shapes and forms are available. For some critical applications such as high-attack zones in glass tanks, the ceramic is fusion cast into large structural shapes and precision cut to obtain maximum density and minimize brick junctures as zones of localized attack. Such melt casting is used for alumina, alumina-zirconia-silica (AZS), alumina-silica, magnesite, chrome-magnesite, zircon, and spinel. Monolithic refractories--castables, plastics (plastic-working consistency), mortars, gunning mixes, and

ramming mixes--are placed or cast directly in the furnace and fired in place. Mortars can also be used to lay ceramic brick and repair worn or cracked refractories. Many of these materials involve cementitious reactions based on calcium aluminate and to a lesser extent portland cement (see the section "Portland Cement and Concretes" in this article). Frequently, users erroneously omit the required firing of the material after the cementitious reaction. The unfired material lacks strength and water resistance. Other systems involve phosphate bond and boron-base binder materials. The drying and firing steps are important in all these materials in order to cause the phase transformations that fully develop the desired phase structure and low porosity required for good strength, abrasion resistance, thermomechanical stability, environmental durability, and resistance to water. Some systems are also used to produce a porous insulating material by evolving gas during setting of the directly applied or cast monolithic.

Clay refractories include fireclay and alumina materials (see Tables 9 and 10). Fireclay refractories are usually made from kaolinite-base clay with minor amounts of other clays. The refractoriness increases as alumina levels are increased from about 25 to 45%. Alkali and iron impurities decrease the maximum use temperature because they modify the glassy bond. Fireclay provides low thermal expansion and intermediate insulation with moderate resistance to thermally induced stress. They provide poor resistance to bases at elevated temperature, but can perform adequately in acidic environments. Fireclay is used in steel pouring pit applications and as a general cost-effective refractory. Alumina refractories (Tables 5, 6, and 11) and are made from bauxite or other raw materials that yield a refractory with 50 to 87.5% alumina. They have superior volume stability and spall resistance as compared to other clay refractories. They are more resistant to chemical attack than fireclay and are used in more severe steelmaking applications. They are used in lower service parts of glass-melting furnaces and steel ladles. Phosphate-bonded and alumina-carbon brick are often included in this category.

Table 11 Composition and selected properties of high-duty refractory oxides

Type	Composition	Melting point		Maximum use temperature in oxygen		Thermal conductivity, kcal/min °C				Refractoriness under load of 196 kPa (28.4 psi)	
		°C	**°F**	**°C**	**°F**	**At 100 °C (212 °F)**	**At 500 °C (930 °F)**	**At 1000 °C (1830 °F)**	**At 1500 °C (2730 °F)**	**°C**	**°F**

(a) Incongruent

Basic refractories are produced from various combinations of magnesite (dead-burned or fused), dolomite, chrome ore, and carbon (see Tables 9 and 10). Magnesia (magnesite) brick consists chiefly of periclase (MgO) in fired, pitch-bonded (tar-impregnated) or chemically bonded forms. For resistance to chemical attack and refractoriness, 80 to 95%

MgO is used. Dolomite brick (CaO) is made from highly calcined dolomite ore ($CaCO_3 \cdot MgCO_3$) usually bonded with pitch or tar to extend service life by preventing hydration of the lime component. Dolomite brick is used in rotary cement kilns and steel ladles. Chrome (chromite) brick is made from natural chrome ore and is a complex combination of spinel minerals based on chrome, iron, magnesium, and aluminum oxides. It contains 30 to 45% chrome oxide. Some silicate phases are also present. They have excellent resistance to basic conditions and moderate resistance to acidic environments. Chrome-magnesite brick has outstanding resistance to steelmaking slags and is used in severe service areas of basic oxygen furnace vessels and electric arc furnaces. Thermal expansion is reduced by using a larger proportion of chrome ore than magnesite. High-purity magnesite often derived from seawater or brine wells provides superior resistance to attack. Pitch and tar-bonded materials and those containing flake graphite are often used. Very low porosity and high homogeneity can be achieved by melting the raw materials with an electric arc and casting large shapes (fusion cast) or by using fusion cast grain as a starting material for brick manufacture (rebonded fused grain, RFG).

High and extra-high alumina refractories are compositions containing more than about 85% alumina (see Tables 10 and 11). They are made from alumina (or bauxite for lower alumina levels) and are densely sintered or fusion cast. Usually, greater refractoriness is accomplished by increasing alumina content--nominally 100% alumina may be used to 1800 °C (3300 °F). Higher alumina levels also result in greater strength and resistance to attack. Induction furnaces and gates for continuous casting often use 90% alumina. Phosphate-bonded alumina is used in molten aluminum manufacture because of its relative resistance to attack and its suitable refractoriness.

Mullite refractories ($3Al_2O_3 \cdot 2SiO_2$) are similar in performance to high alumina refractories (see Tables 10 and 11). The aluminosilicate raw materials must be sintered at very high temperatures or electric arc melted to produce the mullite phase. The thermal conductivity of mullite is significantly lower than alumina, particularly at temperatures below 1000 °C (1830 °F). This provides better insulation than alumina.

Silica refractories are listed in Tables 9 and 10. In Fig. 5 it can be seen that the thermal expansion of crystalline silica (quartz) is very high to about 500 °C (900 °F). In order to prevent thermal shock failure, the heating and cooling rates of silica refractories must be extremely slow through this range. Silica may be classed as superduty with very low alumina and alkali, regular (conventional duty), and coke-oven quality (free of iron spots, chips, and other defects). There are two corresponding ASTM designations based on adding the alumina content and twice the alkali level to yield a flux factor. Type A has a flux factor less than and type B greater than 0.5. Both must have a modulus of rupture greater than 3.5 MPa (500 psi). The fused (glassy) form shows very low expansion and has been developed for applications such as hot patching as well as shrouds, glass tank refractories, and linings for chemical reactors.

Silicon carbide (SiC) refractories have good load-bearing capability at very high temperature, excellent thermal shock resistance, and extremely high thermal conductivity (see Table 9 and Fig. 4). It is increasingly used for kiln furniture supporting and separating whitewares, particularly as ceramic fast firing has become more prevalent. Electric heating elements are also made of SiC. Silicon carbide refractories are produced by electric furnace reaction of sand and coke. Nitride-bonded SiC is used to process molten aluminum.

Zirconia is used as an additive to increase thermal shock resistance and lower corrosive attack in a variety of refractories (AZS, for example). As a refractory (Table 10), it is usually magnesia or calcia stabilized to prevent disruptive phase transformations on heating and cooling. Zirconia refractories are extremely resistant to attack by molten metals, glasses, and slags; have relatively low expansion; and possess high use temperature because of their very high melting point. Applications include the melting and casting of various specialty alloys.

Carbon and graphite can only be used in low oxygen or reducing environments. These refractories are resistant to many molten glasses, ceramics, and metals. Carbon-base refractories have high thermal conductivity and very high use temperatures.

Insulating refractories have a structure and composition to optimize insulating efficiency, maximum-use temperature, and subsidence under compressive load. When a containment refractory does not line the furnace, the inner insulating refractory must also be chemically resistant to the furnace environment--usually furnace gas and evolved by-products. Many insulating refractories are not mechanically resistant or chemically durable (resistant) in a water accident. The best insulating behavior is provided by maximizing the porosity (lightweight brick). The pores should be at a medium to fine level and tortuous to prevent air (gas) circulation. Additional benefit can be derived from a lower thermal conductivity and higher heat reflectivity for the ceramic. Thus, light-colored oxide ceramics are preferred with silica-base materials (fireclay, silica) providing better insulating power than alumina (high alumina, alumina). High porosity levels detract from two additional properties: crush strength and maximum-use temperature. Compressive strength decreases with porosity, but can be improved by selecting a refractory material with sufficient high-temperature strength and a pore

structure that provides some mechanical rigidity due to the structural arrangement of the material. At high temperatures the insulating refractory continues to sinter or deform by viscous flow under load. This process proceeds more rapidly with a greater starting porosity or higher temperature. In glass-bonded material, glass modifiers--particularly alkaline oxides--will accelerate high-temperature subsidence. Formulations with higher temperature ratings, such as alumina, can be selected.

Because strength and subsidence requirements counter insulating power, a layered structure is usually used in furnace construction. The inner material is denser (or may be a containment refractory) designed to resist the highest temperature and the furnace environment. Successive layers are more porous, with greater insulating power, because they need only resist a lower temperature and are not exposed to attack. The outermost layers can be refractory fire-board or fiber-blanket materials with high loft (open volume) to provide maximum insulating power at lower temperatures.

Portland Cements and Concrete

Portland cements are composed chiefly of calcium silicate powders, which when mixed with water to form a paste, react slowly under ambient conditions to yield a hard mass used chiefly for structural applications. The mass is a porous material composed primarily of poorly crystallized calcium silicate hydrate. When mixed with a fine aggregate less than 2 mm (0.1 in.) in size, such as sand, it is termed a mortar. A typical cement-to-aggregate-to-water ratio is 1 to 3 to 0.5 by weight. When the material contains a coarse aggregate greater than 5 mm (0.2 in.) in size, such as crushed rock or river gravel, it is termed a concrete. A typical cement-to-fine aggregate-to-coarse aggregate-to-water ratio is 1 to 2 to 3 to 0.5 by weight. The cementitious portion of the mixture may also contain chemical and/or mineral admixtures (discussed below). Both mortars and cements can be used as castable or moldable materials fabricated in a plant or on-site with steel or fiber reinforcement added for more demanding mechanical performance.

Blended cements are calcined combinations of raw materials such as limestone, low alkali clay, iron ore, and gypsum furnishing the common oxides ingredients: CaO (C), SiO_2 (S), Al_2O_3 (A), Fe_2O_3 (F), FeO (f), and S or SO_3 ($\bar{S}$) (the single letters are the usual industry designation). About 5% gypsum or other calcium sulfate is added during grinding of the fired clinker to prevent rapid setting. Most cements contain various proportions of alite (C_3S), belite (C_2S), aluminate phase (C_3A), ferrite phase (C_4AF), and gypsum ($C\bar{S}H_2$). Table 12 lists the compositions of ASTM standard portland cement types, and Table 13 gives applications and compressive strengths.

Table 12 Approximate composition and fineness ranges for ASTM standard types of portland cement

Compound/property	Composition, wt% /property value				
	Type I	**Type II**	**Type III**	**Type IV**	**Type V**
C_3S	42-65	35-60	45-70	20-30	40-60

Portland/blast	Contains blast	General construction	8.6	1.2	13.1	1.9	25.3	3.7	45.0	6.5	53.3	7.7

The amount of MgO (periclase) in the cement as well as the sodium and potassium levels must be controlled to preserve water and chemical durability. Insoluble silica residue and hydration and carbonation products must also be kept within limits. Impurities can result in additional cement phases or different crystal forms not discussed above. Variations in raw materials, raw material processing, and kiln construction and operation can cause different clinker microstructure with resulting differences in performance.

Admixtures, finely divided materials blended with portland cement, can have significant effects on performance. Pozzolanic mineral additives are most common. These are siliceous or aluminosilicate materials that react with calcium hydroxide and water to form cementitious compounds at ambient temperatures. From 5 to 30% by weight may be added to the cement. Chemical admixtures are water-soluble organic compounds or inorganic salts added in small quantities (0.1 to 2%). Admixtures can significantly alter set time and/or reduce the amount of water required.

Concretes are composed of cement (with or without admixtures) and inert aggregate and reinforcement intended to maintain their form and mechanical properties in the hardened cement. They are formulated to provide suitable workability prior to setting and a required minimum compressive strength with time. To minimize cost, aggregate should be maximized. Greatest final environmental durability is often achieved with a minimum water-to-cement ratio and excess cement to ensure that all spaces between aggregates are filled. Reinforcing steel can be incorporated to provide strength, particularly in tension, and prevent catastrophic failure.

A number of new cements have been developed with significant strength and toughness enhancement (Table 14). These materials have low water-to-cement ratios, and low porosity is an important factor in their relatively high compressive and flexural strength. Special processing also prevents macrodefects such as bubbles, which decrease strength. Densified-with-small-particle (DSP) cements contain fly ash, silica fume, and superplasticizer in their formulation. Macro-defect-

free (MDF) cements incorporate a small amount of polymeric material and one of a number of reinforcement fibers. Calcium-aluminate-base cements can also show superior properties to portland cement and are particularly useful for high-temperature applications. They can also show significant durability to water if fired to sufficient temperature to promote full phase development.

Table 14 Mechanical properties of cements

Material	Strength, MPa	Fracture toughness, MPa
Conventional cement paste	7-10	0.2-0.4
Conventional concrete	2-3	0.2
Conventional fiber reinforced concrete	6-13	5-21
High-strength concrete	8-11	0.7-1.5
DSP cement	15-25	0.4-0.5
MDF cement	150-200	3
Glass fiber reinforced MDF cement	70-124	1.2-2.5
Polymer fiber reinforced MDF cement	54-120	1.7-2.8
Kevlar fiber reinforced MDF cement	58-128	2.1-5.3
Carbon fiber reinforced MDF cement	91-123	2.7-3.2
Aluminum fiber reinforced MDF cement	94-127	2.5-2.8

Engineering Ceramics

Ceramics that exhibit superior properties for demanding engineering applications are called *engineering ceramics.* If they are established materials, they are often referred to as *technical ceramics. Advanced ceramics* are relatively new materials or materials that show exceptional properties at the performance edge of ceramic technology. These terms are used interchangeably here, and mechanical performance is stressed. Several examples of engineering ceramics are presented earlier in this article. A major proportion of refractories are used for demanding engineering purposes and can be classed as technical ceramics. Porcelains and chinas used for electrical and chemical ware applications also could be classed as technical ceramics. Some of the new high-performance cements and concretes can be regarded as advanced materials. The discussion centers on newer monolithic materials with higher performance. A summary of properties of engineering ceramics is given in Tables 15, 16, and 17.

Most engineering ceramics are made from relatively pure powders of well-characterized components with little batch-to-batch variability. Controlled powder-processing techniques and consolidation are employed. Powder agglomeration is avoided as it can lead to inhomogeneity and large pores, which can act as strength-limiting intrinsic flaws and deteriorate other properties. Most advanced ceramics are fired as close to full density as is possible. With rare exceptions, porosity detracts from performance. Development of improved materials concentrates on relationships among composition, processing, microstructure, properties, and performance. Considerable understanding and new basic principles have been achieved during the past two decades and are emphasized in this section. A few examples of important new or developing materials are presented.

Structural Ceramics

Structural ceramics are intended to resist significant loads, be fracture tough, provide beneficial tribological properties, and/or exhibit wear resistance, often taking advantage of the good performance of ceramics at elevated temperature and in corrosive environments. Ceramics also provide high stiffness and low weight. As indicated, microstructural uniformity and low porosity are very important to reliable, high performance. Applications include wear materials, bearings, cutting tools, automotive parts, power-generation equipment, biomedical prostheses, and various aerospace/military uses. Many of the newly developed materials show exciting performance (Table 15) and are receiving increasing industrial acceptance.

Optimization of strength and toughness are often at odds in terms of microstructure. Usually a fine grain size is required for strength, while toughness is enhanced by elongated grain structures that are quite large. Well-engineered efforts to introduce elongated grains can result in an optimal elongated grain microstructure for strength and toughness. Figure 6 shows such an optimum for silicon nitride, an important advanced ceramic for heat engine applications. Phases with elongated grains or whiskers may be added as a reinforcement in the starting batch material. When elongated grains are grown in situ during sintering and/or subsequent firing, the resulting material is said to be self-reinforced. These reinforcements may be distributed isotropically or anisotropically depending on the production method.

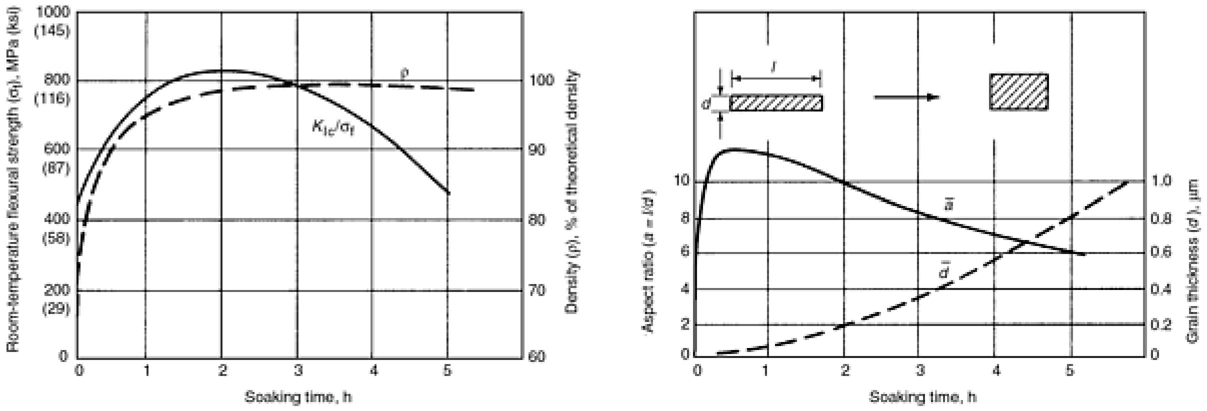

Fig. 6 Changes in flexural strength (σ_{Ic}) and fracture toughness (K_{Ic}) of silicon nitride as a function of aspect ratio and diameter of β-grains. Values of (K_{Ic}) and σ_f vary directly with the microstructure.

The grain structure that results from sintering depends strongly on the grain (powder) size and grain size distribution of the starting material as well as minor additive sintering aids and grain growth inhibitors. One approach to achieving fine ultimate grain size and high strength is to use very fine, uniform starting powder grain size. Some success has been found using uniform nanoscale powders, although such powders do complicate microstructural (final property) control during the materials handling and forming stages. Pore structure and grain growth interact and must be controlled; this can be achieved with selected additives and controlled firing time/temperature (Fig. 7) to minimize porosity and control grain growth. The existence of a few larger starting particles coupled with the effects of additives can cause exaggerated grain growth (Fig. 8). Such grains can act as strength, inhibiting flaws whether on the surface or in the interior of a ceramic. This can also be a method for introducing elongated particles for toughening.

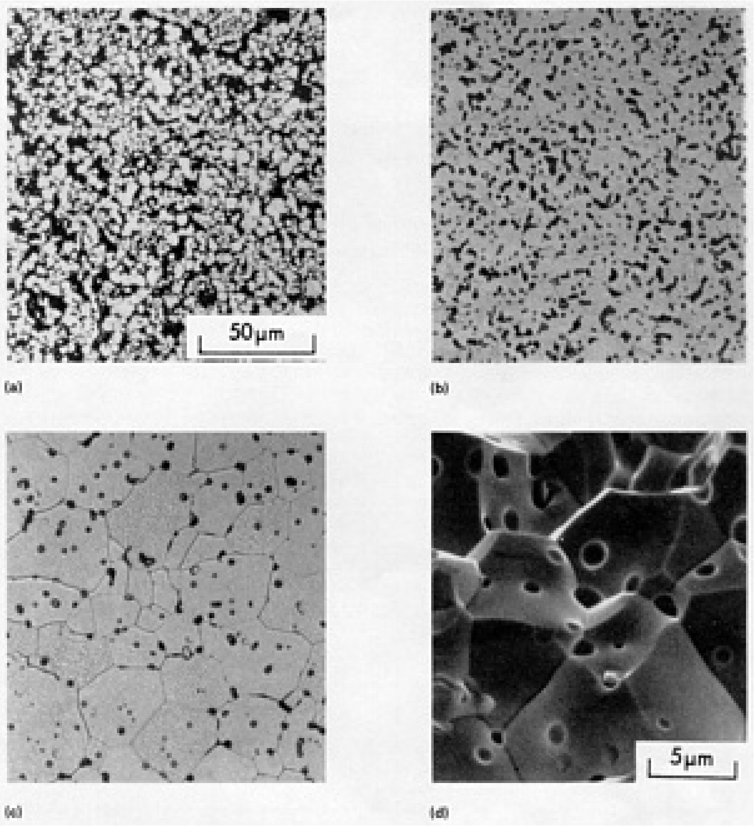

Fig. 7 Progressive densification and grain growth at several stages of sintering: (a) initial stage, (b) intermediate stage, (c) final stage, and (d) fracture surface. The fracture surface micrograph shows the desirable placement of spherical pores on grain boundaries in the final stage of sintering.

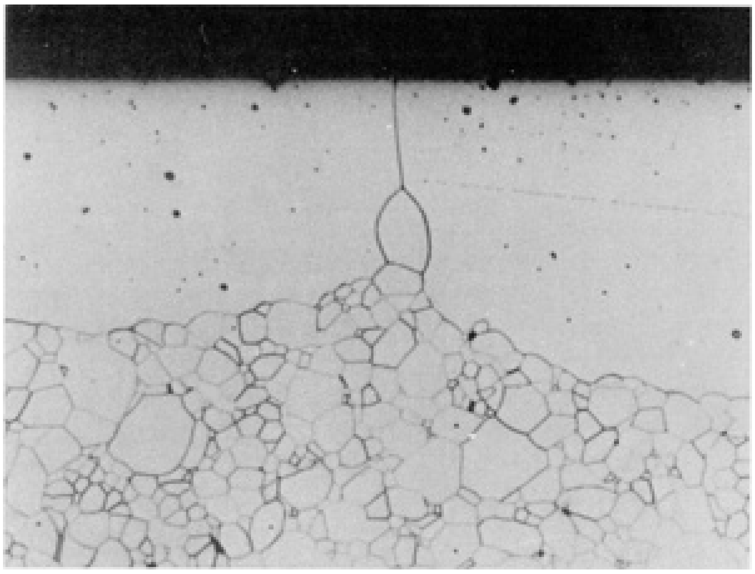

Fig. 8 Evaporation of MgO from the surface region of sintered MgO-doped Al_2O_3 that led to exaggerated grain growth. Source: Ref 7

The sintering additives and impurities can significantly affect final properties. Frequently, they form a glassy phase on grain boundaries that limits the strength and the high-temperature strength of a structural ceramic. Figure 9 shows that hot-pressed silicon nitride (HPSN) and hot isostatically pressed silicon nitride (HIPSN) have significantly higher strength than silicon nitride materials with more grain-boundary phase. The drop-off in strength above about 1100 °C (1850 °F)

can be attributed to softening of a thin grain-boundary layer in the higher-performance materials. Another view is that the grain-boundary phase may provide some toughening at elevated temperature.

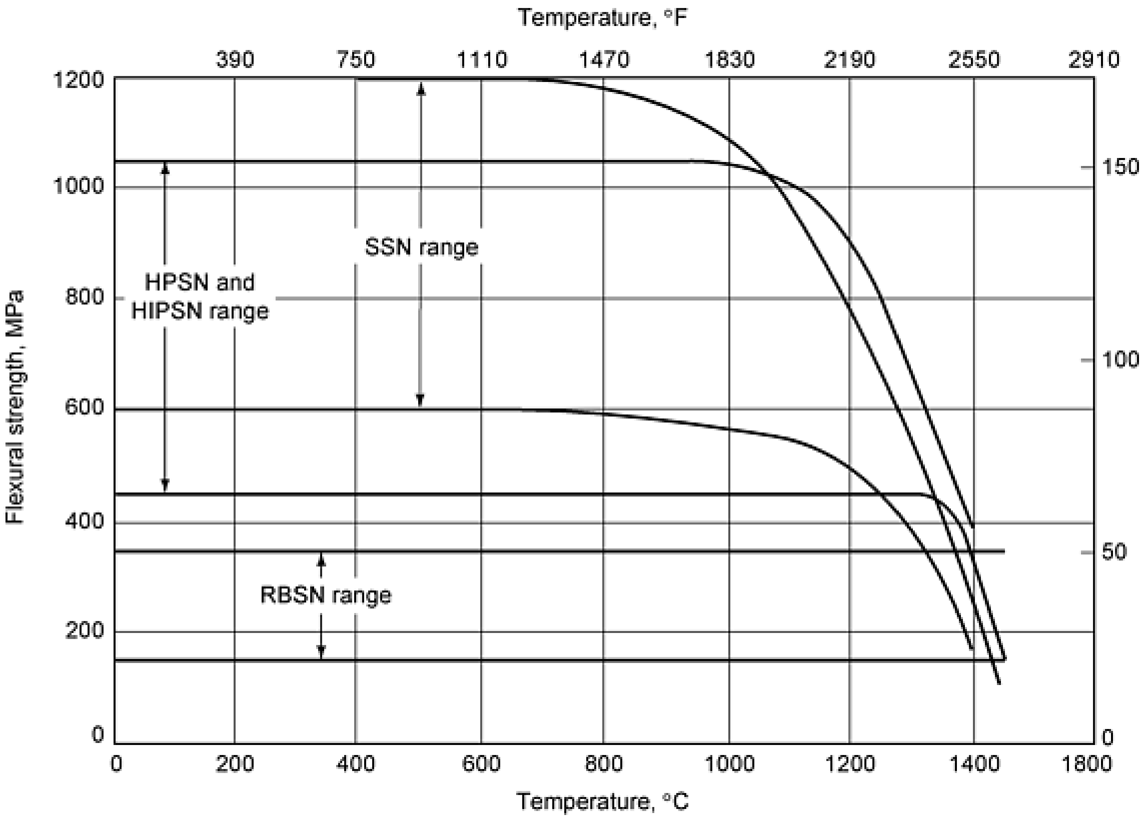

Fig. 9 Variation of flexural strength with temperature for various types of silicon nitride ceramics. SSN, sintered silicon nitride; HPSN, hot-pressed silicon nitride; HIPSN, hot isostatically pressed silicon nitride; RBSN, reaction-bonded silicon nitride

While texture--directional grain structure and/or crystal orientation--exists in many ceramics, its effect on mechanical behavior is not well documented. Some hot-pressed carbide and nitride ceramics have been seen to have as much as a 50% difference in strength relative to hot-pressing direction. The honeycomb monolith for catalytic converters is extruded green with grain orientation of the calcined kaolinite, talc, and alumina, which are its main constituents. After vitrification and cooling, cordierite forms with an orientation that has high strength and low thermal expansion in the long direction of the catalyst support. This is necessary to resist thermal shock failure of the part. In addition to controlling texture, the fine pore structure must maximize surface area for platinum catalyst deposition.

Alumina (Al_2O_3) ceramics are transition materials between technical and advanced ceramics. Alumina is used for such diverse application as electronic substrates, spark plugs, containment and insulating refractories, bearings, chemical containment vessels, water faucet valves, medical prostheses, and halogen lamp enclosures. It is also used for windows (infrared and nonscratch watch crystal) in its single crystal form, sapphire. It displays good strength, chemical inertness, wear resistance, and refractoriness. Alumina ceramics are usually classified according to their nominal alumina content, for example 96% alumina and 99.5% alumina. These are not specific materials because the percentage refers to the weight percent of alumina raw material in the body and many different grades of alumina can be used. The remaining percentage can be any additive, although similar additives are used for most materials. The higher level aluminas, such as 99.5% alumina, are usually made from a high quality technical grade of alumina with about 0.5% magnesia addition. There are usually low level impurities in the alumina which should be summed with the additive quantity to get the overall composition. The additive plus impurities form glass grain boundary phases, which have an important effect on properties. Some alumina dissolves into the glassy phase so that the amount of glass can be several times the amount of additive. For 96% alumina, an additive of silica and alkaline earth oxides is usually part of the formulation. The author has seen this composition vary widely among manufacturers--particularly among small job shops. Switching from one manufacturer to another can result in a rather different product.

A "higher" alumina, one with a greater alumina content, will generally show superior mechanical, thermal, and chemical resistance properties at a greater product cost for the same density (porosity). However, as more additive is incorporated in the alumina ceramic, firing to nominally full density can be done at lower temperature and in shorter time. Higher density results in superior performance, with the exception of thermal insulation, for which porosity is desired. The relationship among the amount of grain boundary glass, the fired density, and the firing cost must be engineered for the particular application.

The specific additives also have a major effect on properties. For example, a more soluble grain boundary phase (more glass modifier ions) can severely impair chemical resistance of even a very high alumina. Alumina grains may also be pulled out of the surface of a weak grain boundary glass under frictional loading. Thus, a valve used for dispensing water-based chemicals may deteriorate rapidly if the wrong additives and starting alumina grade are used. The observed differences in metal joining to alumina result in part because the grain boundary glass composition can affect metallization of alumina electronic substrates. Translucent alumina used for halogen lamp enclosures uses grain boundary glasses that match the refractive index of alumina so that light is not reflected and dispersed from alumina grain boundaries. The author and others have found that careful selection of the grain boundary glass and high microstructural uniformity can lead to major strength and toughness advantages. That is, a major composite strengthening (about double) and toughening effect relative to 99.5% alumina can be engineered by "adding" a major amount of suitable grain boundary glassy phase through the selection of a suitable composition and processing route. It has also been found that crystallizing the grain boundary by heat treatment can lead to considerable strengthening. The concepts of composite formulation and grain boundary heat treatment are now being applied to some proprietary advanced alumina (and other ceramic) formulations.

Transformation-Toughened Zirconia. One remarkable method of microstructural control to yield improved properties is transformation (martensitic) toughening, first observed in zirconia (ZrO_2) ceramics. Zirconia exhibits phase transformations from cubic to triclinic to monoclinic as its temperature is lowered. If the zirconia is stabilized with such materials as yttria, calcia, or magnesia, the triclinic phase can be preserved in a metastable state at ambient (or other temperature) dependent on the amount of additive, heat treatment, cooling rate, grain size, and grain size distribution. As shown in Fig. 10, the tetragonal zirconia can transform to monoclinic under the influence of a crack tip stress. The transformation may cause the crack tip to deflect due to the shear stress (about 1 to 7%) or to be impeded by the local compressive stress (>3%). A very significant toughening effect results (see Fig. 11), which can as much as triple K_{Ic}. A fracture toughness similar to high-strength aluminum alloys results, which makes the ceramic very resistant to impact failure. Flexural strengths as great as 2000 MPa (300 ksi) have been observed. It was found that these (and other structural ceramics) exhibit *R*-curve behavior in which the K_{Ic} increases as a crack grows in slow crack growth.

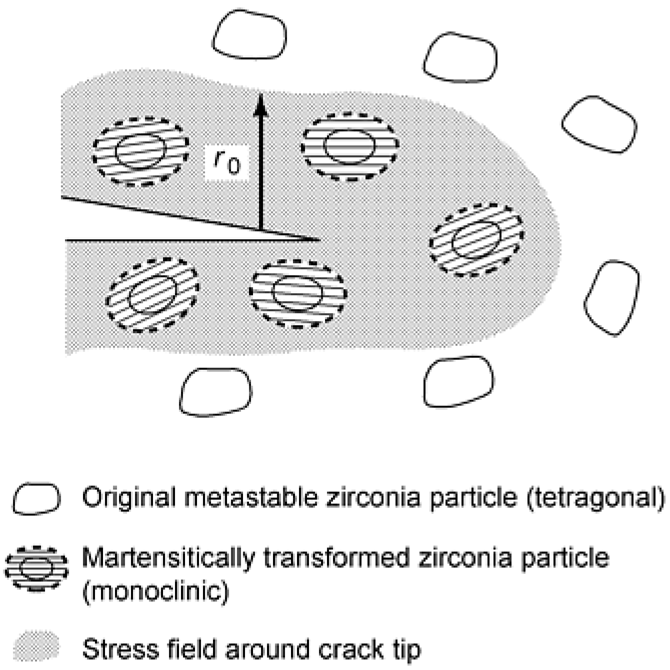

Fig. 10 Stress-induced transformation of metastable ZrO_2 particles in the elastic stress field of a crack

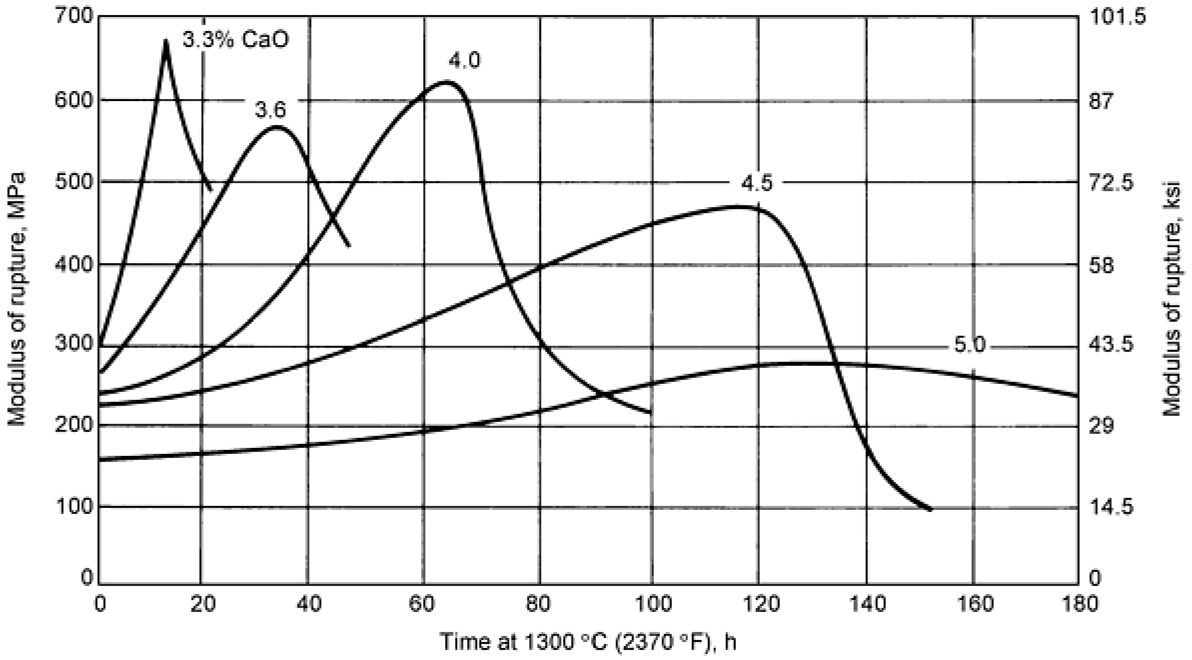

Fig. 11 Strength/aging curves obtained by heat treatment at 1300 °C (2370 °F) for various compositions of CaO-PSZ materials

Zirconia-toughened ceramics also show remarkable resistance to abrasion and wear because surface layers transform under stress (Fig. 12), creating a highly compressive surface layer. This layer resists abrasion and the state of compression will renew if it is worn away. Zirconia cutting tools, thread guides, and wear surfaces have been found to last ten or more times longer than their tool steel counterparts in industrial applications. Some consumer applications such as household knives and scissors as well as breakproof buttons have been commercialized. Metastable tetragonal zirconia particles can also be added to various engineering ceramics and provide a substantial toughening effect. This is shown for alumina, silicon nitride, and silicon carbide in Fig. 13.

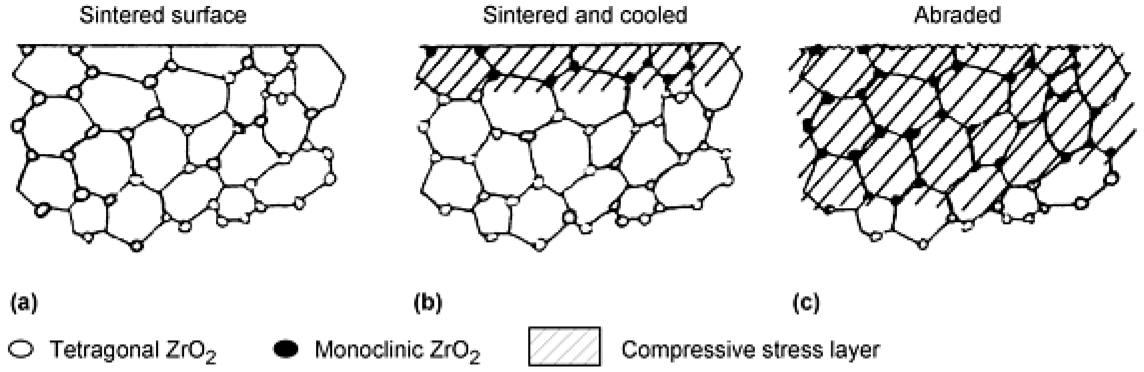

Fig. 12 Diagram of a section through a free surface at (a) the sintering temperature. On cooling, particles of ZrO_2 near the surface (b) transform due to reduced constraint, developing a compressive stress in the matrix. The thickness of this compressively stressed layer can be increased (c) by abrasion or machining.

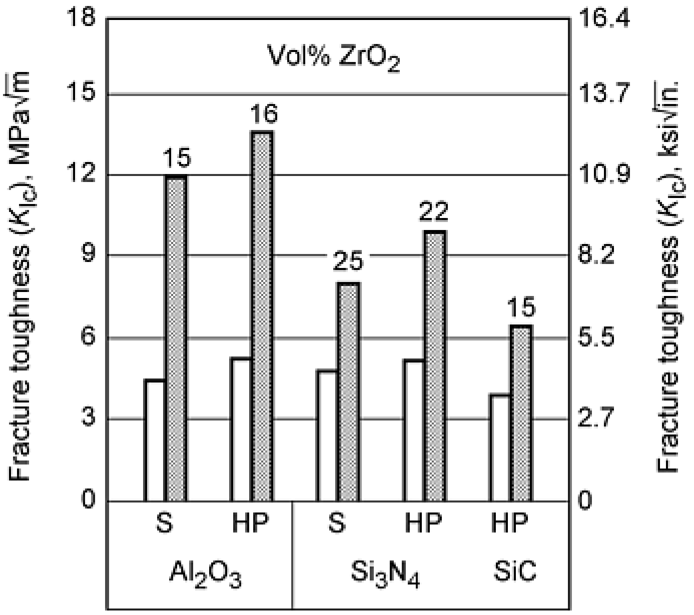

Fig. 13 Increase in fracture toughness (K_{Ic}) observed upon inclusion of zirconia particles in the ceramic matrix. The volume of zirconia added is shown in the shaded histogram. The toughness of the matrix material is shown in the adjacent white histogram bars. S, sintered. HP, hot pressed

The strength and toughness properties of the transformation-toughened materials are useful only to slightly elevated temperature. Applications include industrial knives and cutting tools as well as consumer knives for home and sports use. Ceramic cutting tool blades retain their edge many times longer than the best metal knives--indefinitely in kitchen use. The material is also used for guides and wear surfaces in highly abrasive and corrosive environments. An intriguing application is for nonsparking hammers for flammable environments. The toughened materials are also being used in a variety of tool and die applications. A major success in biomedical applications has been it use as the ball for ball-and-socket joints such as the hip. The chemical inertness of zirconia coupled with the abrasion resistance instilled by transformation toughening have resulted in commercial development of zirconia valves for severe chemical and mechanical environments. Another novel application is for shirt buttons that do not break during aggressive laundering and pressing.

R-curve behavior is possibly the most exciting mechanical material discovery in recent history. It was first observed in zirconia ceramics, but has since been seen for alumina, reinforced materials, composites, and nonoxide ceramics. These materials show "*R*-curve" behavior when the progressive resistance to crack propagation is measured. This is shown schematically in Fig. 14. As a crack propagates, increased resistance to propagation occurs. *R*-curve behavior depends on a well-engineered microstructure. A variety of fiber, particulate, grain boundary and second-phase reinforcements impede or resist crack propagation. A number of systems have been developed, including the zirconia based system mentioned above, with toughness enhancements of a factor of two or more as compared to monolithic ceramics. The fracture toughness is not a single value as reinforcements behind the crack bridge it and hold it together. A microscopic crack could grow several centimeters before the maximum toughness value is achieved. This is something quite new in mechanical behavior of materials and suggests a new approach for relatively brittle materials--a margin of safety can be engineered into the system by employing the increasing resistance to crack propagation over a range of crack sizes. This could imply immunity to failure under conditions of controlled use.

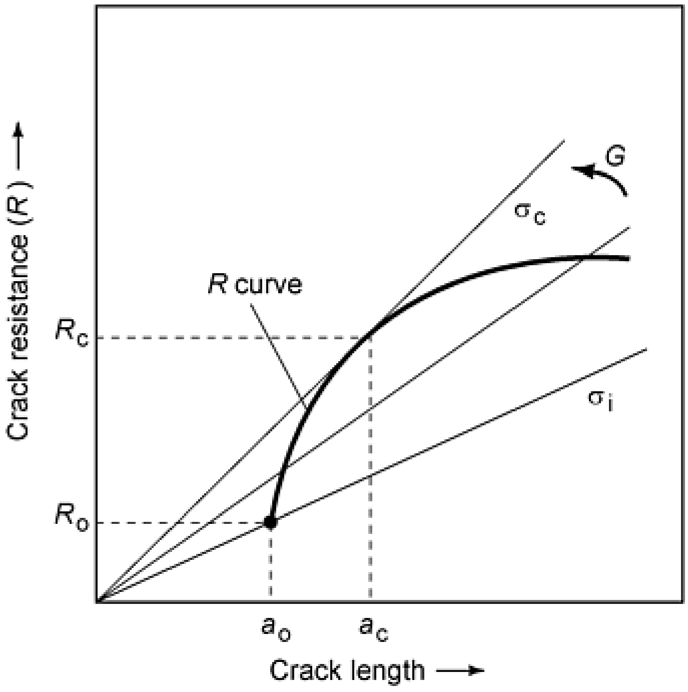

Fig. 14 Schematic representation of *R*-curve behavior. Crack resistance increases with crack length, so catastrophic failure will occur only when the strain energy release rate (*G*) exceeds the critical crack resistance value (R_c). a_o, initial crack size; a_c, critical crack size

Nonoxide ceramics such as silicon nitride (Si_3N_4), silicon carbide (SiC), and boron nitride (BN) show significant strength and toughness at ambient and high (over 1300 °C) temperatures. They are also relatively stable in sever chemical environments because of the covalent nature of their bond structure. The advanced nonoxide ceramics are often called "covalent ceramics." These materials also show a rather low friction coefficient and good wear resistance.

Silicon carbide and silicon nitride have been shown able to sustain high tensile loads at temperature in excess of 1500 °C (2730 °F) and 1300 °C (2370 °F), respectively. They are being implemented for next generation of auxiliary aircraft and turbines for electric power generation and rocket engines. The increased material operating temperature can result in a simpler and more efficient part, without the cooling passages required for a conventional metal turbine blade. For many high-temperature applications, most structural metals show poor creep resistance. These ceramic materials have relatively high fracture toughness and low thermal expansion, making them resistant to thermal shock and mechanical stress at elevated and room temperature. Flexural strengths exceed 700 MPa (100 ksi) for silicon nitride and 400 MPa (60 ksi) for silicon carbide. An example of the strength of these materials with temperature is shown in Fig. 15. These materials are being used in high-performance automotive applications as turbocharger rotors, valves, valve seats, and other parts. They are used regularly for the precombustion chamber and valve parts in truck applications.

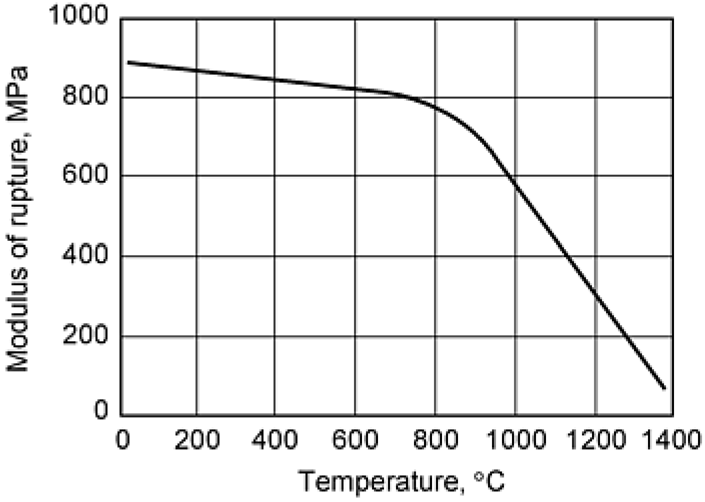

Fig. 15 Bend strength of a typical commercial monolithic silicon nitride as a function of temperature. Higher strength with temperature can be achieved with control of composition and processing, and by the incorporation of reinforcements.

The low friction and wear characteristics of nonoxide ceramics have resulted in a variety of bearing applications for severe environments and elevated temperatures. Other applications include wear plates for grinding and milling machinery, water jet nozzles, and high performance cutting tools. The inertness of the covalent ceramics has been applied to containment of chemically active materials, particularly at elevated temperature.

Grain boundary phases--resulting from additives, oxidized material present on raw material particle surfaces, and oxygen introduced during processing--have a strong effect on properties. When suitable in chemistry and distribution, these secondary phases provide a composite strengthening effect, high temperature resistance, and fracture toughness. However, the reverse effects on properties can occur without sophisticated engineering of the chemistry and microstructure of the nonoxide ceramic. Many of the nonoxide ceramics have been engineered to contain randomly oriented, elongated second-phase particles, which can be "grown" during firing or mechanically mixed in the starting powders. Some materials, such as silicon nitride, have also been "self-reinforced" with elongated grains of the same material, which grows during the sintering process. These materials can provide superior mechanical strength and toughness at ambient and high temperature. Several commercial materials of this type display strong R-curve behavior, which may account for their superior strength and impact resistance in application.

Continuous (ceramic) fiber-reinforced ceramic matrix composites (CFCMCs) show a unique resistance to conventional brittle failure. They also demonstrate a moderate increase in elastic modulus because of the incorporation of high-modulus fiber. The composite strength can be increased significantly, and the material demonstrates a unique "graceful" failure. The ceramic or glass matrix of the composite will fail at a stress higher than the monolithic ceramic, as shown in Fig. 16. Even when the matrix has failed completely the composite does not break. Instead, fibers bridge the crack and hold the material together. In order for matrix cracks to deflect around the fiber the fiber matrix bond cannot be too strong. This is accomplished by providing an interfacial debonding material between fiber and matrix. If the fibers and matrix are strongly bonded, failure cracks proceed straight through the fiber and little strengthening is achieved. For the weakly bonded interface case the entire matrix can crack without fiber failure. Such mechanisms lead to a substantial increase (3 to 4 times is common) in ultimate strength (Fig. 16). A noncatastrophic failure (ultimate strength in Fig. 16) results in which further energy is absorbed in fiber fracture and pull out of the fiber from the matrix. In a tensile test, the sample can be visibly two pieces, with a visible gap, and yet hold together. The result is a new stress-strain behavior, for which the correct design criteria are not yet fully determined. A noncatastrophic failure is possible, and there is some indication that partial failure in the form of matrix cracking can be repaired by a "crack healing" technique. This behavior requires a controlled bond between the fiber and matrix. This bond cannot be too strong in order to achieve the property enhancements. The distribution of fiber has a strong influence on strength and work of fracture (area under a stress-strain curve).

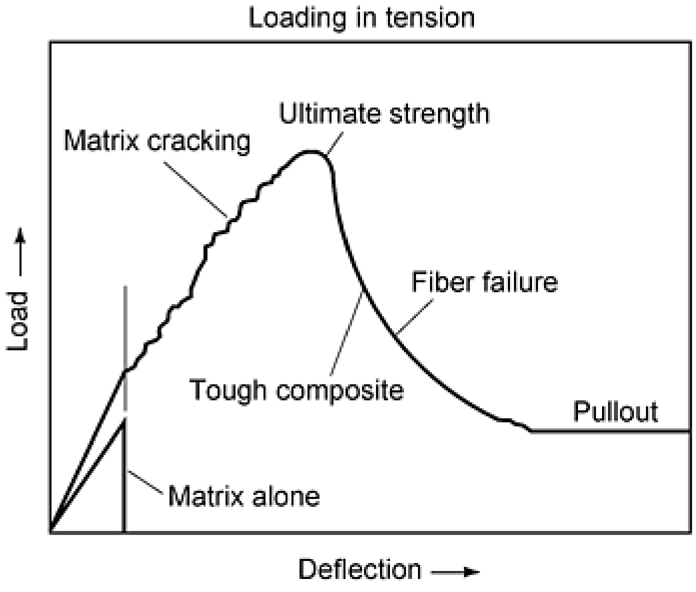

Fig. 16 Schematic load-deflection curve for a fiber-reinforced ceramic-ceramic composite. The increase in elastic modulus (initial slope) is imparted by the high-modulus fiber. An increase in strength occurs to the start of matrix cracking. The ultimate strength is significantly greater than that of the matrix alone. The crack aperture continues to be held together by fiber until fibers pull out of the matrix.

The first matrices for successful ceramic fiber reinforced composites were glasses such as lithium aluminosilicates (LAS glass). These materials were limited to temperatures of several hundred degrees Celsius. Newer, high temperature ceramic matrix composites have been developed that can be used at temperatures well over 1000 °C. Not only the thermal and oxidation resistance of the matrix is important. The environmental resistance of the fiber is also a matter of concern. If the matrix cracks and the fiber is susceptible to oxidation, as, for example, in the case of common silicon carbide reinforcements, the fiber will deteriorate with exposure. Most such fiber is derived from the pyrolysis of organic precursors, and residual oxygen can also detract from high-temperature fiber strength. The temperature resistance has been improved for silicon carbide fiber by improved process control in its manufacture. More oxidation resistant alumina and aluminosilicate fibers have been developed but are still relatively developmental.

The cost of both the fiber and production of a finished composite has prevented widespread application. High-quality silicon carbide fiber costs hundreds of dollars per pound while special fiber may cost as much as several thousand dollars a pound. Highest temperature resistance can be achieved by carbon-carbon composites, but these require proprietary protective coatings to keep from burning in air. Relatively high composite processing costs must be added to these raw material expenses. Much of the activity in this area has been fostered by military and aerospace applications where devices are already being tested and/or used. One application with some promise is electric power generation turbines. An example of a potential commercial application (is for turbine combustor linings. In such an application a 1.25% decrease in pressure drop could be achieved with a 0.75% increase in power and a 0.4% increase in efficiency. This would yield fuel savings of $370,000 per year in a typical turbine as well as significantly reduced emissions.

One new extension of the composite technology is the area of biomimetics. Composites can be designed which mimic the structure of biological systems such as wood, bone and shells. Such materials are of interest because they are often uniquely tough and strong. Composite principles can be extended to these materials. A wide variety of forming methods are used to produce these and other ceramic-fiber ceramic-matrix composites.

Substantial improvements have also been made in ceramic-fiber ceramic-matrix composites containing long fiber ceramic reinforcement. Both increases in strength and work of fracture can be achieved relative to the matrix material alone. Complete failure of the matrix can occur, while fibers still hold together the crack aperture. This implies both safety from catastrophic failure and potential for repairability.

Electronic and Magnetic Ceramics

Ceramics serve in many electronically passive and active roles. Electronic substrates and packages for hybrid microelectronics are made of alumina, beryllia, aluminum nitride, and boron nitride. Transducers and actuators are made from various formulations based on lead zirconate titanate (PZT), lead magnesium niobate (PMN), and lead magnesium titanium niobate (PMTN). Oxygen sensors are made from zirconia and temperature sensors from nickel and iron oxides and pyroelectrics ($LiTaO_3$). Barium titanate and other related materials are used for small, high-reliability ceramic capacitors. Semiconducting ceramics such as silicon carbide show promise for elevated-temperature applications, while high-temperature (high T_c) superconductors based on $YBa_2Cu_3O_{7-x}$ are already being used in some devices such as superconducting quantum interference devices (SQUIDs).

Hard and soft magnetic ceramics can be made from a variety of ferrites or garnets and magnetoplumbites or γ-Fe_2O_3. Applications include recording tape, high-speed switching (miniature) transformers, inductors, microwave generators, cryogenic refrigerators, and recording heads.

The properties of both electronic and magnetic ceramics depend very strongly on composition, including trace chemistry, and structure of raw materials as well as the processing and firing route chosen. Subtle changes in microstructure, chemistry, chemical distribution, grain-boundary material, and oxidation state can have profound effects on properties. It is beyond the scope of this article--which has focused on mechanical performance--to develop these issues further, but many of the considerations presented for mechanical applications can be extended to electronic and magnetic materials.

Effects of Composition, Processing, and Structure on Properties of Engineering Plastics

A.-M.M. Baker and C.M.F. Barry, University of Massachusetts Lowell

Introduction

PLASTICS are so prevalent in our lives that it is easy to overlook the vast differences in their properties and how specialized many polymers have become. Consider the differences between aramid bulletproof vests and the polyurethane

foam used in pillows. Why can plates made of crystallized polyethylene terephthalate be microwaved successfully while plastic film wrap (polyvinylidene chloride) has poor elevated-temperature properties? Consider how different polycarbonate is from plastic foam (expanded polystyrene); why is one plastic suitable for motorcycle helmets and the other for disposable coffee cups?

The answers to these questions lie in the chemical nature of the plastic and in the morphology assumed by the polymer chains. Plastics are polymeric materials that have been compounded with fillers, colorants, reinforcing agents, thermal stabilizers, plasticizers, and other modifying agents or additives. Table 1 shows the structures and transition temperatures of selected polymers. This article clarifies the importance of chemical composition and morphology to mechanical properties and reviews basic plastic processing techniques.

Table 1 Structures and properties of selected commodity and engineering plastics

Common name	Tensile strength, MPA	Glass transition temperature (T_g), °C	Melting temperature (T_m), °C	Repeating unit
Low-density polyethylene (LDPE)	10-12	-120	110	High-density polyethylene (HDPE)	26-33	-120	135	Linear low-density polyethylene (LLDPE)	15-32	-120	125	 where x = 1 to 5
Isotactic polypropylene (PP or i-PP)	31-37	-10	165	Cis-1,4-polyisoprene, natural rubber	. . .	-67	15-50	Trans-1,4-polyisoprene, gutta percha or balata	. . .	-71	56-65

(a) When vulcanized.

The difference between plastics and metals or ceramics is that plastics can be melted at relatively low temperatures and formed into a variety of shapes. Advantage can be taken of their non-Newtonian flow behavior in selecting a suitable molding or finishing process. Atoms can be specifically selected to design a polymer with the desired properties through a fundamental understanding of how submolecular, molecular, intermolecular, and supermolecular forces behave. A polymer scientist can custom polymerize a plastic to meet specific application requirements. This article starts at the most fundamental building-block level, atomic, then expands to a discussion of molecular considerations, intermolecular structures, and finally supermolecular issues. An explanation of important physical properties, many of which are unique to polymers, follows, and the final section discusses processing techniques.

More detailed information about properties and performance of polymers is provided in *Engineering Plastics,* Volume 2 of the *Engineered Materials Handbook,* and in the *Engineered Material Handbook Desk Edition,* both published by ASM International. Related coverage in this Volume is contained in the articles "Design with Plastics" and "Design for Plastics Processing."

Effects of Composition, Processing, and Structure on Properties of Engineering Plastics

A.-M.M. Baker and C.M.F. Barry, University of Massachusetts Lowell

Composition: Submolecular Structure

Polymers are organic molecules, with the carbon atom playing a critical role in developing their final properties. Hydrogen, oxygen, nitrogen, fluorine, and chlorine are among the many atoms that are built into polymer structures in order to tailor specific properties. Table 2 lists common atoms found in plastics and gives both the electronegativity (relative tendency to attract electrons) of the atom, as well as the number of unpaired electrons present in the outer shell. The number of unpaired electrons governs the number of covalent bonds the atom will form. The electronegativities of the constituent atoms that make up the polymer control its polarity. This, in turn, regulates the ability of the polymer to form the secondary bonds (e.g., hydrogen bonds) that have marked effects on the final thermomechanical properties.

Table 2 Number of covalent bonds formed and electronegativities of atoms commonly found in plastics

Atom	Total number of electrons	Number of unpaired electrons	Number of covalent bonds formed	Electronegativity[a]
H	1	1	1	2.1

C	6	4	4	2.5
N	7	3	3	3.0
O	8	2	2	3.5
F	9	1	1	4.0
Si	14	4	4	1.8
P	15	3	3 or 5	2.1
S	16	2	2 or 6	2.5
Cl	17	1	1	3.0
Br	35	1	1	2.8

(a) Electronegativity data from Ref 7

Carbon is of fundamental importance as the most basic building block of all polymers. Carbon contains six valence electrons, two of which are located in the inner, most protected orbital, and all or four of which are in the outer orbital. It is the presence of four outer orbital electrons (exactly halfway between zero and eight) that causes carbon to be a neutral atom. Consequently, the electronegativity of carbon is 2.5. Metal atoms tend to be large, with a propensity to lose electrons when forming bonds; thus, their electronegativities are lower than 2.5. Elements that tend to gain electrons have electronegativities greater than 2.5. Carbon atoms share electrons when forming bonds with other carbons and, while the resultant materials can vary dramatically from diamond to graphite to hydrocarbon polymers such as polyethylene, the neutral carbon-carbon covalent bonds are stable to heat and ultraviolet (UV) light exposure.

Because carbon can form four bonds, it may bond more than once with other carbon atoms. As shown in Fig. 1, carbon-carbon single bonds are relatively stable. While carbon-carbon double bonds are shorter (as evidenced by their greater bond dissociation energy), they are more subject to attack by atmospheric oxygen. Consequently, polymers, such as polyisoprene and polybutadiene, are usually compounded with antioxidants. Carbon-carbon triple bonds are even more sensitive to oxygen attack. Although these are rarely found individually in commercial polymers, alternating triple and single bonds (called conjugated triple bonds) impart electrical conductivity to polymers, such as polyacetylene. Conjugated double bonds are more rigid. Rings of carbon-carbon single bonds, such as found in cyclohexane, assume nonplanar configurations. In contrast, rings of conjugated carbon-carbon double bonds, which occur in benzene, phenyl groups, and phenylene groups, are rigid and planar. As is discussed later in this article, these groups impart rigidity to polymers such as polystyrene (PS) and polycarbonate (PC).

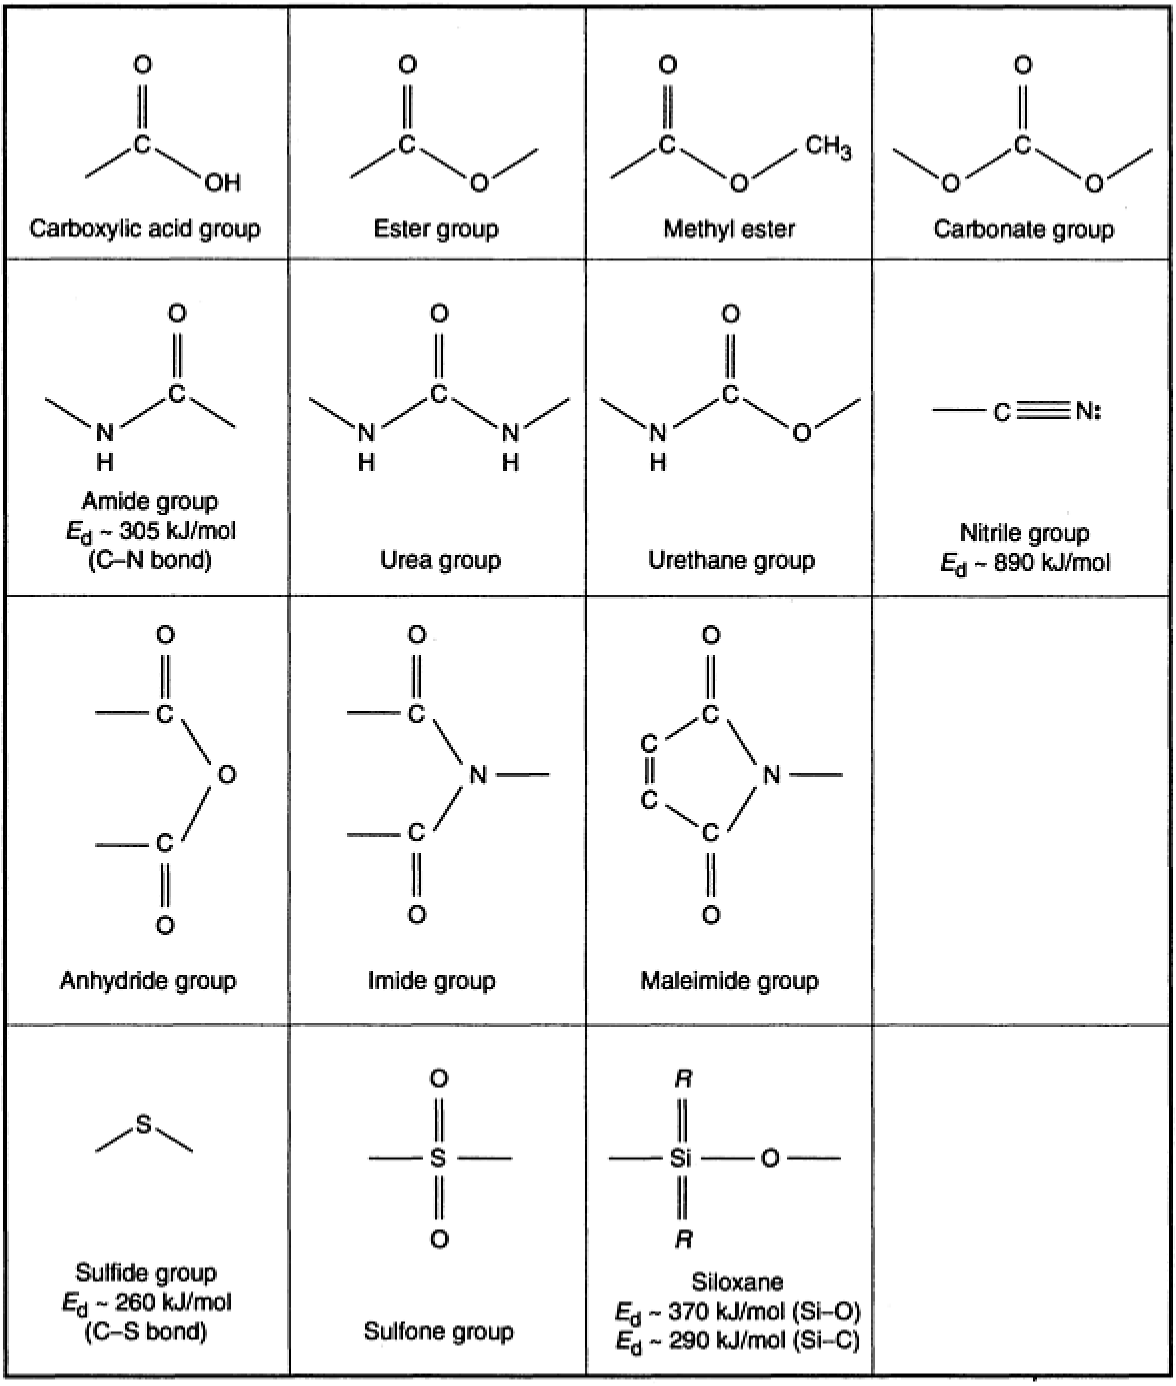

Fig. 1 Chemical groups and some bond dissociation energies (E_d) used in plastics. Adapted from Ref 8; dissociation energies from Ref 9

Attaching other elements to a carbon atom introduces polarity, which changes the balance of the electron cloud. This can be regarded as either reducing the stability of an all-carbon material, or increasing its reactivity. Introducing polarity to the molecule through electronegativity differences between atoms has significant effects on thermal properties such as melting temperature (T_m) and mechanical properties such as Young's modulus (E). The presence of polar bonds produces higher thermal and mechanical properties in engineering plastics compared to those in nonpolar materials. Figure 1 presents chemical groups commonly found in plastics and the bond dissociation energies (E_d) for selected groups.

Hydrogen. Because the electronegativity of hydrogen, 2.1, is only slightly more electropositive than carbon, carbon-hydrogen bonds are almost as stable as carbon-carbon bonds. In the absence of atmospheric oxygen, carbon-hydrogen bonds have good thermal and UV stability. Materials containing aliphatic (i.e., noncyclic) carbon-hydrogen bonds, such as polyethylene (PE) and polypropylene (PP), are marked by low surface energies, low adhesion, and low coefficients of

friction. This makes PP automobile bumpers difficult to paint and is the why printing inks adhere poorly to untreated PE bags. Aromatic carbon-hydrogen bonds (for example, in a benzene ring) are stabilized by resonance and are more stable than aliphatic carbon-hydrogen bonds.

Hydrogen can also bond to elements other than carbon, such as oxygen, in the case of the common hydroxyl group, —OH. Due to the electronegativity of oxygen, the hydroxyl group is more polar and less balanced, making this bond more highly reactive than the previous bonds considered.

Oxygen. With an electronegativity of 3.5, oxygen introduces significant polarity to polymers. It is a unique atom in that it has two pairs of readily available unbonded electrons that can form fairly strong hydrogen bonds with neighboring molecules. These unbonded electron pairs also impart high surface energy to oxygen-containing polymers. Thus, such polymers have higher mechanical properties and provide better adhesion than nonpolar hydrocarbon polymers. Hydrogen bonds are further discussed in the section on intermolecular arrangements.

Carbon and oxygen are the components of several major functional groups shown in Fig. 1. The stability of the —C—O—C— ether bond is dependent on attached groups. Because aromatic ethers have a resonating system that includes the two electron pairs from the oxygen, the larger extended structure is stabilized through resonance. This contributes to the high thermal stability and high heat-distortion temperatures of engineering plastics such as polysulfones (PSUs) and polyetherketones (PEKs). In contrast, the bond of a hydrogen to an atom adjacent to the oxygen in an aliphatic ether (referred to as the α-hydrogen) is destabilized in the presence of the oxygen. Thus, polymers--such as polyvinyl acetals and cellulosics--exhibit instability because their —O—CH_2—O— linkages are particularly sensitive to acid hydrolysis.

The carbonyl group of ketones, esters, and carbonates (shown in Fig. 1) strongly absorbs UV light in the 2800 to 3200 Å range, thus leading to polymer instability and poor outdoor aging characteristics. The ester group may hydrolyze and degrade upon exposure to water; manufacturers capitalize on this reactivity to produce polyvinyl alcohol (PVOH) from polyvinyl acetate (PVAC). Polyvinyl alcohol is a water-soluble, film-forming polymer that finds extensive use in applications ranging from photographic film to packaging. Polyvinyl acetate is not water soluble and is used in adhesives, textile applications, and latex paint.

Nitrogen, with an electronegativity of 3.0, generally forms strong bonds with carbon and, as in the case of oxygen, the unbonded electron pair generates a highly polar molecule available to form secondary bonds. The presence of both oxygen and nitrogen in the amide, urea, and urethane groups leads to strong hydrogen bonding and high sensitivities to water in the corresponding polymers. An alternative bond that nitrogen can form with carbon is an extremely rigid triple bond. This nitrile group is instrumental in generating high-modulus, heat-resistant engineering plastics such as styrene-acrylonitrile (SAN) copolymers and acrylonitrile-butadiene-styrene (ABS).

Fluorine is the most electronegative of all elements, with an electronegativity of 4.0. Its small atomic radius means that the carbon-fluorine bond length is very short. The strong bonds it forms with carbon impart low surface energy to fluoropolymers and allow them to be used for nonwetting applications such as nonstick cookware. The carbon-fluorine bond is also low in friction, which is suitable for high-lubricity applications such as mold lubricants and self-lubricating gears and bearings. This bond is extremely stable to heat, UV light, and chemical exposure making it appropriate for high-temperature plastics and elastomers. Table 3 highlights the effects of different degrees of fluorination on maximum-use temperature from PE to polytetrafluoroethylene (PTFE). It is evident that the reduction in fluorine content generates thermal instability, but does result in a more easily processed polymer. Highly fluorinated plastics such as PTFE are not melt processible by traditional methods.

Table 3 Continuous service temperature as a function of degrees of fluorine substitution on polyethylene

Name	Continuous service temperature, °C	Repeat structure
PE	60-75	
PVF	100-120	PVDF	150	PTFE	250	
Source: Ref 10

Chlorine. While chlorine has seven valence electrons like fluorine, its larger atomic radius reduces its electronegativity to 3.0. Thus, chlorine bonds less strongly to carbon than does fluorine. The presence of such a large and electronegative atom generates polarity that has a marked effect on mechanical properties such as stiffness. A nonpolar molecule, PE, has a tensile modulus of 175 to 280 MPa and a T_m of 105 to 110 °C. Polyvinyl chloride (PVC), which substitutes a single chlorine atom onto the PE structure, has a tensile modulus of 2400 to 6500 MPa and a glass transition temperature (T_g) (amorphous) of 75 to 105 °C.

Composition: Molecular Structure

Polymer molecules contain multiple repeat units called mers. The number of repeat units can be varied and this strongly affects the thermal, mechanical, and rheological properties of plastics as shown in Table 4. Polymer size is quantified primarily by molecular weight (MW), molecular-weight distribution (MWD), and branching.

Table 4 Effect of molecular weight on polyethylene

Number of $-CH_2-CH_2-$ units	Molecular weight (MW)	Softening temperature, °C	Character of polymer at 25 °C
1	30	-169[(a)]	Gas
6	170	-12[(a)]	Liquid
35	1,000	37	Grease
140	4,000	93	Wax
250	7,000	98	Hard wax
430	12,000	104	Plastic
750	21,000	110	Plastic
1,350	38,000	112	Plastic

Source: Ref 11

(a) Melting point.

Molecular weight is generally defined as either number average ($\overline{M}_n$) or weight average ($\overline{M}_w$) depending on whether the length of each molecule is averaged according to numbers of molecules present at that length (as in the case of $\overline{M}_n$) or whether large molecules are more heavily considered (as in the case of $\overline{M}_w$). Equations 1 and 2 define $\overline{M}_n$ and $\overline{M}_w$, respectively, as:

$$\overline{M}_n \equiv \frac{\sum_{i=1}^{\infty} w_i}{\sum_{i=1}^{\infty} N_i} = \frac{\sum_{i=1}^{\infty} M_i N_i}{\sum_{i=1}^{\infty} N_i} \quad \textbf{(Eq 1)}$$

$$\overline{M}_w \equiv \frac{\sum_{i=1}^{\infty} M_i w_i}{\sum_{i=1}^{\infty} w_i} = \frac{\sum_{i=1}^{\infty} M_i^2 N_i}{\sum_{i=1}^{\infty} M_i N_i} \quad \textbf{(Eq 2)}$$

where w_i is the weight of polymer species i, N_i is the number of moles of species i, and M_i is the molecular weight of that species. If a polymer system has 7 moles of 20,000 MW species and 5 moles of 60,000 MW species, then the $\overline{M}_n$ and the $\overline{M}_w$ can be calculated as follows, according to Eq 3 and 4, respectively:

$$\overline{M}_n = \frac{(7 \cdot 20{,}000) + (5 \cdot 60{,}000)}{(7 + 5)} \cong 37{,}000 \qquad \textbf{(Eq 3)}$$

$$\overline{M}_w = \frac{(7 \cdot 20{,}000^2) + (5 \cdot 60{,}000^2)}{(7 \cdot 20{,}000) + (5 \cdot 60{,}000)} \cong 47{,}000 \qquad \textbf{(Eq 4)}$$

Because in the case of $\overline{M}_w$ the higher MW fractions of a polymer contribute more heavily, $\overline{M}_w$ is always greater than or equal to $\overline{M}_n$. $\overline{M}_n$ can be measured by methods that depend on end-group analysis or colligative properties such as osmotic pressure, boiling-point elevation, or freezing-point depression. $\overline{M}_w$ can be measured by light-scattering techniques or ultracentrifugation, both of which depend on the mass of species present (Ref 12).

As shown in Fig. 2, many physical and mechanical properties vary significantly as a function of MW, up to a threshold value, whereupon they level off asymptotically at higher MWs. Molecular entanglement can be dramatically demonstrated by the relationship of melt viscosity, η, to $\overline{M}_w$; melt viscosity being a measure of the tendency of the material to resist flow. Below a critical $\overline{M}_w$, denoted as M_c, there is little chain entanglement, and the melt viscosity increases linearly with $\overline{M}_w$ until it reaches the M_c threshold. At this point the melt viscosity increases as an exponential function of $\overline{M}_w$, with the exponent approximating 3.4 for many polymers, as shown in Fig. 3. In the elevated-slope region, molecular entanglements inhibit molecular slippage. The increased occurrence of physical chain entanglements associated with higher MWs accounts for the elevation of melt viscosity.

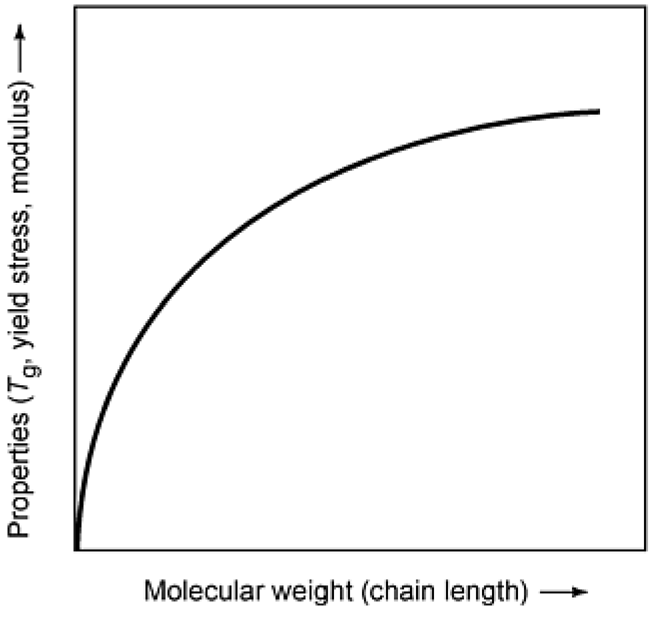

Fig. 2 General influence of molecular weight on polymer properties. Source: Ref 13

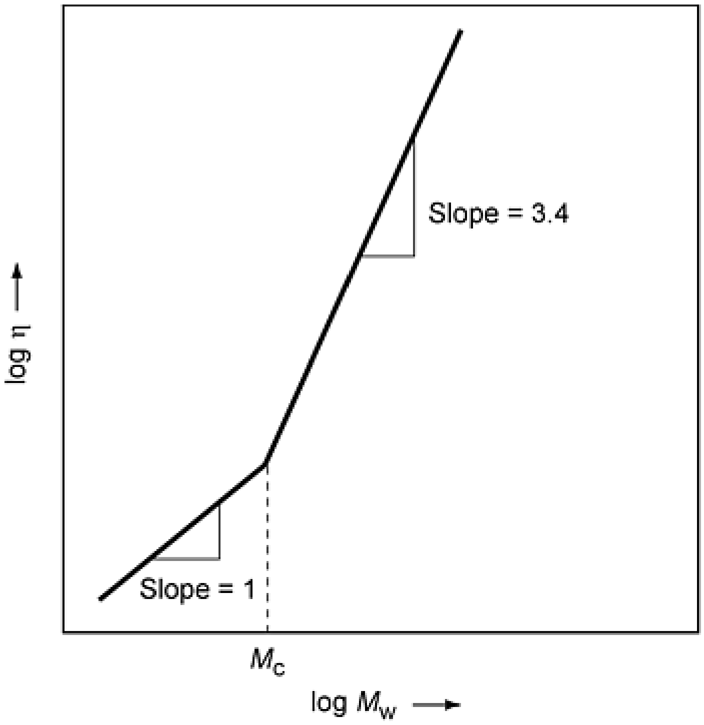

Fig. 3 Viscosity dependence on molecular weight exhibiting M_c. Source: Ref 14

Below M_c the chains are short enough to align in the direction of flow and to slip past each other with relative ease. Once the critical length has been achieved, entangled polymers offer more resistance to the stresses inducing flow. This property, associated with the high MWs of engineering plastics, dramatically distinguishes them from Newtonian rheological behavior as is further explored in the sections on thermal and mechanical properties in this article.

This concept of M_c can be related to mechanical properties intuitively. The degree of intermolecular attractive forces is limited by the chain length. For example, at low MWs (below M_c), chain disentanglement can occur. Above a certain size (greater than M_c), the system is highly entangled and has maximized its intermolecular bonding such that it is now limited by the strength of the chain backbone. Most industrial engineering plastics have MWs well above M_c so that moderate changes in MW will not appreciably affect properties such as yield stress or modulus.

$\overline{M}_n$ finds relevance in relating properties that depend on small molecules (like environmental stress cracking resistance), while $\overline{M}_w$ is well suited for relating properties that depend on intermolecular attractions, because as chain length increases, the number of intermolecular bonds per molecule also increases. This is important when the property of interest measures the ability of a material to disentangle chains.

The breadth of MW range in a sample can be represented by a polydispersity index, which is equal to the ratio of $\overline{M}_w$ to $\overline{M}_n$. A material with a broad range of MWs (i.e., a high polydispersity index or broad MWD) will melt at lower temperatures than the equivalent material with a narrow range of MWs because the components with lowest MW will melt first.

Recent use of metallocene catalysts during polymerization has resulted in greater control over MWD. The narrow MWD linear low-density polyethylenes (LLDPEs) have better strength and heat-sealing properties because the lower MW components are no longer present. However, the lack of shorter polymer chains increases melt viscosity to such a degree that processing problems are often encountered. The use of blends of high- and low-MW LLDPE generates a bimodal MWD that produces a balance of good strength and ease of processing.

Chain branching also has a significant effect on flow properties. For a polymer of a given MW, the more highly branched the structure is, the lower its density will be and the lower the degree of entanglement. Moreover, for any given polymer, the lower its MW, the more flexible it will be as there are a greater number of chain ends per unit volume for short chain

species. Chain ends reduce packing efficiency, and the additional free volume available offers sites into which the polymer can be displaced under stress. Once the MW is greater than the M_c the end-group concentration change is insignificant for further MW increases, and the mechanical properties plateau when the total intermolecular attractions are greater than the strength of the polymer backbone.

In addition to MW and chain branching, repeat units can be added in either a random or ordered fashion. In atactic polymers, such as PS and polymethyl methacrylate (PMMA), the mers are added randomly. In contrast, the repeat units of isotactic and syndiotactic polymers are ordered. Because the side chains of atatic polymers are randomly oriented as shown in Fig. 4(a), they inhibit crystallization (as is discussed later in this article). In isotactic polymers (Fig. 4b) the side chains all extend from the same side of the backbone, while in syndiotactic polymers they alternate sides (Fig. 4c). This regularity facilitates crystallization.

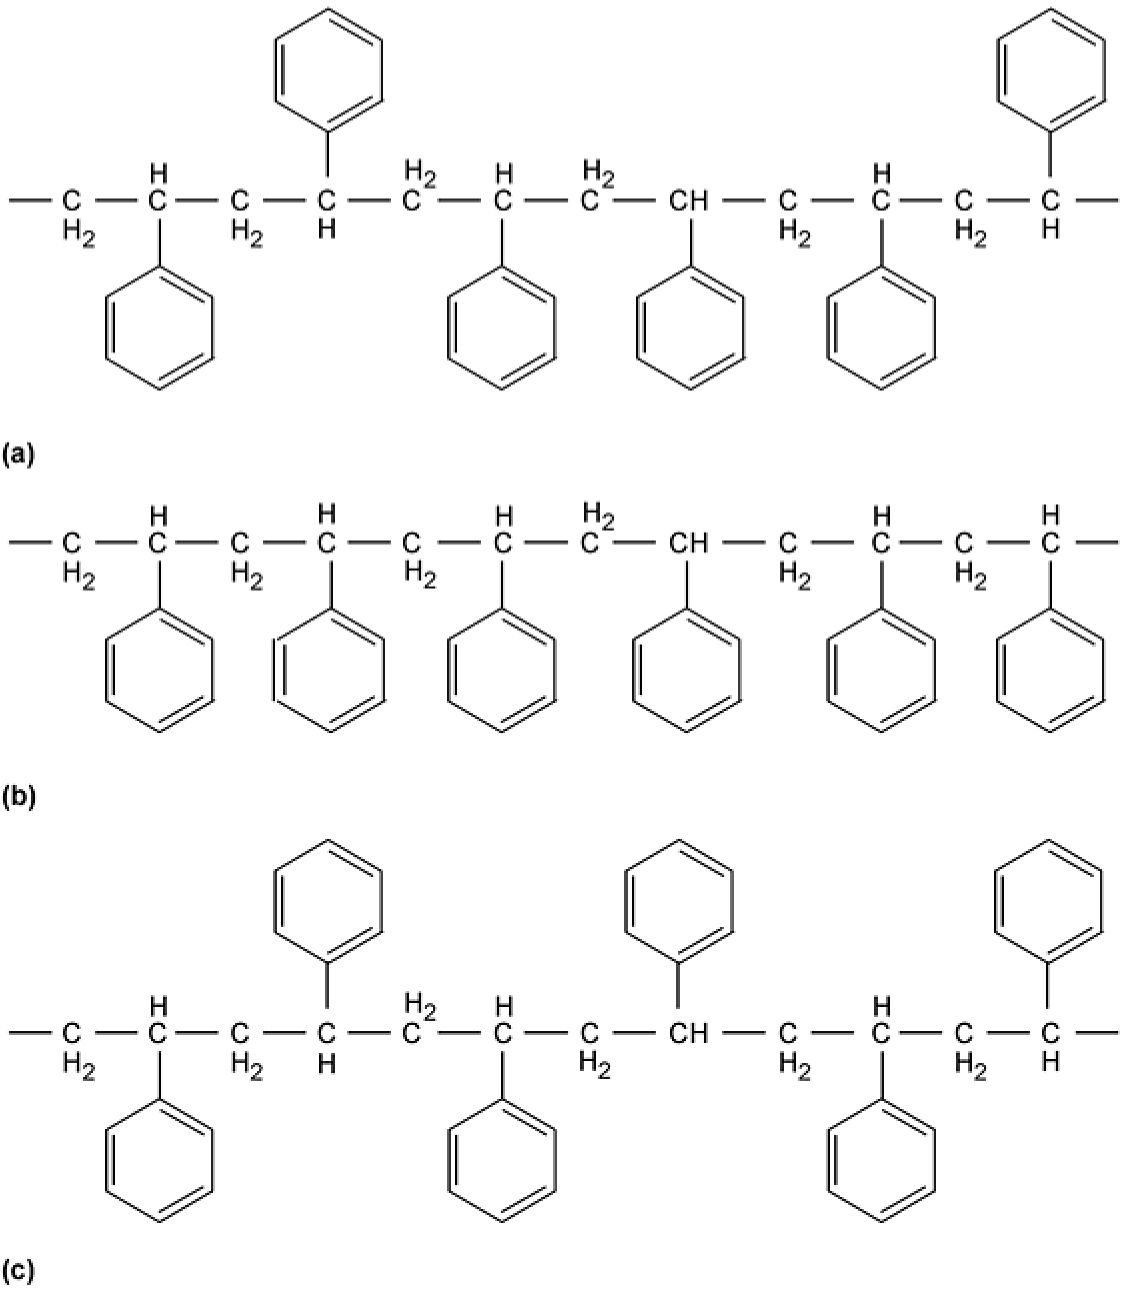

Fig. 4 Tacticity in polymers as shown by (a) atactic, (b) isotactic, and (c) syndiotactic polystyrene

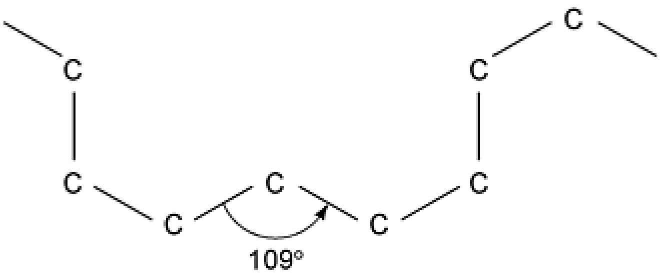
Inherent Flexibility. Before expanding the scope of consideration to include interactions between neighboring molecules, it is important to appreciate the inherent flexibility of the backbone of any given molecule. In this discussion it is first assumed that every carbon-carbon bond segment is completely free to assume any position as long as the

equilibrium requirement that the carbon-carbon bond angle be maintained at 109° is met. A random conformation that might occur can be shown as:



Inclusion of the hydrogen atoms (which fill the valence electron requirements of carbon) in the spatial consideration introduces limitations to the flexibility. The hydrogen atoms impose restrictions on the number of energetically viable positions that the chain can assume. Figure 5 plots an example of different energetically favorable conformations for the case of ethane (C_2H_6). It considers what happens as one carbon is rotated around the carbon-carbon bond and demonstrates the effects of trying to force the hydrogen atoms of one carbon atom to be spatially close to the hydrogen atoms of an adjacent carbon atom.

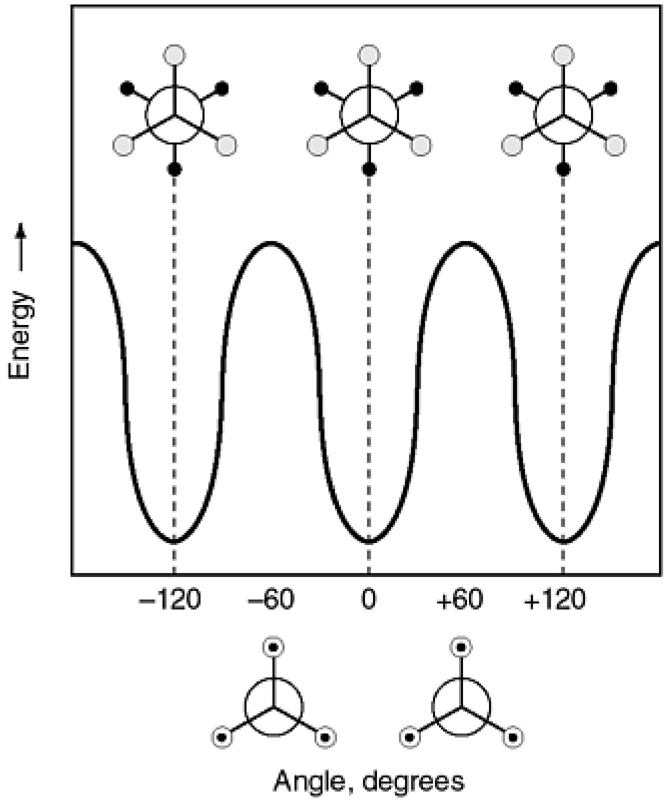


Fig. 5 Steric hindrance of ethane. Source: Ref 15

Figure 6 dramatically demonstrates the effects of the replacement of two hydrogens by carbon-carbon triple bonds. For example, there are fewer atoms surrounding the central carbon of methylacetylene, which allows greater freedom of rotation for the carbon-carbon single bond. Of course, the greater electron density of the carbon-carbon triple bond does restrict the motion of that bond. Consideration of neopentane shows the resulting reduction of degrees of freedom when substituent hydrogens are replaced by the considerably more bulky methyl (—CH_3) groups. Introduction of the electronegative oxygen-containing side groups further increases stiffness of the backbone by reducing flexibility not only due to the size of this side group but because of electrical repulsion as well.

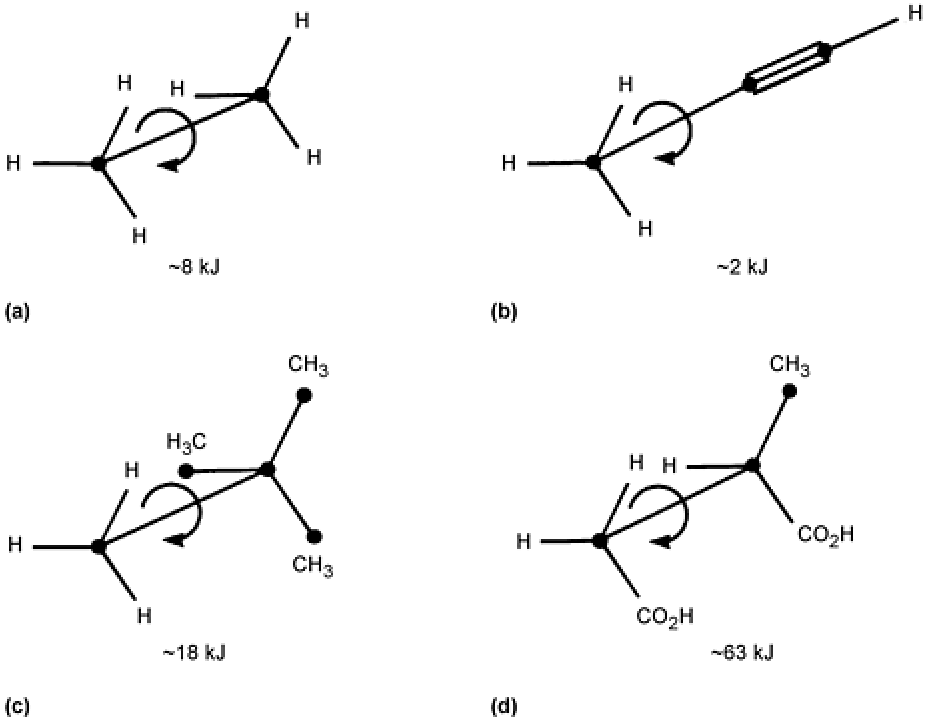

Fig. 6 Rotational energy barriers as a function of substitution. (a) Ethane. (b) Methylacetylene. (c) Neopentane. (d) Methylsuccinic acid. Source: Ref 16

This concept accounts for the flexibility of rubbers, such as cis-1,4-polybutadiene (Table 1), that have double bonds on their main chain. The double bond eliminates two hydrogen atoms, and the additional free volume results in additional flexibility. One of the most flexible polymers, polydimethylsiloxane (PDMS), has a flexible ether linkage on the main chain and nonpolar side groups, which accounts for its lack of rigidity. The ether oxygen only forms bonds with two carbon atoms, and the lack of hydrogen atoms means that ether linkages are surrounded by ample free volume. This promotes ease of rotation. Flexibility is also introduced by ether linkages due to the smaller atomic radius of oxygen atoms compared to those of carbon atoms. The structure of PDMS, one of the few commercially significant polymers without carbon on its backbone, is shown in Table 1. Cis-1,4-polybutadiene is used for flexible hose, gasketing, and rubber footwear application, while PDMS is used for embedding electrical components, high-temperature gaskets, and rubber-covered rollers for laminators.

Ring structures on the backbone reduce flexibility. The presence of a phenylene group combined with the resonance among the adjacent oxygen structures of polyethylene terephthalate (PET) explains its rigidity. This is one reason why PET is well suited for the manufacture of thin-walled soda bottles. Materials such as polyacrylonitrile (PAN) and PVC are all rigid due to electrical repulsion (the nitrile group is highly polar) as well as steric hindrance (chlorine is a large atom). The repeating unit structures for PET, PAN, and PVC are shown in Table 1.

These molecular factors account in part for the elevated T_g and elastic moduli values of engineering polymers; these are discussed later in the section "Thermal and Mechanical Properties of Solid Engineering Plastics" in this article. Polyacrylonitrile is used principally for synthetic (acrylic) fibers because its rodlike molecules form highly crystalline bundles and the high degree of hydrogen bonding provides high mechanical, thermal, and chemical resistance. With its low cost and relatively high modulus, PVC is used for water and gas pipes, window frames, siding, gutters, and identification and credit cards.

Main chain restrictions to rotation are important when considering inherent flexibility, but side chains and their morphology also play an important role. Side-chain contributions to molecular flexibility are affected by three characteristics:

- Presence of branching in the side chain
- Length of the side chain
- Polarity of the side chain

Branched side chains are even bulkier than their linear counterparts and offer greater steric hindrance. Steric hindrance is the restriction of free rotation due to spatial limitations imposed by the presence of atoms. This reduced flexibility is manifested as higher gas transition and wetting temperatures. Cyclic side groups stiffen the molecule, although this stiffening effect is diminished as the cyclic group occurs further from the main backbone. This can be seen when considering the phenyl group, which introduces significant steric hindrance, is present on increasingly long side chains. Table 5 indicates the effect of length of side chain on thermal transitions. When the phenyl group is pendant to the main chain, as in the case of PS, the T_m is 240 °C. Locating further away by one carbon atom reduces T_m to 208 °C, and when it is two carbon units away the T_m is only 160 °C.

Table 5 Effect of side-chain length on glass transition and melting temperatures

Side chain structure	Glass transition temperature (T_g), °C	Melting temperature (T_m), °C
	83	240
	60	208
	10	160

Source: Ref 17

There is an interesting limitation to the lowering of thermal transition temperatures by increasing the length of purely aliphatic (linear chains, without rings) side chains. It occurs when the reduction of stiffening through increased intermolecular distance is offset by side-chain crystallization. After the aliphatic side chain reaches eight to ten carbon units in length, side-chain crystallization can occur which again increases T_g and T_m. This is demonstrated in Table 6 and Fig. 7 for a series of polyolefins (saturated polymers containing only carbon and hydrogen). While PE has a T_m of 137 °C, introduction of a one-carbon side chain in PP increases the T_m to 176 °C due to limited chain mobility. However, longer side chains increase the free volume enough to reduce T_m until the side-chain length exceeds eight to ten carbons. These long side chains then have sufficient mobility to crystallize and again increase T_m.

Table 6 Effect of length of aliphatic side chain on glass transition and melting temperatures of polyolefins

Olefin	Number of carbons in side chain	Glass transition temperature (T_g), °C	Melting temperature (T_m), °C
PE	0	-122	137
PP	1	-19	176

Poly-(1-butene)	2	-24	120
Poly-(1-pentene)	3	-47	70
Poly-(1-hexene)	4	-50	-55
Poly-(1-heptene)	5	. . .	-40
Poly-(1-octene)	6	-60	-38
Poly-(1-dodecene)	10	. . .	45
Poly-(1-octadecene)	16	. . .	70

Source: Ref 18

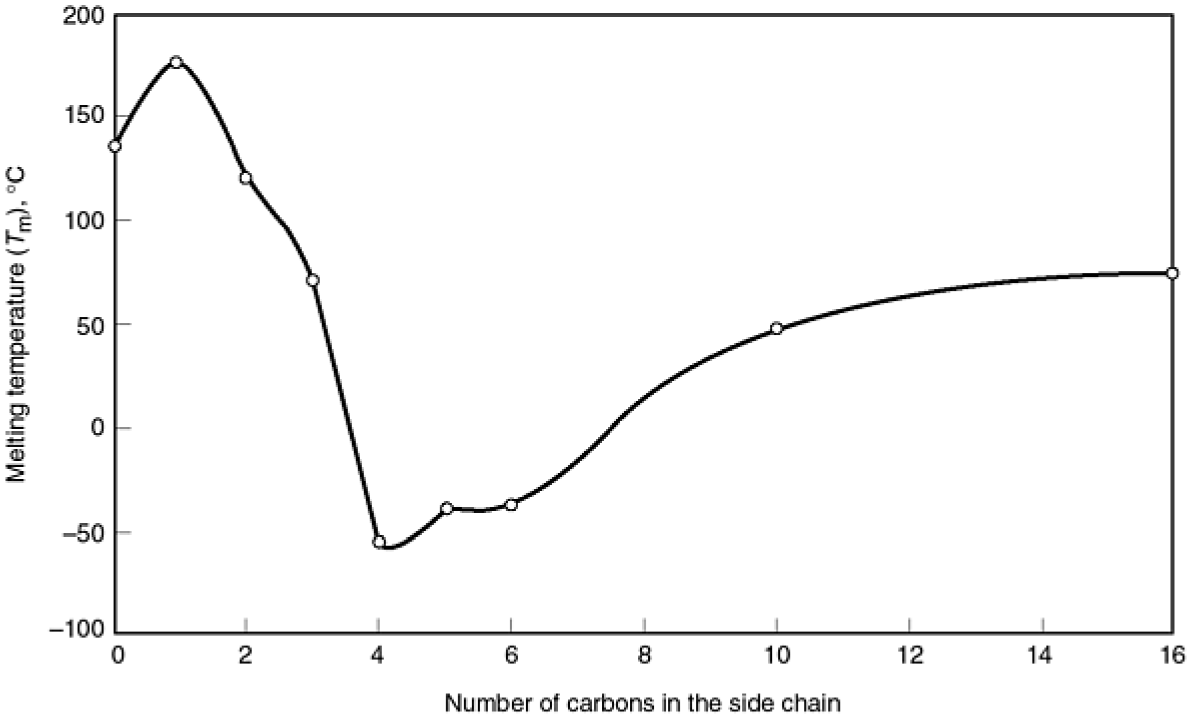

Fig. 7 The effect of aliphatic side chain on the melting temperature of polyolefins

Electrical repulsion between polar side chains disrupts random coil formation of the backbone and imposes what is known as "rigid-rod" conformation. This occurs in engineering thermoplastics such as PTFE and PAN.

Composition: Intermolecular Considerations

Intermolecular arrangements are governed by both spatial considerations (such as order and distance to neighboring molecules) and by the presence of attractive forces between molecules. Intermolecular order is defined as either amorphous, crystalline, or oriented, as shown in Fig. 8.

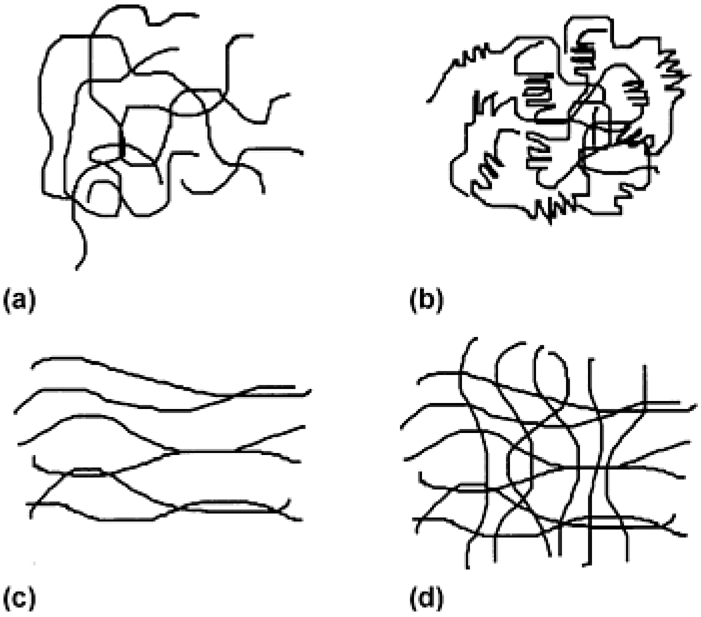

Fig. 8 Schematic view of intermolecular order in polymers. (a) Amorphous. (b) Semicrystalline. (c) Uniaxial orientation. (d) Biaxial orientation

Amorphous Versus Semicrystalline. While amorphous materials assume random, three-dimensional structures, semicrystalline polymers have very ordered, tightly packed three-dimensional arrangements connected by amorphous regions. In the melt or solution, the chains of all polymers, except liquid crystalline polymers (LCPs), exhibit random or amorphous configurations. Liquid crystalline polymers form randomly arranged rodlike bundles. Upon cooling of the melt or evaporation of the solvent, some polymers remain amorphous whereas others crystallize. The state is determined by the regularity and flexibility of the polymer structure and the rate at which the melt is cooled or the solvent evaporated.

Polymers, such as atactic PS, atactic PMMA, atactic PP, and PVC, have large side chains or pendant groups added at irregular intervals. Because these groups prevent such polymers from forming crystalline regions, polymers with irregular

structures are usually amorphous. When the pendant group or side chain is small enough, such as in PVOH and PAN, the side group can be tucked into ordered structures resulting in polymers that are semicrystalline. Moreover, regular addition of even large side groups permits the formation of tightly packed regions. Consequently, isotactic PP and syndiotactic PS are semicrystalline polymers, whereas the atactic forms are amorphous.

Because chain mobility is required to form ordered structures, polymers with regular, but rigid, structures cannot crystallize under normal processing conditions. Polycarbonate can crystallize if annealed at sufficiently high temperatures for long periods of time; however, under typical processing conditions PC is amorphous. In contrast, the structure of PE is so flexible that crystallization occurs even when the polymer melt is quenched (cooled rapidly).

Amorphous polymers exhibit a T_g that is the temperature at which the amorphous regions become mobile. In contrast, semicrystalline polymers exhibit both a T_g and a T_m. At this latter temperature, the ordered crystalline regions melt and become disordered random coils. While the magnitude of the T_g of a polymer depends only on the inherent flexibility of the polymer chain, the magnitude of T_m is also a function of the attractive forces between chains.

Although the degree of crystallinity in a given polymer varies with the processing conditions, the maximum degree of crystallinity depends on the polymer structure. Polymers such as PE, PP, polyoxymethylene (POM), and nylon 6/6 have regular, flexible structures that permit high levels of crystallization. As indicated in Table 7, increased branching that reduces the regularity of the polymer structure and its density, also decreases the degree of crystallinity. The molecular architecture of these grades, shown in Fig. 9, explains why HDPE can achieve the highest level of crystallinity. Because the linear molecule is unimpeded by the random branches found in low-density polyethylene (LDPE), it can assume a tightly packed crystalline form.

Table 7 Properties of polyethylenes of varying degrees of crystallinity

Property	Low density	Medium density	High density
Density range, g/cm^3	0.910-0.925	0.926-0.940	0.941-0.965
Crystallinity, approximate %	42-53	54-63	64-80
Melting temperature (T_m), °C	110-120	120-130	130-136
Hardness, Shore D	41-46	50-60	60-70
Tensile modulus, MPa	97-260	170-380	410-1240

Source: Ref 19

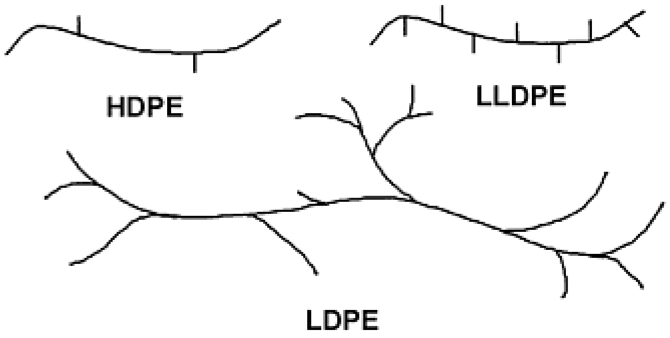

Fig. 9 Molecular architecture of high-density, low-density, and linear low-density polyethylenes. Source: Ref 20

The influence of crystallinity is best illustrated through the properties presented in Table 7 for PEs of various degrees of crystallinity. As shown in Table 7, the T_m, modulus, and hardness increase with crystallinity.

Orientation. Oriented polymers are often confused with semicrystalline polymers. In the case of oriented polymers, localized regularity is induced by mechanical deformation and is limited to small areas. Straining of polymers can result in stretched areas of parallel, linear, partially ordered structures as shown in Fig. 8(c). This uniaxial orientation results from forming processes such as fiber spinning, pipe and profile extrusion, and flat-film extrusion. The polymer chains can also be aligned parallel and perpendicular (transverse) to the primary direction of flow as shown in Fig. 8(d). Blown-film extrusion and blow molding inherently produce this biaxial orientation. In contrast, in the production of PET sheet, uniaxial orientation occurs during extrusion while the biaxial orientation is induced during a secondary stretching operation. Biaxial orientation is also the underlying concept of shrink-wrap films that revert to their amorphous conformations when enough heat is applied to reverse the induced orientation. Rotomolding and other low-shear processes produce little orientation.

Intermolecular Attractions. Secondary intermolecular attractive forces that promote crystallinity include London dispersion forces, dipole forces (either induced or permanent), hydrogen bonding, and ionic bonding. These secondary bonds do not actually connect two atoms through equally shared electrons the way that a primary covalent bond does; therefore, the energy required to break secondary bonds is less than the 300 to 420 kJ/mol (Ref 21) strength of covalent bonds. The interatomic distance of covalent bonds is quite short, generally between 1 and 2 Å(Ref 21). When primary, or covalent, bonds join adjacent polymer chains, the polymer is cross-linked.

London dispersion forces are the weakest of the secondary bonds with energies of 4 to 8 kJ/mol and an intermolecular distance of 3 to 5 Å(Ref 21). They are the only secondary interactions in linear, nonpolar hydrocarbons and fluoropolymers. The mobility of the valence electron clouds in these polymers results in transient states of electrical imbalance, and this momentary polarity draws two molecules together. London dispersion forces also provide significant intermolecular attractions in polar polymers, such as PVC, nylons, and PET, which form other secondary bonds.

Dipole Forces. In the presence of a polar molecule, an induced dipole can be set up in a neighboring molecule. Dipoles are the result of a covalent bond between atoms of differing electronegativities, and the resulting polarity accounts in large part for high thermal and mechanical properties of polar polymers such as PVC. These forces result in an intermolecular attraction of 4 to 21 kJ/mol (Ref 21) and often control solubility.

Hydrogen bonding occurs when the electron pair of an electronegative atom is shared by a hydrogen. The typical length of these bonds is 3 Å, with strengths of 6 to 25 kJ/mol (Ref 21). The degree to which hydrogen bonding occurs is related to the number of hydrogen bonding sites available, which in turn is related to the MW of the molecule. The facility with which they are formed is aided by regular, crystalline structures. Hydrogen bonding accounts for the high strengths of aliphatic polyamides such as nylon 6/6, and is so strong in aromatic polyamides, such as aramid fibers, that the polymers degrade before they melt.

Ionic bonding is less common than hydrogen bonding. Ionic bonding is the binding force that results from the electrostatic attraction of positively and negatively charged ions. Ionomers, with their equal numbers of positively and negatively charged ions, have high T_m and moduli. Overall, they are electrically neutral. Bond strengths are of the order of

42 to 84 kJ/mol (Ref 21). These bonds are easily eliminated by polar liquids (of high dipole moments) such as water because surface ions are readily extricated when in contact with these liquids.

Cross-linking is the creation of a three-dimensional network by forming covalent bonds between polymer chains as shown in Fig. 10. While the degree of cross-linking can vary, highly thermoset systems are typically rigid. Upon exposure to elevated temperatures, cross-linked polymers cannot melt and flow. The covalent bonds that form the three-dimensional network prevent melting and also do not permit dissolution in solvents. Thermoset systems, such as unsaturated polyester, epoxy, thermoset polyurethanes, polyureas, phenol formaldehyde, and melamine formaldehyde, are shaped and cross-linked during processing. Representative structures are shown in Table 8.

Table 8 Representative structures of thermoset plastics

Common name	Representative polymer structure
Phenol-formaldehyde, phenolic	Melamine-formaldehyde, melamine	Urea-formaldehyde	Epoxy	
Unsaturated polyester	Polyurethane	Silicone	
Source: Ref 8

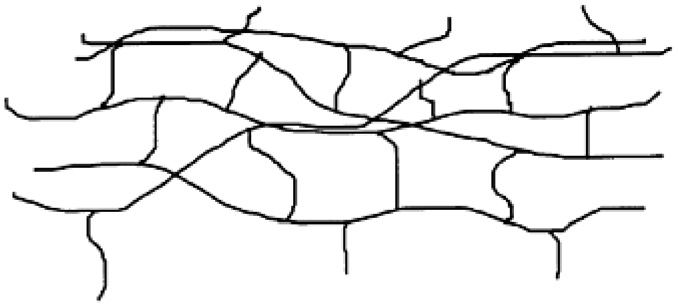

Fig. 10 Schematic of a cross-linked polymer

Normally thermoplastic resins, such as PE, can also be cross-linked after the shaping operation. Cross-linking of PE does not introduce many cross-links because PE is quite unreactive. The few cross-links that form actually reduce regularity and therefore crystallinity. Thus, the modulus of semicrystalline thermoplastics is not increased upon cross-linking, although hot creep is reduced. Hot creep is the deformation of plastics exposed to stress and elevated temperatures for prolonged periods. Polyethylenes used in wire coating are frequently cross-linked for this reason.

Effects of Composition, Processing, and Structure on Properties of Engineering Plastics

A.-M.M. Baker and C.M.F. Barry, University of Massachusetts Lowell

Composition: Supermolecular Considerations

Supermolecular considerations include copolymerization, polymer blends, plasticization, incorporation of additives, and foaming.

Copolymerization. Copolymers are polymer molecules that contain several different repeat units. Usually two monomers are polymerized into one of four different configurations: random, alternating, block, or graft (Fig. 11). In random copolymers the units are distributed randomly along the polymer chains, whereas with alternating copolymers every second repeat unit is the same. Block copolymers also contain alternating segments of each monomer, but the segments are usually several repeat units long. Graft copolymers consist of a main chain composed of only one repeat unit with side chains of the second monomer.

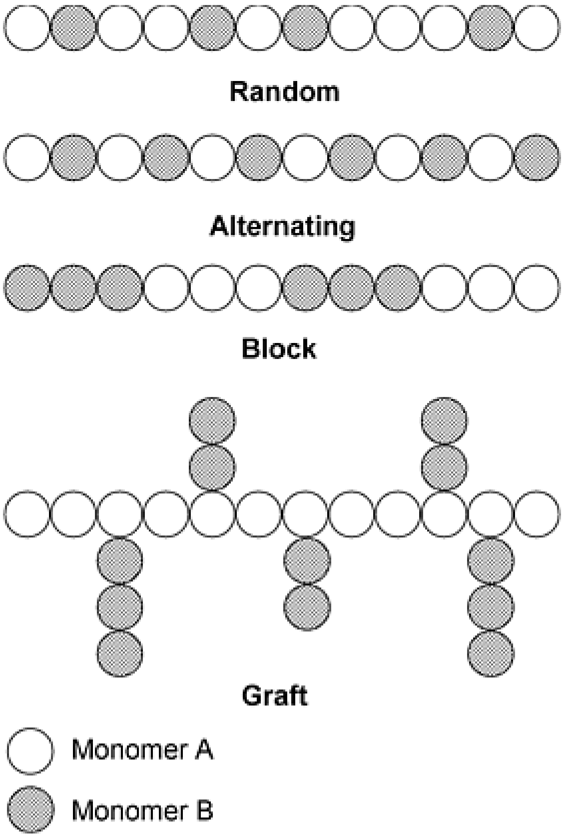

Fig. 11 Copolymer configurations. Source: Ref 22

The properties and processing characteristics of copolymers are often very different from those of the component polymers. Processing and properties can also vary with the ratio of the components and their arrangement within the

copolymer. Block and graft copolymers can form two-phase systems similar to those observed with immiscible polymer blends.

Examples of random copolymers are ethylene propylene rubber (EPR), polystyrene-co-acrylonitrile (SAN), and fluorinated ethylene propylene (FEP). Ethylene propylene rubber is an amorphous elastomer, whereas PE and PP are semicrystalline plastics. Because acrylonitrile (which as PAN is difficult to process) is the minor component of SAN, it increases the melt temperature and stiffness of the PS without affecting its processibility. Fluorinated ethylene propylene is a melt-processible copolymer, while its major component, PTFE, is not.

Typical block copolymers are polyetheramides, hard segment-soft segment polyurethanes, and "styrenic" elastomers (for example, styrene-butadiene-styrene, or SBS, and styrene-ethylene-butylene-styrene, or SEBS). Graft copolymers are present in impact-modified polystyrene (HIPS) and ABS terpolymers. Alternating copolymers have, until recently, been laboratory curiosities.

Polymer Blends. While copolymers are mixtures of monomers that were joined together during polymerization, polymer blends are mixtures of polymer chains. The component polymers may be miscible, immiscible, or partially miscible. In the case of miscible blends, the polymers mix on a molecular level to produce a single phase. The most prominent example of this is modified polyphenylene oxide, which is a blend of polyphenylene oxide (PPO) with either PS or HIPS. Such systems exhibit a single T_g, and the mechanical properties are not affected by processing any differently than homopolymers.

With immiscible blends, the polymers cannot mix on a molecular level and therefore separate into two phases that exhibit the transition temperatures of the component polymers. In partially miscible blends, intermolecular attractions between the component polymers produce two phases that are not as sharply separated as those of immiscible blends. These blends exhibit transition temperatures that are shifted from those of the component polymers. The properties of both immiscible and partially miscible blends are sensitive to composition and processing conditions. For immiscible latex systems, such as HIPS and ABS, the size of the rubbery phases and the degree of grafting between the rigid and rubbery phases is determined during the polymerization process. However, for mechanically blended systems, the morphology is determined during the blending process and can be altered during injection molding.

Immiscible and partially miscible blends can be made compatible to provide better adhesion between the two phases. Typically, a third component, such as a block copolymer or reactive copolymer, is added to the blend to form a link between the phases.

Plasticizers are small molecules that are added to plastics to reduce viscosity during processing and to increase the flexibility of the finished product. Plasticizers such as phthalates are typically incorporated into vinyl compositions to produce flexible PVC automotive upholstery, raincoats, and luggage. Water and solvents are used as temporary plasticizers during the processing of polymers such as cellulosics and PAN.

Additives can produce significant changes in the properties and processibility of polymers. Some additives such as colorants, antioxidants, and thermal stabilizers, do not affect the mechanical properties, but may influence viscosity during processing. In contrast, mineral fillers and glass or carbon fibers affect both mechanical properties and processibility. Fillers such as talc, calcium carbonate, and silica often reduce cost and increase the modulus, melt viscosity, and the deflection temperature under load. While fibers can significantly improve mechanical properties, their performance depends on orientation and fiber length, both of which can be affected by processing.

Foams. In foamed plastics a dispersed gaseous phase is incorporated into the plastic from the physical introduction of air or nitrogen, the degradation of chemical blowing agents or the addition of microballoons (hollow glass or plastic microspheres) to the polymer. This gas phase reduces the weight and thermal conductivity of the plastic. While the resulting foams are classified many ways, they can generally be divided into open-cell and closed-cell foams. The individual cells (gas phases) of closed-cell foams are separated, whereas in open-cell foams these cells interconnect. Consequently, closed-cell foams are typically buoyant and are frequently used for life jackets, buoys, and other flotation devices. Foamed plastics can be made from either thermoplastic or thermoset polymers, and the modulus of the base polymer determines the flexibility of the foam. Because the walls of flexible foams collapse when pressure is applied, these materials easily dissipate mechanical and acoustic energy. This makes flexible foams particularly suitable for packaging, cushions, padding, and related applications. In contrast, high-modulus polymers produce rigid foams with a high ratio of load-bearing strength to weight. These foams typically find applications in airplane wings and automotive parts.

Thermal and Mechanical Properties of Solid Engineering Plastics

A typical plot of stress versus strain behavior for an engineering thermoplastic is shown in Fig. 12. This classic relationship is characterized by a linear region (shown as segment AB), which is called the linear viscoelastic region. In this region the polymer chains stretch and disentangle in response to the stress being imposed. The ratio of stress to strain (the slope) is known as either Young's modulus or the elastic modulus. Behavior in this region is like that of a purely elastic, ideal solid, governed by Hooke's law:

$$\sigma = E\varepsilon \qquad \textbf{(Eq 5)}$$

where σ is stress, ε is strain, and the proportionality constant E is known as the spring constant or as stated earlier, Young's modulus or the elastic modulus.

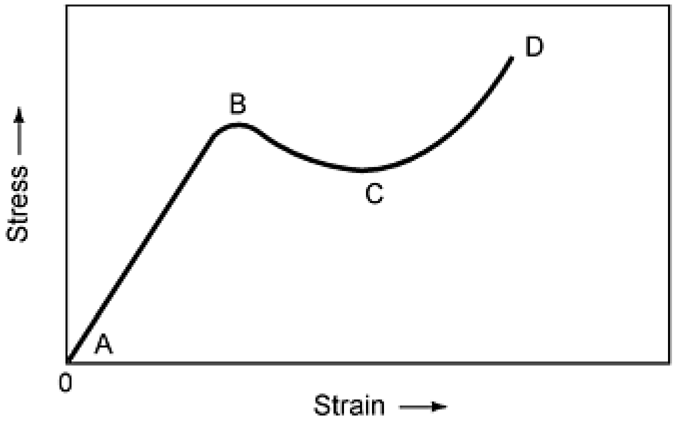

Fig. 12 Typical stress-strain curve for a polymer

Beyond this point, known as the yield point (shown as point B in Fig. 12), increased strain can be achieved with reduced stress. Secondary bonds are broken, and the strain is now irreversible. Permanent deformations such as necking begin to occur. Prior to point B, removal of stress allows the material to recover its original dimensions.

Eventually, at point C, the slope increases due to mechanically induced orientation of the polymer chains. This orientation in the direction of the imposed stress effectively increases the strength of the material. Finally, the breaking point (D) is achieved where the ultimate, or breaking, stress and strain are defined. For tensile properties, the stress is often referred to as tensile strength whereas the strain is elongation.

The stress-strain behavior presented in Fig. 12 varies strongly as a function of both strain rate and temperature. At very high strain rates, the molecules do not have adequate time to disentangle from each other and physically respond to the imposed stress. High-speed testing, known as impact testing, yields a high modulus response and low ultimate strains. In cases where the stress is imposed very slowly, the polymer chains have adequate time to disentangle and deform.

Temperature also plays an important role. At very low temperatures, polymer molecules do not have much thermal energy or mobility. Therefore, they exhibit higher moduli and lower ultimate strains than at higher temperatures. At elevated temperatures, the molecules are more flexible and can distort and orient in response to the stress imposed by testing. Figure 13 shows the response of the same engineering plastic to different strain rates and different temperatures.

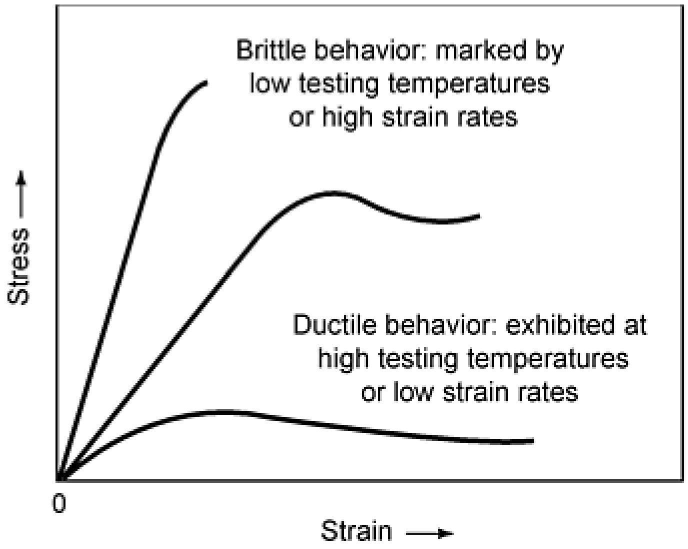

Fig. 13 Mechanical behavior of a plastic tested under different temperatures and strain rates

Figure 14 highlights the mechanical behavior of different plastics. "Strong" and "weak" are distinguished by differences in ultimate stress values, while "hard" and "soft" are differentiated by Young's moduli differences (the slope of the linear region). "Brittle" refers to a low ultimate strain, and "tough" is generally related to a large area under the stress-versus-strain curve. This definition of tough can be misleading because reinforced plastics have low ultimate strains, but are almost unbreakable.

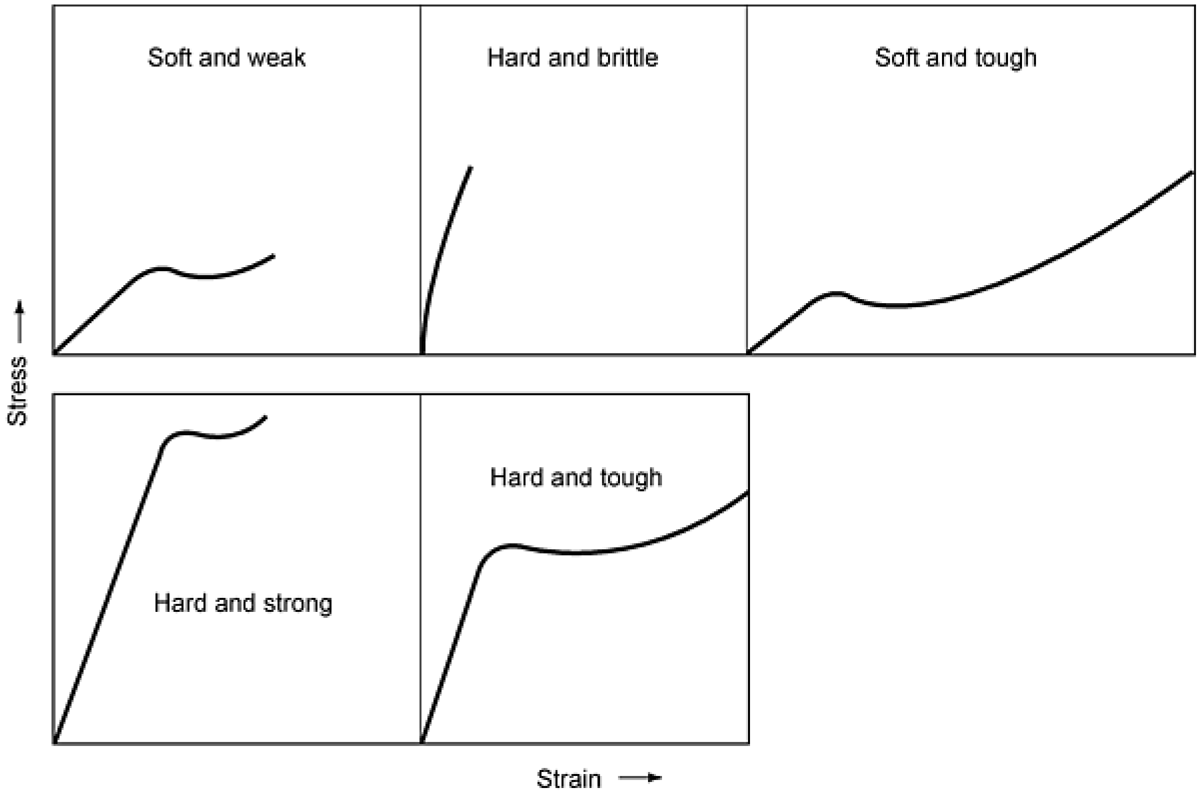

Fig. 14 Tensile stress-strain curves for several types of polymetric materials. Source: Ref 23

The classic relationship of elastic modulus to temperature for polymers is presented in Fig. 15. The glassy state is characterized by limited motion of small segments of the molecule, one to four atoms in length. Behavior in this region is like that of a purely elastic, ideal solid. In the leathery region, the modulus decreases by up to three orders of magnitude for amorphous polymers. The temperature at which the polymer behavior changes from glassy to leathery is known as the T_g. This corresponds to approximately 2.5% free volume, which is the unoccupied space between molecules. The rubbery plateau has a relatively stable modulus. As temperature is further increased, rubbery flow begins, but motion does not yet involve entire molecules. In this region, deformations begin to become nonrecoverable as permanent set takes place. There is little elastic recovery in the liquid flow region, and these viscous materials, if ideal, would obey Newton's law:

$$\sigma = \eta \dot{\varepsilon} \quad \textbf{(Eq 6)}$$

where σ is stress, $\dot{\varepsilon}$ is strain rate, and the proportionality constant η is referred to as viscosity. The transition from the rubbery plateau to liquid flow occurs at the T_m. At this temperature, entire molecules are in motion.

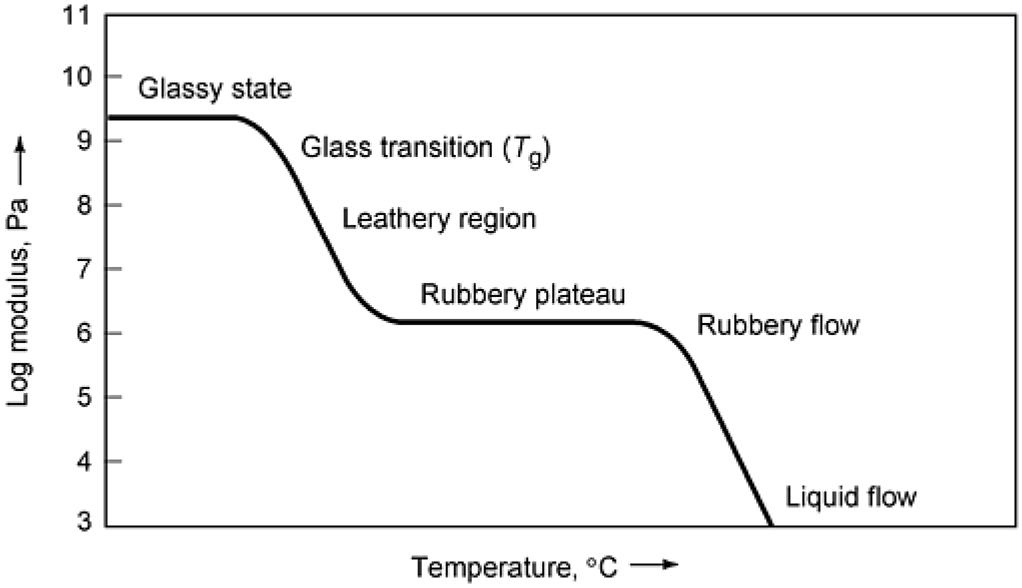

Fig. 15 Thermal dependence of elastic modulus for a typical polymer. Source: Ref 24

Effects of Structure on Thermal and Mechanical Properties. Because free volume is generally associated with end-group concentration, T_g is a function of MW, particularly $\overline{M}_n$. Higher MWs mean longer chains, typically reduced relative concentration of end groups, and a reduction in the associated free volume. This leads to greater opportunity for molecular entanglements, which behave as physical (albeit temporary) cross-links and thus drives the onset of T_g to higher temperatures. Addition of plasticizer is a means of reducing the overall "effective" MW through the incorporation of typically low MW entities into the plastic. While unimolecular plasticizers provide significant increases of free volume, which allows for enhanced rotational degrees of freedom for the plasticized polymer, more permanent polymeric plasticizers with their greater MW and internal plasticizers (flexible segments incorporated into the polymer) permit far less mobility. Consequently, the latter two must be added in larger amounts to achieve the same effects as produced with unimolecular plasticizers.

Increasing polarity in the polymer produces stronger attractive forces between molecules. As shown in Fig. 16, this so stiffens the polymer that the onset of T_g can be delayed. Because more thermal energy is required to overcome the stronger polar attractive forces of the molecules, T_m is increased. Thus, the nonpolar high-density polyethylene (HDPE), the moderately polar POM, and the highly polar nylon 6/6 exhibit T_g of -120, -50, and 60 °C, respectively, while their T_m increase as 135, 175, and 264 °C, respectively.

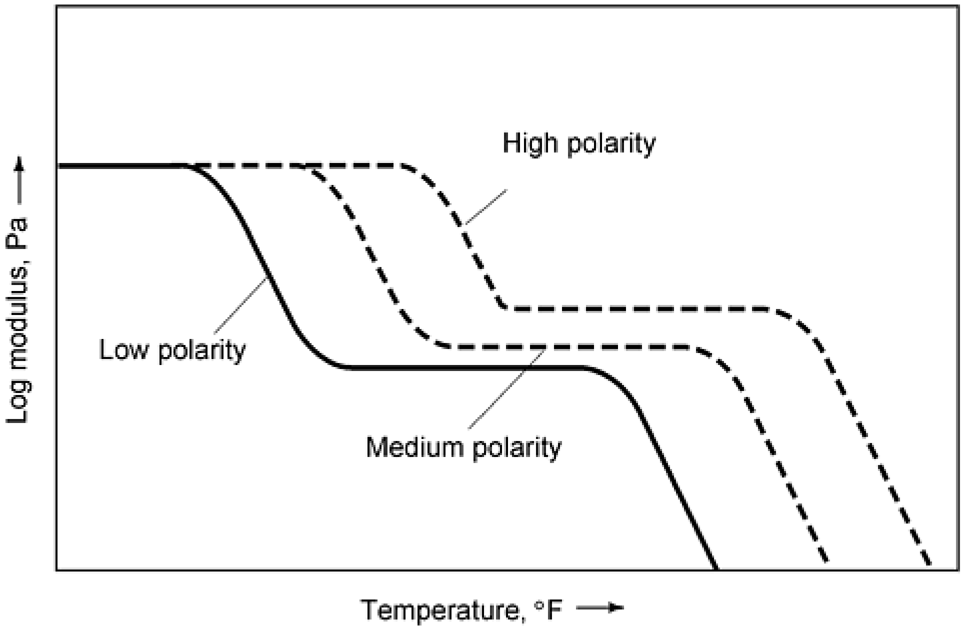

Fig. 16 Effect of temperature on modulus for polymers with different polarities. Source: Ref 25

Figure 17 presents the effect of crystallinity on the modulus-temperature relationship. At T_m the crystal structure is overwhelmed by thermal motion of the chains, and flow occurs. Increasing the degree of crystallinity does not affect the T_g, which involves much smaller structural components than the crystal lattice. However, polymers with higher degrees of crystallinity do require higher temperatures in order to melt. Higher degrees of crystallinity lead to higher T_m and rubbery plateaus, which occur at higher moduli.

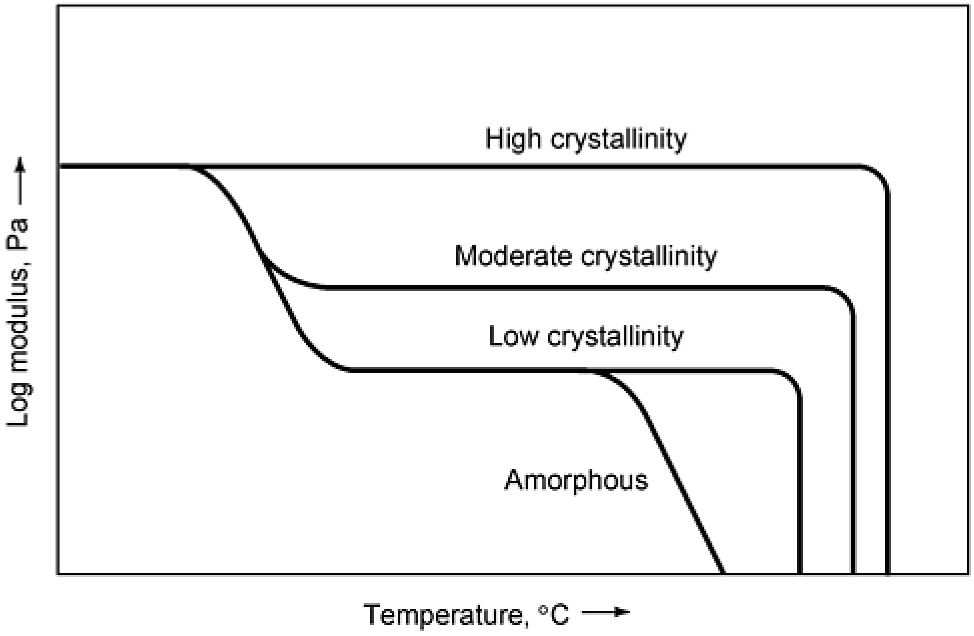

Fig. 17 Effect of temperature on modulus at various degrees of crystallinity. Source: Ref 26

High MWs extend the rubbery region as increased entanglements serve to postpone flow or deformation. In the extreme case of numerous covalent bonds linking molecules together, cross-linked polymers never exhibit the transition from the rubbery plateau into the flow regime. The covalent bond cross-links preclude flow, and the rubbery plateau simply

extends until the decomposition temperature, at which point the covalent bonds are broken down. As the degree of cross-linking is increased, the onset of the rubbery plateau occurs at increasingly higher moduli as shown in Fig. 18.

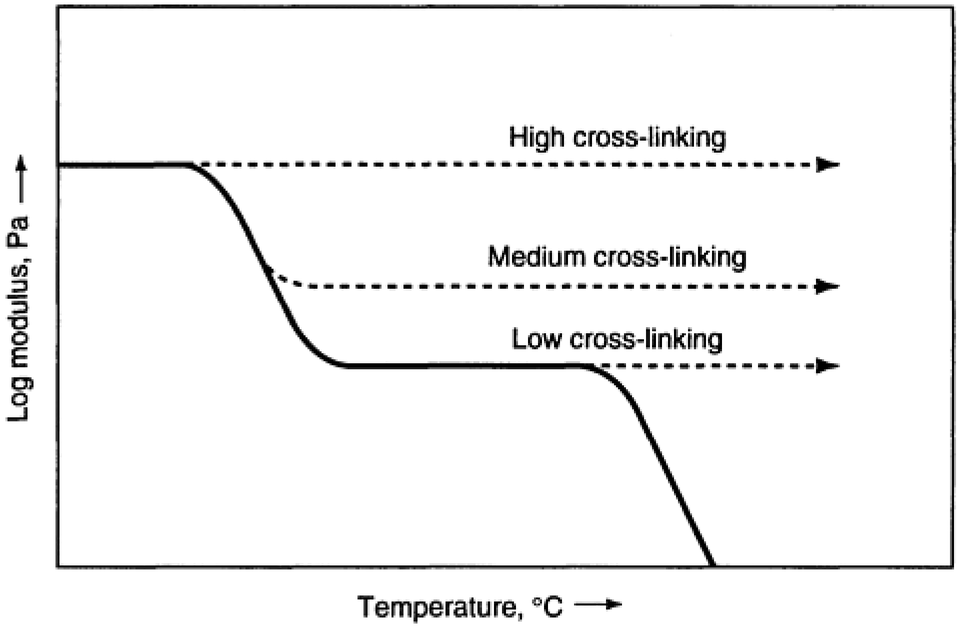

Fig. 18 Effect of temperature on modulus for different degrees of cross-linking. Source: Ref 25

Thermal and Mechanical Properties of Molten Engineering Plastics

Newton's law, given by Eq 6, only applies to ideal, viscous materials. A plot of log viscosity versus log shear rate for polymer melts (Fig. 19) exhibits three different regions of behavior. Regions A and C are Newtonian in that the viscosity is invariant with shear rate. Region A is often referred to as the "lower Newtonian plateau" and represents the viscosity at rates of shear that are low enough to allow the molecules to remain randomly tangled. As the rate of shear increases, region B is entered where molecules are now starting to align in the direction of flow. Because these aligned molecules offer less resistance to flow, viscosity is reduced. Finally, in region C, often referred to as the "upper Newtonian plateau," the molecules are aligned as much as possible and further increases in shear rate are no longer able to further reduce resistance to flow. This is the minimum viscosity that the molecules can achieve at a given temperature.

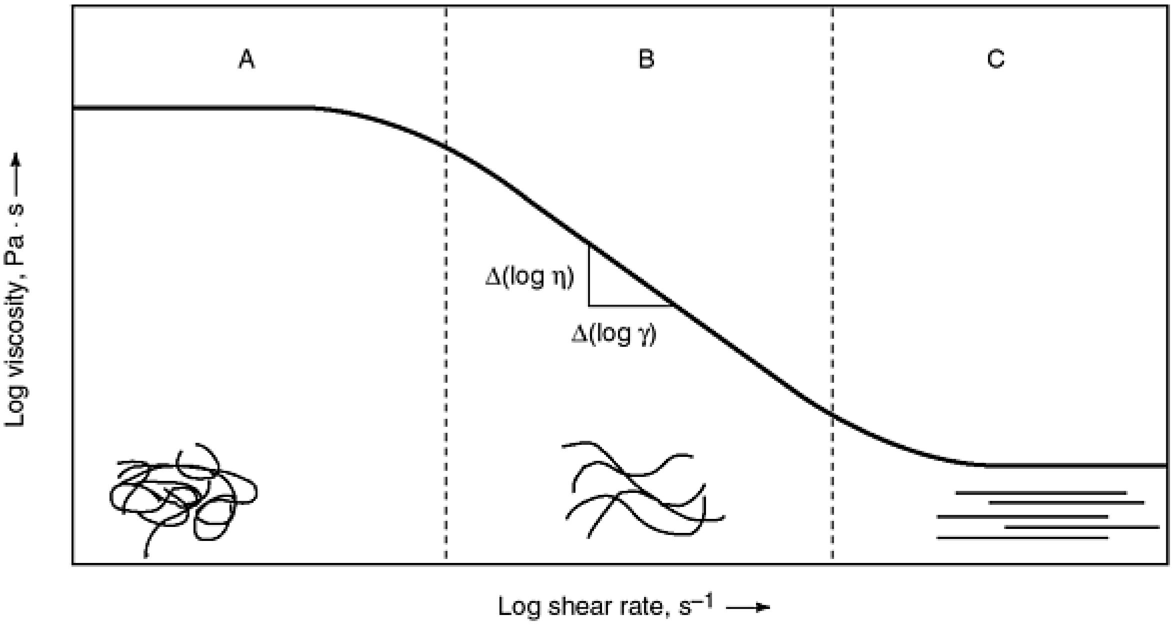

Fig. 19 General pseudoplastic behavior. Source: Ref 27

Processes such as extrusion and injection molding generate shear rates that are within region B, where the viscosity versus shear rate relationship is often approximated by the power law, given in Eq 7:

$$\eta = k\dot{\gamma}^{n-1} \quad \textbf{(Eq 7)}$$

where η is the viscosity, $\dot{\gamma}$ is shear rate, k is a material constant called the consistency index, and n is a constant called the power-law index. Power-law indices approximate the shear sensitivity of a polymer; values for common polymers are given in Table 9. Polymers that have very stiff backbones, such as PC and PS, tend to exhibit lower Newtonian plateaus that extend to shear rates of 1000 s^{-1} or more. Consequently, as is discussed in the section "Processing" in this article, shear thinning does not often reduce the viscosity of these polymers during extrusion.

Table 9 Sample power-law indices (*n*) for common plastics

Polymer	*n*
LDPE	0.35
LLDPE	0.60
HDPE	0.50
PP	0.35
PS	0.30
ABS	0.25

Viscoelasticity

Mechanical analogs to purely elastic Hookean solid behavior and purely viscous Newtonian melt behavior help describe why polymers have intermediate (viscoelastic) properties, which are time dependent. Most commonly, a spring is used to model Hookean behavior, and a dashpot (representing a piston in a viscous "hydraulic fluid"-like material) represents viscous behavior. These models, and their concomitant stress and strain behaviors are shown in Fig. 20(a) and 20(b).

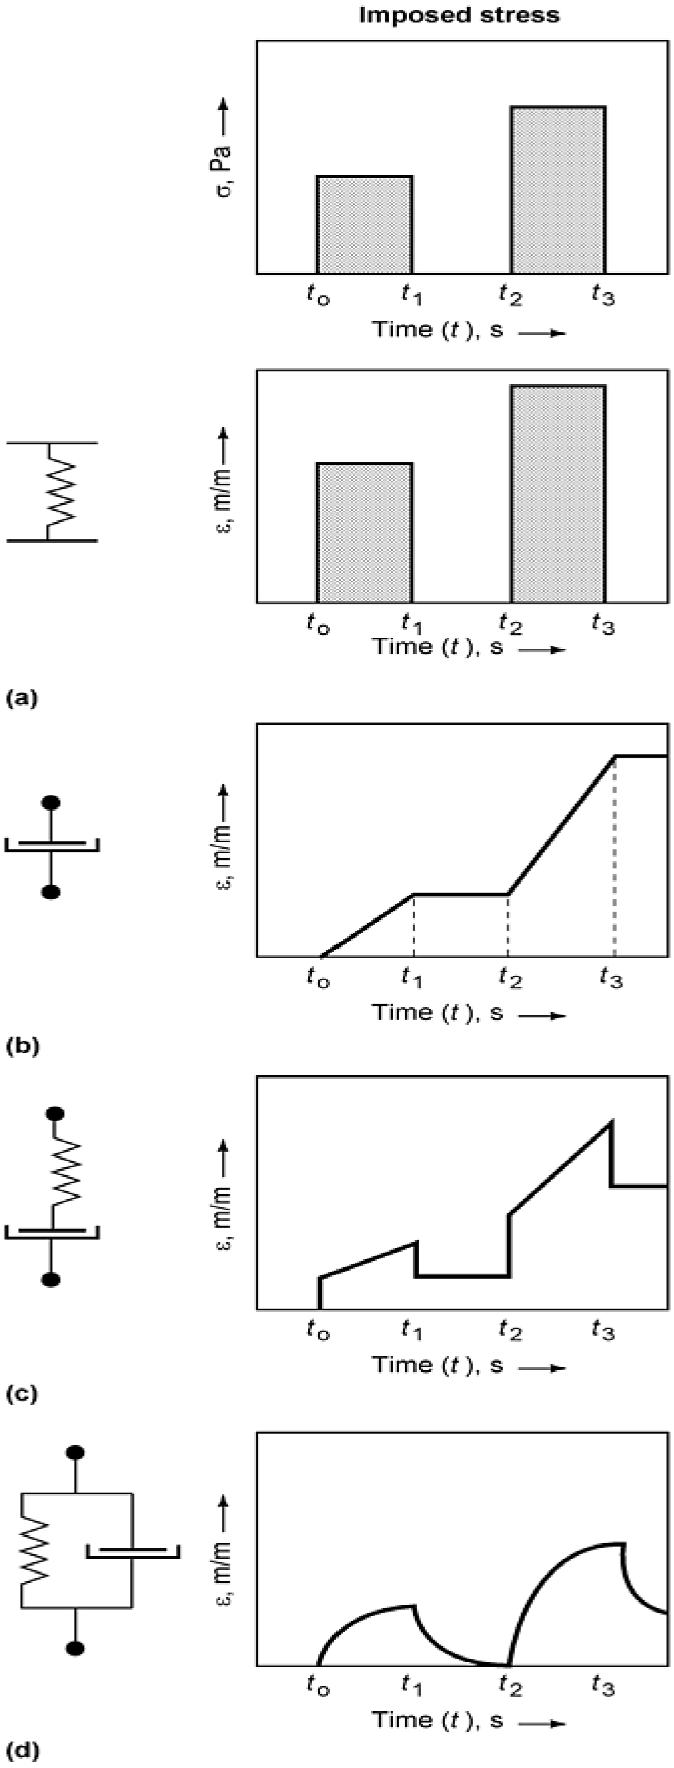

Fig. 20 Mechanical models and typical behavior. (a) Ideal Hookean solid ($\sigma = E\dot{\varepsilon}$; spring model; elastic response). (b) Ideal viscous Newtonian liquid ($\sigma = \eta\dot{\varepsilon}$; dashpot model). (c) Maxwell's mechanical model for a viscoelastic material. (d) Voigt's mechanical model for a viscoelastic material. Source: Ref 29

Application of a deforming force (i.e., pulling) on the spring results in an immediate stretching and thus an immediate strain. Once the force is released, the spring immediately recovers its initial length. Pulling with twice the force results linearly in twice the strain. The case of the dashpot, however, is significantly different. When the "piston" has a force applied to it, it slowly starts to move (no instant displacement as in the case of the spring), and when the force is released, the dashpot stays in its new conformation. Once a force causes an ideal viscous polymer melt to flow, it remains in its new position.

Two models, combining the spring and the dashpot either in series or parallel, have been developed that attempt to better describe real polymer flow behavior. These models, Maxwell and Voigt, are named after their creators and are shown in Fig. 20(c) and 20(d). Figure 21, very similar to Fig. 15, shows which mechanical analogs model different regions of the log modulus versus temperature curve. The behavior shown in the Voigt model helps to explain the action known as creep. Creep occurs when, under a static load for extended periods of time, increased strain levels slowly develop, as in the case of a refrigerator that after many years distorts a linoleum floor. The Maxwell model describes stress relaxation, which occurs when polymers are subjected to a constant strain environment. Over time, the molecules relax and orient themselves to the strained position, thereby relieving stress. This occurs in applications such as threaded metal inserts into plastic parts and threaded plastic bottle caps.

Effects of Composition, Processing, and Structure on Properties of Engineering Plastics

A.-M.M. Baker and C.M.F. Barry, University of Massachusetts Lowell

Properties of Engineering Plastics and Commodity Plastics

Engineering plastics generally offer higher moduli and elevated-service temperatures compared to the lower-cost, high-volume, commodity plastics such as PE, PP, and PVC. These improved properties are due to chemical substituents, inherently rigid backbones, and the presence of secondary attractive forces as discussed earlier in this article. Engineering thermoplastics (e.g., POM, PC, PET, and polyether-imide, or PEI) are polymerized from more expensive raw materials, and their processing requires higher energy input compared to that of commodity plastics, which is why the engineering thermoplastics are more expensive.

Structures of Commodity Plastics. It is interesting to note the T_m elevation of HDPE from LDPE. The effect of the branched structure on density and morphology enables the high-density version to form more tightly packed crystalline regions that require more thermal energy to overcome the cohesive forces keeping the plastic from melting. Substituting a methyl group in place of a hydrogen, in the case of PP, increases T_m and tensile strength further above that of HDPE. In this case, steric hindrance due to the additional size of the methyl group stiffens the chain and restricts rotation. The substitution of a large and highly electronegative chlorine atom in PVC prevents crystallization and also increases the onset of T_g, both due to steric hindrance effects and to the attractive polar forces generated. Polar attractive forces are so extensive that the tensile strength can be seen to increase to 55 MPa. Polystyrene is amorphous and transparent due to the atactic positioning of the pendant phenyl group, whose randomness destroys crystallinity. The tensile strength of PS is less than that of PVC due to the lack of the highly polar pendant group.

Structures of Engineering Plastics. Phenylene and other ring structures (Table 1) attached directly into the backbone often stiffen the polymer significantly, imparting elevated-thermal properties and higher mechanical properties such as increased strength. Polyoxymethylene is essentially PE with an ether substitution, but it has a much higher T_m (200 °C versus 135 °C for HDPE) because of its polarity. Both of these features promote a highly crystalline morphology. The high dimensional stability, good friction and abrasion characteristics, and ease of processing of this polymer make it a popular engineering plastic for precision parts.

Polycarbonate has an extended resonating structure because of the carbonate linkage. It has such a stiff backbone that crystallization is impeded, and the resultant amorphous structure is transparent, much like PET. Physical properties of PET, however, depend strongly both on its degree of crystallinity, which is governed by degree of orientation imparted during processing, and on its annealing history. The high strength, ease of processing, and clarity of PET make it ideal for soda bottles and polyester fibers. Polycarbonate has high strength, stiffness, hardness, and toughness over a range of -150 to 135 °C and can be reinforced with glass fibers to extend elevated-temperature mechanical properties. The high impact strength of high-MW PC makes it suitable for applications such as motorcycle helmets. The carbonate linkage of PC causes a susceptibility to stress cracking.

Polyetherimide has both imide groups and flexible ether groups, resulting in high mechanical properties but with enough flexibility to allow processing. Its highly aromatic (presence of benzene rings) structure allows it to be used for specialty applications.

Polyetheretherketone (PEEK), PPO, and PPS also rely on backbone benzene rings to yield high mechanical properties at elevated temperatures. Both sulfur and oxygen are electronegative atoms, creating dipole moments that promote intermolecular attractions and thus favorably affect elevated-temperature properties.

While the composition of thermoset plastics vary widely, the three-dimensional structure produced by cross-linking prevents melting and hinders creep. Overall properties such as stiffness and strength are determined by the flexibility of the polymer structure and the number of cross-links (cross-link density). Because epoxies, phenolics, and melamine formaldehyde contain aromatic rings, they are typically rigid and hard. Epoxies are used for adhesives, assorted electronics applications, sporting goods such as skis and hockey sticks, and prototype tooling for injection molding and thermoforming. Melamine formaldehyde is easily colored and so is often found in household and kitchen equipment, electronic housings, and switches. In contrast, phenolics are naturally dark colored and are limited to electronic and related applications where aesthetics are less important. Silicones with their flexible ether linkages are softer and often

used as caulking and gasket materials. Thermoset polyurethanes vary widely from flexible to relatively rigid depending on the chemical structure between urethane groups. Unsaturated polyesters are used for potting and encapsulating compounds for electronics and in glass-fiber-reinforced molding compounds.

This discussion of the major commodity and engineering plastics is by no means complete. It is meant rather to include concepts touched on earlier in evaluating structures in relation to their resultant properties.

Effects of Composition, Processing, and Structure on Properties of Engineering Plastics

Electrical Properties

Volume and/or surface resistivity, the dielectric constant, dissipation factor, dielectric strength, and arc or tracking resistance are considered important electrical properties for design. These properties relate to structural considerations such as polarity, molecular flexibility, and the presence of ionic impurities, which may result from the polymerization process, contaminants, or plasticizing additives. Table 10 shows some typical electrical property values for selected plastic materials.

Table 10 Electrical properties of selected plastics

Plastic	Surface resistivity, Ω	Volume resistivity, Ω· cm	Dielectric strength, kV/mm	Dielectric constant		Dissipation factor	
				At 50 Hz	**At 10^6 Hz**	**At 50 Hz**	**At 10^6 Hz**
LDPE	10^{13}	>10^{16}	>70	2.3	2.3	2×10^{-4}	2×10^{-4}
PTFE	10^{17}	>10^{18}	60-80	2.1	2.1	2×10^{-4}	2×10^{-4}

Volume resistivity is a measure of the resistance of an insulator to conduction of current. Most neat polymers have a very high resistance to flow of direct current, usually 10^{15} to 10^{20} $\Omega \cdot$ cm compared to 10^{-6} $\Omega \cdot$ cm for copper. Electrical conductivity in normally insulating polymers results from the migration of ionic impurities and is affected by the mobility of these ionic species. Generally, plasticizers with their increased mobility and high relative concentration of end groups reduce resistivity and therefore increase electrical conductivity. Because absorption of water increases the mobility of ionic species, this also reduces volume resistivity. Thus, the volume resistivity of nylon 6/6 is reduced by four decades when the polymer absorbs water at ambient conditions. Addition of antistatic agents decrease surface resistivity because the polar additives migrate to the surface of the polymer and absorb humidity. In contrast, conductive fillers, such as carbon black powders and aluminum flake, can form three-dimensional pathways for conduction through insulating polymer matrices. Finally, highly conjugated polymers such as polyacetylene and polyaniline provide sufficient electron movement to reach semiconductor conductivity. For full conductivity, they rely on dopants.

Dielectric Constant and Dissipation Factor. In the presence of an electric field, polymer molecules will attempt to align in that field. The dielectric constant (or permittivity), ε or ε', is a measure of this polarization. While the dielectric constant varies from 1 for a vacuum (where nothing can align) to 80 for water, the values for polymeters (shown in Table 10) are generally so low that most polymers are insulators. The dielectric constant also varies with temperature, rate or frequency of measurement, polymer structure and morphology, and the presence of other materials in the plastic. The dielectric constant of polymers typically peaks at the major thermal transition temperature (T_g and/or T_m) and then decreases because of random thermal motions in the melt. As shown in Fig. 22(a), the dielectric constant decreases abruptly as frequency increases.This occurs between 1 Hz and 1 MHz and is a result of the inability of the dipoles to align with the high-frequency electric fields. The dielectric loss, ε'', is a measure of the energy lost to internal motions of the material, and as shown in Fig. 22(b), peaks where the dielectric constant changes abruptly. The dissipation factor, tan δ, which is given by:

$$\tan \delta = \frac{\varepsilon''}{\varepsilon'} \qquad \textbf{(Eq 8)}$$

is a measure of the internal heating of plastics. Thus, little heating should occur in insulators (tan $\delta < 10^{-3}$), whereas high-frequency welding necessitates that tan δ be much greater (Ref 32).

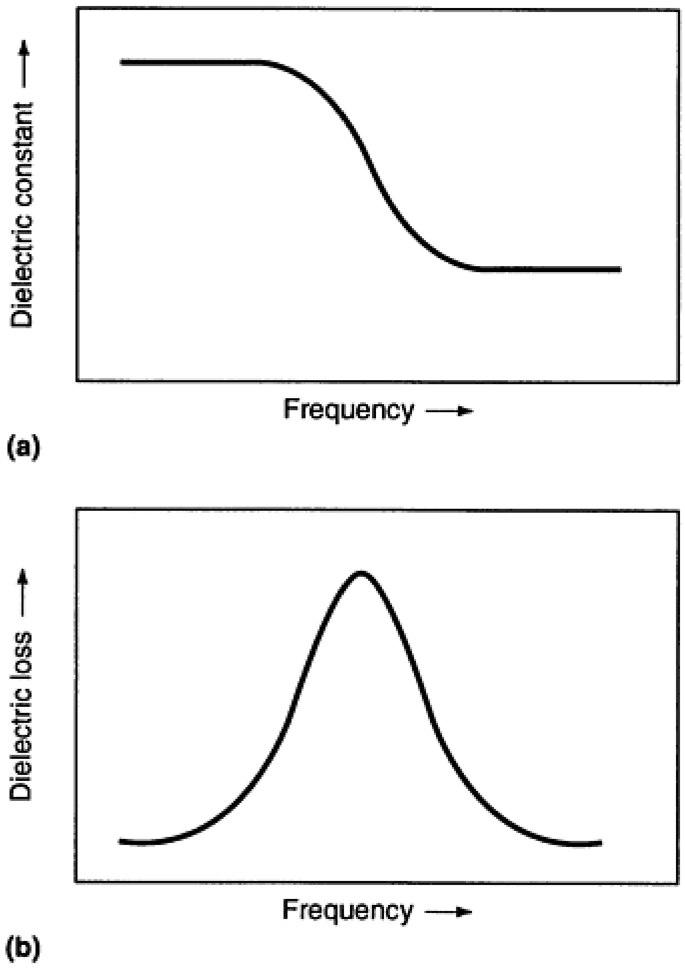

Fig. 22 Frequency dependence of the (a) dielectric constant and (b) dielectric loss. Source: Ref 31

Because polymer molecules are typically too long and entangled to align in electric fields, the dielectric constant usually arises from shifting of the electron shell of the polymer and/or alignment of its dipoles in the field. For nonpolar polymers, such as PTFE and PE, only electron polarization occurs and the dielectric constant can be approximated by:

$$\varepsilon = n^2 \qquad \textbf{(Eq 9)}$$

where n is the optical refractive index of the polymer. These values vary little with frequency, and changes occurring with increased temperatures are caused by changes in free volume of the polymer. In contrast, the dielectric constants of polar polymers, such as PVC and PMMA, are greater than n^2 and change substantially with temperature and frequency. Backbone flexibility or ease of rotation of polar side groups allows some polymers to orient quickly and easily. If the electric field alternates slowly enough, the molecule may be able to align or orient in the field depending upon its flexibility and mobility. Consequently, relatively flexible polymers, such as PVC and PMMA, exhibit greater decreases in dielectric constant with increased frequency than polymers, such as PEI and PSU, that have rigid backbones. The additional free volume and mobility of the plasticized PVC allows the molecules to align with minimal delay; as shown in Table 10, this doubles the dielectric constant at low frequencies.

Dielectric Strength. As the electric field applied to a plastic is increased, the polymer will eventually break down due to the formation of a conductive carbon track through the plastic. The voltage at which this occurs is the breakdown voltage, and the dielectric strength is this voltage divided by the thickness of the plastic. The dielectric strength decreases with the thickness of the insulator because this prevents loss of internal heat to the environment. Dielectric strength is increased by the absence of flaws.

Arc Resistance. In contrast to the dielectric strength, arc resistance is the ability of a polymer to resist forming a carbon tracking on the surface of the polymer sample. Because these tracks usually emanate from impurities surrounding electrical connections, arc resistance is measured by the track times. Polymers, such as PC, PS, PVC, and epoxies (which have aromatic rings, easily oxidized pendant groups, or high surface energies), are prone to tracking (Ref 33) and exhibit typical track times of 10 to 150 s (Ref 34). However, polyesters may have better tracking resistance than phenolics because of the heteroatomic backbone that disrupts the carbon track. Nonpolar aliphatic compounds or those with strongly bound pendant groups usually have better arc resistance; thus, the tracking times for PTFE, PP, PMMA, and PE are greater than 1000 s (Ref 33).

Optical Properties

Transparency, opacity, haze, and color are all important characteristics of plastics. Optical clarity is achieved when light is able to pass relatively unimpeded through a polymer sample. This is usually defined by the refractive index, *n*, which is shown in Fig. 23 and given by:

$$n = \frac{\sin \alpha}{\sin \beta} \quad \text{(Eq 10)}$$

where α is the angle of incident light and β is the angle of refracted light. While *n* for most polymers is 1.40 to 1.70, it increases with the density of the polymer and varies with temperature. In order for a material to be clear, light has to be transmitted with minimal refraction. Unstressed, homogeneous, amorphous polymers, such as PS, PMMA, and PC, exhibit a single refractive index and thus are optically clear. However, when these polymers are severely oriented, and therefore stressed, the areas with different refractive indices produce birefringence in the molded products. Because amorphous, but heterogeneous, systems, such as the immiscible polymer blends ABS and HIPS, typically exhibit a refractive index for each polymer phase, they are usually opaque or translucent. Semicrystalline polymers, such as HDPE and nylon-6/6, effectively have two phases, the amorphous and crystalline regions. Consequently, semicrystalline polymers are usually not transparent. Finally, introduction of any nonpolymeric phases, such as fillers or fibers, into the plastic material induces opacity because these phases have their own refractive indices.

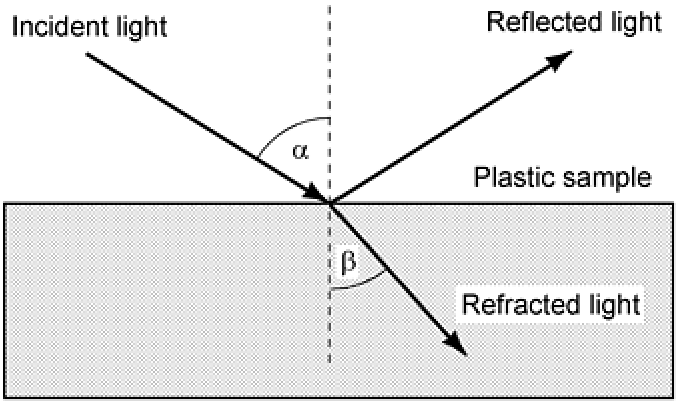

Fig. 23 Light refracted by a plastic sample

Optical clarity can also be controlled by polymerization techniques. When the refractive indices of multiphase systems are matched, these plastics can be optically clear, but usually only over narrow temperature ranges. Neat poly-(4-methyl-1-pentene) (TPX) is clear because the bulky side chains produce similar densities (0.83 g/cm^3), and thus similar refractive indices, in the amorphous and crystalline regions of the polymer. Matching of refractive indices of PVC and its impact modifier is often used in transparent films for food packaging. Domains (second phases) that are smaller than the 400 to 700 nm wavelengths of visible light will not scatter visible light, and thus do not reduce clarity. In impact-modified polymers, the minor rubbery phase is usually dispersed as particles with diameters greater than 400 nm, so most of them are opaque. However, when the domains have diameters less than 400 nm or when the two phases form concentric rings whose width is too narrow to scatter visible light, the blends are clear.

When crystals are smaller than the wavelength of visible light, they will also not scatter light and the plastic will be optically clear or translucent. These crystal sizes can be controlled by quenching, use of nucleating agents, stretching, and copolymerization. In quenching, the plastic melt is rapidly cooled below the transition temperature of the polymer. The resultant reduction in thermal mobility of the polymer molecules limits crystal growth because the molecules are not able to form ordered structures. While quenching is more easily accomplished with thin parts and films, nucleating agents can reduce crystal size in a wider range of parts. The agents are small particles at which the crystallization process can begin. Consequently, many such sites competing for polymer chains will reduce the average crystal size. Stretching also promotes clarity because the mechanical stretching can break up large crystals, and the resultant thinner films are more liable to transmit light without refraction. Finally, copolymerization can reduce the regularity of the polymer structure enough to inhibit formation of large crystals. As discussed earlier, structural regularity is required of a polymer is to pack into tightly order crystallites, and randomization of the structure results in smaller areas capable of being packed together.

The surface character of processed parts also controls optical properties. Smooth surfaces reflect and transmit light at limited angles, whereas rough surfaces scatter the light. Consequently, smooth surfaces produce clear and glossy products while rough surfaces appear dull and hazy. Because surface character is usually controlled by processing, it is discussed in the next section.

Unmodified polymers are usually clear to yellowish in color. Other colors are produced by dispersing pigments or dyes uniformly within the plastic. Poor dispersion can produce the marbled or speckled appearances favored for cosmetic cases. However, degradation of polymers will produce yellowing or browning of the plastic. Polymers such as PVC, which are particularly subject to degradation, are also discussed in the section "Processing" in this article.

Chemical Properties

Solubility is the ease with which polymer chains go into solution and is a measure of the attraction of the polymer to solvent molecules. The old adage of "like dissolves like" can be explained by considering the balance of forces that occur during dissolution of the polymer. Solubility is determined by the relative attraction of polymer chains for other polymer chains and polymer chains for solvent molecules. If the polymer-solvent interactions are strong enough to overcome polymer-polymer interactions, dissolution occurs; otherwise, the polymer remains insoluble. Swelling can be considered as partial solubility because the solvent molecules penetrate the polymer, but they cannot completely separate the chains.

When solvents and polymers have similar polarities, the polymer will dissolve in or be swollen by the solvent. Because longer chains are more entangled, higher MW hinders dissolution. Semicrystalline polymers are much harder to dissolve than similar amorphous materials. The tightly packed crystalline regions are not easily penetrated because the solvent molecules must overcome the intermolecular attractions. Elevated temperatures, which increase the mobility of solvent molecules and polymer chains, facilitate dissolution. The presence of cross-links completely prevent dissolution, and such polymers merely swell in solvents.

Plasticizers must be soluble in the polymer to prevent migration to the surface (blooming) and extraction by solvents. Consequently, the relatively expensive primary plasticizers for PVC closely match the solubility of the polymer, while less expensive secondary plasticizers are less compatible with the PVC.

Permeability is a measure of the ease with which molecules diffuse through a polymer sample. The low densities of polymers compared with metals and ceramics allow enhanced permeation of species such as water, oxygen, and carbon dioxide. If there are strong interactions between the polymer and the migrating species, adsorption will be high, but permeation may be low as the migrating species is delayed from diffusing. For example, the electronegative chlorine atoms substitution in polyvinylidene chloride (PVDC) enhances adsorption of oxygen, nitrogen, carbon dioxide, and water while its tightly packed chain arrangement restricts diffusion of these species. Thus, PVDC films (commonly used as plastic wrap) are extremely valuable in food packaging operations. As shown in Fig. 24, permeability can also be inhibited by the addition of platelike fillers, which increase the distance that water must travel in order to pass completely through the plastic.

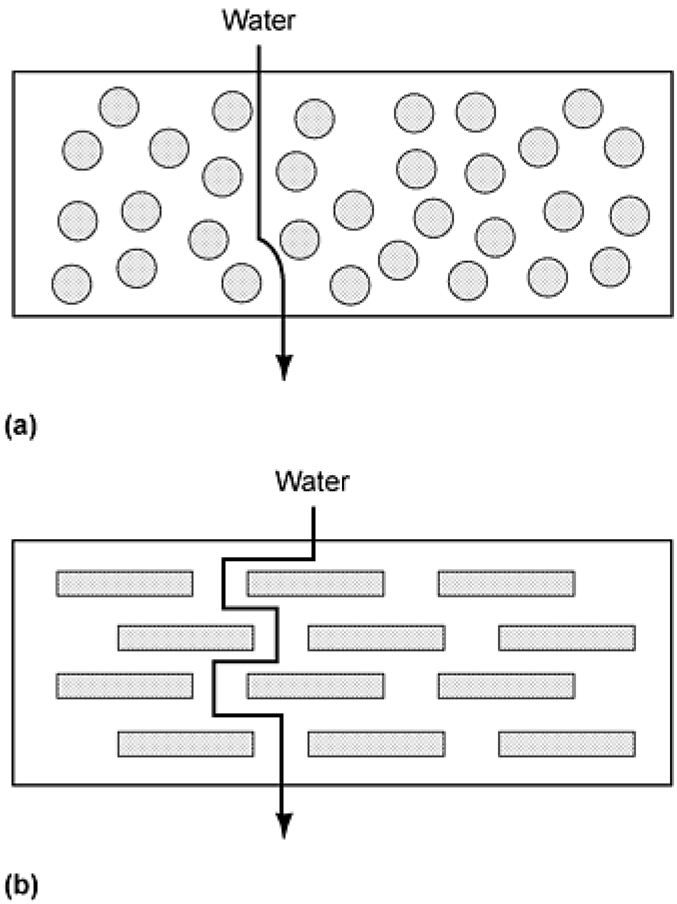

Fig. 24 Barrier pigment effect. Water passes relatively unobstructed through a polymer with spherical additives (a), but must travel around platelike fillers (b). Source: Ref 35

Environmental stress cracking occurs when a stressed plastic part is exposed to a weak solvent, often moisture. The stress imparts strain to the polymer, which allows the solvent to penetrate and either extract small molecules of low $\overline{M}_n$, or to plasticize and weaken the polymer. The stress then causes fracture at these weak areas. Polymers which are exposed to UV light are particularly susceptible to environmental stress cracking. Resistance is enhanced when the permeability of the polymer to water is low.

Processing

Most thermoplastic processing operations involve heating, forming, and then cooling the polymer into the desired shape. This section briefly outlines the most common plastics manufacturing processes. The factors that must be considered

when processing engineering thermoplastics are also discussed. These include melt viscosity and melt strength; crystallization; orientation, die swell, shrinkage, and molded-in stress; polymer degradation; and polymer blends.

Overview of the Major Thermoplastics Processing Operations. Although there are a number of variants, the major thermoplastics processing operations are extrusion, injection molding, blow molding, calendering, thermoforming, and rotational molding. Characteristics of each of these processes are described briefly below. Additional information is provided in the article "Design for Plastics Processing" in this Volume.

Extrusion is a continuous process used to manufacture plastics film, fiber, pipe, and profiles. The single-screw extruder is most commonly used. In this extruder, a hopper funnels plastic pellets into the channel formed between the helical screw and the inner wall of the barrel that contains the screw. The extruder screw typically consists of three regions: a feed zone, a transition or compression zone, and a metering or conveying zone (see Fig. 10 in the article "Design for Plastics Processing" in this Volume). The feed zone compacts the solid plastic pellets so that they move forward as the solid mass. As the screw channel depth is reduced in the transition zone, a combination of shear heating and conduction from the heated barrel begins to melt the pellets. The fraction of unmelted pellets is reduced until finally in the metering zone a homogeneous melt has been created. The continuous rotation of the screw pumps the plastic melt through a die to form the desired shape.

The die and ancillary equipment produce different extrusion processes. With blown-film extrusion, air introduced through the center of an annular die produces a bubble of polymer film; this bubble is later collapsed and wound on a roll. In contrast, flat film is produced by forcing the polymer melt through a wide rectangular die and onto a series of smooth cooled rollers. Pipes and profiles are extruded through dies of the proper shape and held in that form until the plastic is cooled. Fibers are formed when polymer melt is forced through the many fine, cylindrical openings of spinneret dies and then drawn (stretched) by ancillary equipment. In extrusion coating, low-viscosity polymer melt from a flat-film die flows onto a plastic, paper, or metallic substrate. However, in wire coating, wire is fed through the die and enters the center of the melt stream before or just after exiting the die. Finally, coextrusion involves two or more single-screw extruders that separately feed polymer streams into a single die assembly to form laminates of the polymers. Typical extrusion pressures range from 1.5 to 35 MPa.

While single-screw extruders provide high shear and poor mixing capabilities, they produce the high pressures needed for processes such as blown and flat-film extrusion. Screw designs are changed to improve mixing, to shear gel (unmelted polymer) particles, and to provide more efficient melting. The latter designs are particularly critical to the extrusion of PE films where partially melted polymer particles are not desirable.

In addition to single-screw extruders, twin-screw extruders are available. While twin-screw extruders use two screws to convey the polymer to a die, the configuration of the screws produce different conveyance mechanisms. Intermeshing twin-screw extruders transfer the polymer from channel to channel, whereas nonintermeshing twin-screw extruders--like single-screw extruders--push the polymer down the barrel walls. In addition, intermeshing corotating twin-screw extruders tend to move the polymer in a figure-eight pattern around the two screws. Because this produces more shear and better mixing, corotating twin-screw extruders are well suited to mixing and compounding applications. Intermeshing counterrotating twin-screw extruders channel the polymer between the two screws. Twin-screw extruders also permit tighter control of shear because twin screws are usually not a single piece of metal, but two rods on which component elements are placed. Consequently, screw profiles can be "programmed" to impart specific levels of shear.

In contrast to the single- and twin-screw extruders, ram extruders have no screw, but merely use a high-pressure ram to force the polymer through a die. This provides for minimal shear and much higher pressures than available in single-screw extruder. However, ram extrusion is a batch operation, not a continuous operation.

Injection molding is a batch operation used to rapidly produce complicated parts. Plastic pellets are fed through a hopper into the feed zone of a screw and melted in much the same way as occurs in a single-screw or ram extruder. However, rather than being forced through a die, in an injection-molding machine the melt is accumulated and subsequently forced under pressure into a mold by axial motion of the screw. This pressure is typically quite high and for rapid injection and/or thin-walled parts can exceed 100 MPa. Once the part has cooled sufficiently, the mold is opened, the part ejected, and the cycle recommences. The use of multiple-cavity molds allows for simultaneous production of a large number of parts, and often little finishing of the final part is required. Polymer from multiple plasticating units (extruders) can also be injected sequentially into the same mold to form "coinjected" parts. In gas-assisted injection molding, gas is injected into the melt stream and accumulates in thicker sections of the part, whereas in foam processes the introduced gas forms small pockets (cells) throughout the melt.

Blow molding operations generate hollow products, such as soda bottles and automobile fuel tanks. The three basic processes are continuous extrusion, intermittent extrusion, and injection blow molding. In continuous-extrusion blow molding, a tube of polymer is continuously extruded. Pieces of this tube (called parisons) are cut off, inserted into the mold, and stretched into the cavity of the blow mold by air pressure. Although intermittent extrusion blow molding is similar, the tube of plastic is injected from the extruder rather than continuously extruded. In the injection blow molding process. a plastic preform, which for bottles resembles a test tube with threads, is injected molded. Then this preform is brought to the forming temperature (either as part of the cooling from injection molding or after being reheated) and expanded into the blow mold. Stretch blow molding is a variant of the blow-molding process, in which the preform is stretched axially by mechanical action and then expanded in the transverse direction to contact the walls of the mold.

Calendering uses highly polished precision chromium rolls to transform molten plastic continuously into sheet (>0.25 mm) or film ($\leq$0.25 mm) for floor coverings. This process can also be used to coat a substrate, for example, cords coated with rubber for automotive tire use (Ref 36). Usually an extruder provides a reservoir of plastic melt, which is then passed between two to four calender rolls whose gap thickness and pressure profiles determine the final gage of the sheet being formed. Chill rolls are used to reduce the sheet temperature, and a windup station is generally required to collect the sheet product.

Thermoforming operations are used to produce refrigerator liners, computer housings, food containers, blister packaging, and other items that benefit from its low tooling costs and high output rates. In this process, infrared or convection ovens heat an extruded or calendered sheet to its rubbery state. Mechanical action, vacuum and/or air pressure force the heated sheet into complete contact with cavity of the thermoforming mold.

Rotational molding, or rotomolding, involves charging a polymeric powder or liquid into a hollow mold. The mold is heated, and then cooled, while being rotated on two axes. This causes the polymer to coat the inside of the mold. Because rotomolding produces hollow parts with low molded-in stresses, it is often used for chemical containers and related products where environmental stress crack resistance is required. It can also be used for hollow parts with complicated geometries that cannot be produced by blow molding.

Melt viscosity and melt strength are major factors to be considered when choosing a resin and a processing operation. While flexible polymers are generally less viscous than polymers with more rigid structures, MW, MWD, and additives are used to tailor plastics for specific processes. Resins are typically rated by their melt index, which is the flow of the melt (in grams per 10 min) through a geometry and under a load specified by ASTM D 1238 (Ref 37). Although this generates the flow at very low shear rates, it is an indication of the melt viscosity of the plastic. Extrusion blow molding processes require that the melt index be below 2 g per 10 min, whereas other extrusion processes require somewhat greater flow. In contrast, high-melt-index resins (6 to 60 g per 10 min) are necessary in extrusion coating, injection molding, and injection blow molding.

Low-viscosity polymers such as nylon 6/6 tend to leak (drool) from the nozzles of injection-molding machines, so they require special nozzles for injection molding. Aliphatic nylons exhibit narrow melting ranges and so need special screws in which the transition zone is relatively short, typically two or three turns (flights). Molecular weight distribution also factors into the extrusion of relatively low-viscosity polymers such as PEs. A wider MWD provides easier processing, but is detrimental to final properties such as strength and heat sealing. Narrower MWDs, particularly with linear polymers such as HDPE and LLDPE, often necessitate changes to extruder.

High-viscosity polymers, such as PC and PSU, typically require high injection pressures and clamping tonnages. If, however, the pressure required to fill the cavity exceeds the maximum injection pressure for the press, then the cavity is underfilled. When the injection pressure is greater than clamp pressure (tonnage), then the melt can force its way through the parting line (where the mold opens to eject the finished part) and damage the mold. The former problem is common in high-speed or thin-wall injection molding of PC and other high-viscosity resins. While increasing processing temperatures does decrease the melt viscosity, increased plasticating (screw) speeds do not reduce viscosity much due to the rigid backbones of PC and PSU, which extend the lower Newtonian plateau beyond the shear rates typical of plasticating units. However, high shear is still produced during injection and can break the polymer chains, which lowers mechanical properties, such as the impact strength of PC. High-flow resins (melt index > 40 g per 10 min) are available, but these generally exhibit lower MWs with the corresponding changes in properties. Other high-flow resins, which are usually immiscible blends of the primary polymer with a higher-flow plastic or additive, also affect final thermomechanical properties.

Very-high MW or very rigid structures produce polymers that are not truly melt processible. In high-MW materials such as ultrahigh-molecular-weight polyethylene (UHMWPE) and PTFE, the intermolecular attraction and excessive chain length do not allow the materials to melt. Heat will soften these polymers, but they are usually processed as slurries in which a solvent or oil carries the unmolten polymer particles. Because this requires excessive pressure, PTFE is often processed using a ram extruder. Ultrahigh-molecular-weight polyethylene needs less pressure, but is also processed on ram or twin-screw extruders to prevent excessive shearing (as is discussed later in this article). The high MW ($\sim 10^6$ Daltons, Ref 38) of the PMMA used for Plexiglas (trademark of Rohm and Haas Corp.) sheet does not permit melt processing, but rather the sheet is cast (polymerized) from the monomer (molding grade PMMA resins have MWs in the range of 60,000 Daltons, Ref 38).

The very inflexible structures of polyimides and aromatic polyamides do not permit melt processing. While polyimides are cast, more flexible variations, such as PEI and polyamide-imide (PAI) are melt processible. Similarly, copolymers and other variants of PTFE are melt processible. In both cases, the properties of the melt-processible polymers are less than those of the originals. Polyphenyl oxide is barely processible. However, blends of PPO with PS or HIPS are.

Additives such as processing aids and colorants can severely alter the viscosity of a polymer. It is not unusual for the same polymer compounded in different colors to have very different flow characteristics. Fillers and fibers typically increase melt viscosity. High loadings of fine particulate fillers, such as carbon black and titanium dioxide, can alter the low shear-rate behavior of the plastic; because these materials exhibit yield stresses, more force or pressure is required to initiate movement of the molten polymer. Regrind (processed polymer from runners and sprues) is often recombined with the virgin resin. However, because the regrind usually has a lower MW than the virgin resin, the flow characteristics of the mixture differ from those of the neat polymer.

Control of viscosity is critical in several processes. In coextrusion, the polymers must form layers and not mix with each other. Thus, the maximum viscosity difference for multimanifold dies is 400 to 1, whereas it is 2 or 3 to 1 for feed blocks where the molten layers are in contact longer. In gas-assisted injection molding, the polymer viscosity determines where the bubble will form. Viscosity also allows the polymer flow in rotary molding and extrusion coating.

Melt strength is the ability of the molten polymer to hold its shape for a period of time. Because long entangled polymer chains produce melt strength, these resins are high-MW polymers (with the related low-melt index values). However, polymers, such as PS, PET, and some nylons, which do not permit sufficient entanglement, always have low melt strength. Consequently, the processing equipment must accommodate this. Fiber extrusion lines usually place the extruder two or three floors above the windup units and draw the low-melt-strength fibers with gravity. This technique has also been used in blown-film extrusion of nylons. Polystyrene and PET are generally processed using flat-film extrusion so that the melt flows from the die to chill rollers that support the melt. As discussed earlier, biaxially oriented PET films are then produced by heating the flat film to its rubbery state and stretching it on a center frame. Low-melt-strength polymers must always be injection blow molded.

Sheet materials used for thermoforming require hot strength to prevent excessive sagging of the rubbery polymeric sheet during heating. While this strength is also related to the MW and MWD, it incorporates the transition temperatures of the polymer. Because amorphous polymers exhibit broad transitions from their T_g to the molten state, they are easily thermoformed. The sharper melting transitions of polymers, such as PP, PET, and nylons, provide narrow processing temperature ranges and tend to be either too solid to form or too molten and sag. Broadening of the MWD of PP and copolymerization of PET have produced grades of these resins suitable for thermoforming. There are also special techniques that use the ductility of PP to thermoform parts.

Crystallization has two components: nucleation and crystal growth. Nucleation is the initiation of crystallization at impurities in the polymer melt and is enhanced by rapid cooling rates and nucleating agents. Crystal growth is favored by slower cooling rates (which allows the molecules enough thermally induced mobility to assume a crystalline structure). Although the maximum crystallinity occurs if the polymer is held at 0.9 T_m (K), the degree of crystallinity developed is a function of the temperatures achieved and how long the molten plastic is kept warm. Consequently, because rapid cooling produces no crystallinity or many small crystallites, it is used to produce optically clear PE-blown film and blow-molded PET bottles. Slower cooling or annealing--which produces fewer, but larger, crystals--is not always favored because mechanical properties such as impact strength are adversely affected. Moreover, while the intermolecular bonding that occurs in a crystalline polymer results in improved mechanical and thermal properties, the desire for crystalline, stress-annealed parts is balanced by economics, which usually dictate that plastics be cooled as rapidly as possible to reduce production time.

The volumetric changes (tight molecular packing) associated with crystallization produce shrinkage in plastics products. Consequently, the semicrystalline plastics shrink far more than amorphous plastics, and the degree of shrinkage varies with the cooling rate. Typical shrinkage values are presented in Table 11, but the incorporation of additives--such as fillers and glass fibers, which interrupt or enhance crystallinity--can affect shrinkage. Because flexible polymers, such as aliphatic nylons and PP, exhibit high levels of shrinkage, particularly in thick cross sections, they reduce shrinkage during extrusion by utilizing the high pressures of ram extruders to process the polymers slightly below their melting temperatures.

Table 11 Typical shrinkage values for selected polymers

Polymer	Shrinkage, mm/mm	
	Polymer	**Polymer with 30% glass fiber**
HDPE	0.015-0.040	0.002-0.004
PP	0.010-0.025	0.002-0.005
PS	0.004-0.007	. . .
ABS	0.004-0.009	0.002-0.003
POM	0.018-0.025	0.003-0.009
Nylon 6/6	0.007-0.018	0.003
PET	0.020-0.025	0.002-0.009
PBT	0.009-0.022	0.002-0.008
PC	0.005-0.007	0.001-0.002
PSU	0.007	0.001-0.003
PPS	0.006-0.014	0.002-0.005

Source: Ref 39

Crystallinity can also vary through the thickness of a part with the rapidly cooled outside surfaces and the slowly cooled core having different levels of crystallinity. This effect, which varies with polymer type and processing conditions, can alter plastic properties. With flexible polymers, such as PP, crystallization occurs throughout the thickness. However, at relatively slow injection speeds and low mold temperatures, relatively rigid polymers, such as syndiotactic PS, polyphenyl sulfide (PPS), and polyketones, produce layers of amorphous polymer at the surface and core of the part with a semicrystalline region between these layers (Ref 40). At high temperatures, these polymers behave more like PP.

Orientation. Different levels of orientation--and the related phenomena of die swell, shrinkage, and molded-in stress--are introduced during processing. Because gravity is the only force acting on the melt during rotational molding, very

little orientation occurs in this process. Uniaxial orientation results from pipe, profile, flat-film and fiber extrusion, and calendering, whereas blow molding and blown-film extrusion induce biaxial orientation. While the actual orientation in injection molding varies with the mold design, the high flow rates generally align the polymer molecules in the direction of flow. Thermoforming also orients the polymer chains according to the design of the product.

Die swell is the expansion of the polymer melt that occurs as the extruded melt exits the die. This occurs when the aligned polymer chains escape the confines of the die and return to their random coil configuration. Die swell is dependent on processing conditions, die design, and polymer structure. It typically increases with screw speed (output rate) and decreases with higher melt temperatures and longer die land lengths. Increased MW, which produces more entanglement, also increases die swell.

Melt Fracture. At high extrusion rates, the polymer surface may also exhibit sharkskin or melt fracture. When the shear stress during extrusion exceeds the critical shear stress for the polymer, a repeating wavy pattern known as sharkskin occurs. In high-MW polyolefins this may disappear as the shear rate reaches the stick/slip region where the defect is present, but not visible. At even higher speeds, the polymer surface breaks up again in the defect known as melt fracture. This is particularly important in continuous and intermittent extrusion blow molding where these high-MW polymers are used; the output rates for continuous extrusion blow molding are typically below the critical shear rate, while those for intermittent extrusion blow molding place the process in the stick/slip region.

Shrinkage. Although shrinkage results from the volumetric contraction of the polymer during cooling, it is influenced by the relaxation of oriented polymer molecules. During processing the polymers align in the direction of flow, and their relaxation causes swelling perpendicular to this direction. Consequently, shrinkage in the direction of flow is usually much greater than transverse to flow. Addition of fillers and fibers, which also align in the flow, reduces shrinkage because they prevent the aligned molecules from relaxing. While rapid cooling can prevent the aligned polymer chains from relaxing, these chains contribute to molded-in stress.

Molded-in stress is the worst in regions where the polymer chains are highly aligned and not allowed to relax. Thus, processes with high levels of orientation produce the greatest molded-in stress. The stressed areas are points of attack for chemicals and sources of future breaks and cracks. Annealing will remove some of these stresses and is routinely required for some polymers such as PSUs. Because processes such as thermoforming and injection blow molding do not actually melt the plastic, but shape it at lower temperatures, the stretching produces high levels of molded-in stress. Usually the gate region of an injection-molded part will have the highest stresses, and consequently gate location is an important consideration in part design and failure analysis.

Polymer Degradation. Polyvinyl chloride, other chlorine-containing polymers, fluoropolymers, and POM tend to degrade under normal processing conditions. The dehydrochlorination of PVC occurs relatively easily and requires tightly controlled processing conditions. Hydrochloric acid formed during the degradation of PVC is not only corrosive to the equipment, but it catalyzes further degradation. The remaining polymer becomes increasingly rigid and discolored due to the formation of conjugated carbon-carbon double bonds. A similar reaction occurring in fluoropolymers produces the equally corrosive hydrofluoric acid. In contrast, POM depolymerizes from the ends of the polymer in an action called "unzipping"; this produces formaldehyde, which further catalyzes the depolymerization. To prevent or minimize degradation of PVC (or other chloropolymers and fluoropolymers), stabilizers are added to the plastic. With POM, copolymerization with cyclic ethers (such as ethylene oxide) or incorporation of blocking groups at the ends of the polymers (end capping) prevents unzipping.

Because many engineering polymers were produced by condensing two components to produce water, the presence of water during melt processing reverses this reaction. Thus, chains are broken, the MW is reduced, and properties decrease. In addition, water migrates to the surface of the part, resulting in the visual defect known as splay. While water uptake varies with the polarity and storage conditions of the plastic, most engineering plastics require drying before processing. Of the polymers shown in Table 12, only HDPE, PP, and rigid PVC are usually processed without some drying. While undried ABS and PMMA will not exhibit chain scission, they are typically dried to prevent splay. The remaining polymers in Table 12 are subject to chain scission and visual defects. Control of the water content in PET is of major importance for clarity of blow-molded bottles.

Table 12 Water absorption, processing temperatures, and maximum shear conditions for selected polymers

Polymer	Water absorption, %	Processing temperatures, °C	Maximum shear stress, MPa	Maximum shear rate, $10^3 s^{-1}$
HDPE	<0.01	180-240	0.20	40
PP	0.01-0.03	200-260	0.25	100
PMMA	0.10-0.40	240-260	0.40	40
PVC, rigid	0.04-0.40	140-200	0.20	20
ABS	0.20-0.45	200-260	0.30	50
POM	0.25-0.40	190-230	0.45	40
Nylon 6/6	1.00-2.80	270-320	0.50	60
PET	0.10-0.20	280-310	0.50	. . .
PBT	0.08-0.09	220-260	0.40	50
PC	0.15	280-320	0.50	40
PS	0.30	310-340	0.50	50

Source: Ref 8, 39

The combination of temperature and shear can also degrade plastics. The long entangled polymer chains of UHMWPE are easily severed in single-screw extruders. Heat-sensitive polymers such as PVC also degrade when the viscous dissipation from shear raises the melt temperature above the degradation temperature. Because counterrotating twin-screw extruders have positive material conveying characteristics, uniform residence time, and uniform temperature distributions, they are used for extruding materials such as rigid PVC. Ultrahigh-molecular-weight polyethylene is often processed on twin-screw extruders or ram extruders (which have little shearing action). While shear can be a problem in extrusion processes, it is usually greatest in injection molding where polymer is forced at high velocities through small orifices. As indicated in Table 12, the processing temperatures and maximum shear conditions vary from polymer to polymer. However, as mentioned previously, when forcing highly viscous melts through thin channels, these maximum values are easily exceeded. Excess shear rates produce chain scission, whereas excess shear stress tends to produce cracking and related defects in the plastics product.

When continuous-glass fibers or glass mats are processed using traditional thermoset processing techniques, the glass fibers usually remain unbroken. However, the discontinuous glass fibers commonly added to engineering resins are often broken during plastication and molding. As shown in Fig. 25, the fiber length is critical to the strength of the "composite." Reduction of the fiber length below a critical value results in a rapid decrease in strength. Consequently, glass fibers are often compounded into polymers using the controlled shear of twin-screw extruders. Special nonreturn valves (at the end of screws in injection-molding machines) also minimize fiber degradation.

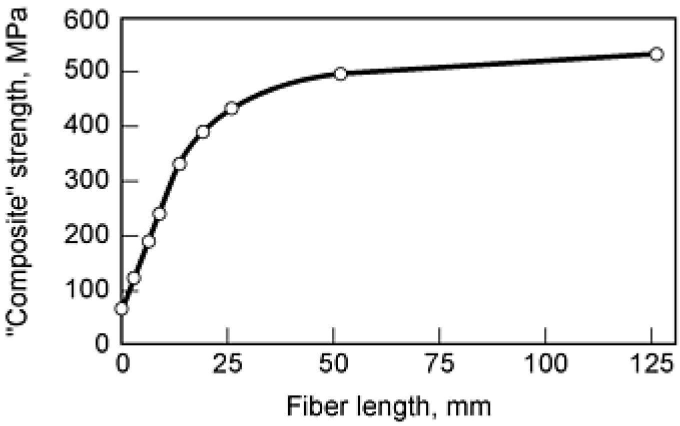

Fig. 25 The effect of fiber length on material strength. Source: Ref. 41

Blends. The properties of immiscible and partially miscible blends depend on their processing conditions. Some are engineered so that one phase migrates to the air interface and governs surface properties. In immiscible polyblends, morphology is very sensitive to temperature and shear. These determine the size of the domains and whether the domains are spherical, elongated, or laminar. Phases may elongate in the flow direction.

Effects of Composition, Processing, and Structure on Properties of Composites

R. Laramee, Intermountain Design Inc.

Introduction

COMPOSITES fabricated with fiber reinforcement and a resin, carbon, or metal matrix are versatile materials that offer several advantages for today's innovative and demanding designs. In general, composites are lightweight, strong, and impact and fatigue resistant. They can be cost competitive, and are adaptable to many applications. Composites can be readily tailored in composition and manufacturing processing to meet specific engineering-design applications and loading conditions.

This article describes the interaction of composition, manufacturing process and composite properties and how variations in the composition, manufacturing, shop process instructions, and loading/environmental conditions can affect the use of a composite product in a performance/service life operation.

For composite matrix and reinforcement systems, the reinforcement type and orientation will in most instances be the dominant contributor to properties. With the use of good coupling agents, the reinforcement and matrix can be more effective in working together to resist all loading conditions. Fillers can be used effectively to lower density and cost, change strength properties, and facilitate the manufacturing process.

Generally, in manufacturing, a longer process time with a higher pressure and temperature will result in higher properties and an improved product. Knowledge of the environment and the loading conditions will enable the design/manufacturing product team to specify any necessary coatings, optimal structural cross sections, a maintenance schedule, and inspection criteria that will anticipate possible problems.

However, in the actual application of composites to primary and secondary structures--a trade-off among weight, cost, size, and stress/deflections with other materials--composites may not be the answer for every problem. As existing and future designs for mass vehicles such as automotive, trains, ships, and aircraft are evaluated, a hybrid mixture of metal alloys and composites may provide the optimal solutions. An open, creative, and aggressive mind plus good material databases and unique design concepts will go far to provide a balanced materials application to a broadening field of problem solutions.

The design properties of resin-matrix composites are based on a standard composition and a standard processing cure, with planned variations to meet specific design applications. Standard compositions range from a 33 to 66% matrix material plus a 33 to 66% reinforcing fiber. These percentages hold true for resin-, carbon-, and metal-matrix compositions. For resin-matrix composites, the standard processing cures include pressures from 0 to 1700 kPa (0 to 250 psi), temperatures from room temperature to 177 °C (350 °F), and time at maximum temperature of 1 h/in. of component thickness.

Databases of mechanical and thermal properties versus temperature exist for standard materials, as supplied by prepreg suppliers such as Thiokol Inc. and Fiberite Inc. for resin-matrix composites, and as developed in-house for carbon- and metal-matrix products by other manufacturers, for various processing cycles. The following discussion provides data on matrix composition, manufacturing, and mechanical properties.

Effects of Composition, Processing, and Structure on Properties of Composites

R. Laramee, Intermountain Design Inc.

Composition of Composites

For a standard composite panel or structural shape, the ratio of matrix material (resin, metal, or carbon) to the fiber reinforcement ranges approximately from 1:2 to 2:1. The fiber is the main tailoring element for design properties, while fiber orientation and fillers can provide secondary fine tuning for the product application.

The resin, carbon, or metal matrix provides (1) stable dimensional control to the fiber laminate, (2) a small participating component for properties, and (3) a shear resistance between reinforcing fibers. A coupling agent enhances resin matrix-to-fiber bonding, while the filler can fine tune such properties as density, cost/pound, processing viscosity, strength, and flame-retardant characteristics.

Reinforcing-fiber characteristics such as density; fiber diameter, strength, and modulus; fiber-filament bundle size; and woven-fiber fabric type or chopped-fiber form are initially optimized approximately by the "rule of mixtures" to help meet the composite properties needed for the design application engineering criteria for product operation and performance.

In addition, the selection of the ratio of matrix to reinforcement constituents is influenced by the loading patterns to the product, environmental operating conditions, the standard manufacturing-processing methods, reinforcement forms, costs, and completion time for the particular company and industry.

Reinforcement forms for the various matrix systems are shown in Fig. 1. Table 1 identifies a short list of current reinforcements, matrix materials, and coupling agents. Most frequently used reinforcements include:

- Uniaxial continuous fiber for end-tape filament winding, braiding, or pultrusion
- Fabric (warp and fill continuous fiber) for tape wrapping and lay-up fabrication processes
- Chopped, continuous short-fiber reinforcement for molding compounds, injection or resin-transfer molding, and bulk- or sheet-molding compound as a charge for compression molding

Coupling agents are added to assist the binding of organic and inorganic fibers to the resin matrix.

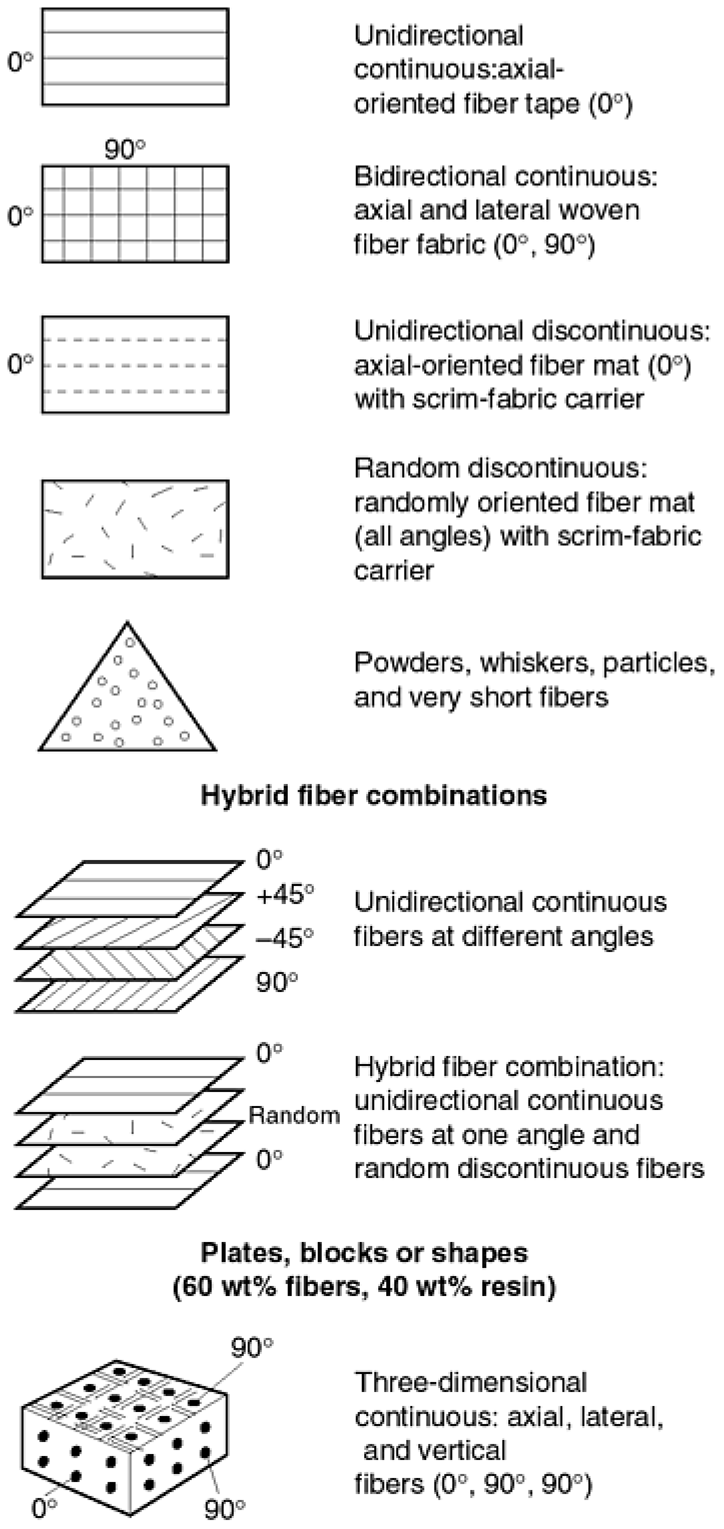

Fig. 1 Reinforcement forms for resin-, carbon-, and metal-matrix composite systems. Source: Ref 1, 2

Resin, carbon, or metal matrix, with or without fillers, can be added to the reinforcement fibers or woven fabric as a partially staged resin (partially solidified, stabilized, or cured liquid resin) or as a metal sheet or foil or powder form, or matrix material can be added to the fibers (in situ) during placement onto or into the open- or closed-mold surface. The matrix can be in the form of a liquid, powder, particles, foil, sheet, or fiber.

Fillers or additives can replace up to 33% of the weight of a resin matrix to tailor composite properties for such characteristics as density, wear resistance, color, ductility, flame-smoke retardation, moisture resistance, lubricity, and

dimensional stability. The components added to the resin matrix will also change the cost per pound, the softening and gelation of the final cure process and a change of the service temperature.

Currently, twelve or more fiber-reinforcement systems are available for resin-matrix-composite fabrication into industrial, commercial, and aerospace products. However, this article concentrates mainly on four fiber types: glass, aramid, carbon, and graphite. Figure 2 shows a comparison of the fiber characteristics and properties. Density ranges from 1.44 to 2.48 g/cm^3, strength from a minimum of 2200 MPa (320 ksi) to a maximum of 4585 MPa (665 ksi), and modulus from 85 to 345 GPa (12 to 50 × 10^6 psi), and service-temperature capability in inert atmospheres from 500 to 3040 °C (930 to 5500 °F). Reinforcements for metal- and carbon-matrix composites are shown in Table 2. Typical property variations for three reinforcements are:

Reinforcement	Density, g/cm^3	Tensile strength		Elastic modulus	
		MPa	**ksi**	**GPa**	**10^6 psi**
Boron metal deposited on a carbon fiber	2.3	5030	730	400	58
Alumina powder pressed, sintered, and formed into fiber	<4.0	450	65	205	30

Table 2 Reinforcements for metal- and carbon-matrix composites

Fiber	Density gm/cm^3	Diameter		Tensile strength		Tensile modulus	
		μm	**μin**	**GPa**	**10^6 psi**	**GPa**	**10^6 psi**

Matrix materials include resin, carbon, and metal. Resin systems include at least 36 types or hybrid combinations, divided into thermoplastics (heat affected) or thermoset (heat permanently cured) divisions. The baseline room-temperature properties and service temperatures of three thermoplastic and three thermosetting resins in Fig. 3 show the ranges of density from 1.14 to 1.43 g/cm^3, tensile strength from 53 to 112 MPa (7.7 to 16.2 ksi), tensile modulus from 875 to 4135 MPa (127 to 600 ksi), and service temperature from 130 to 370 °C (266 to 700 °F).

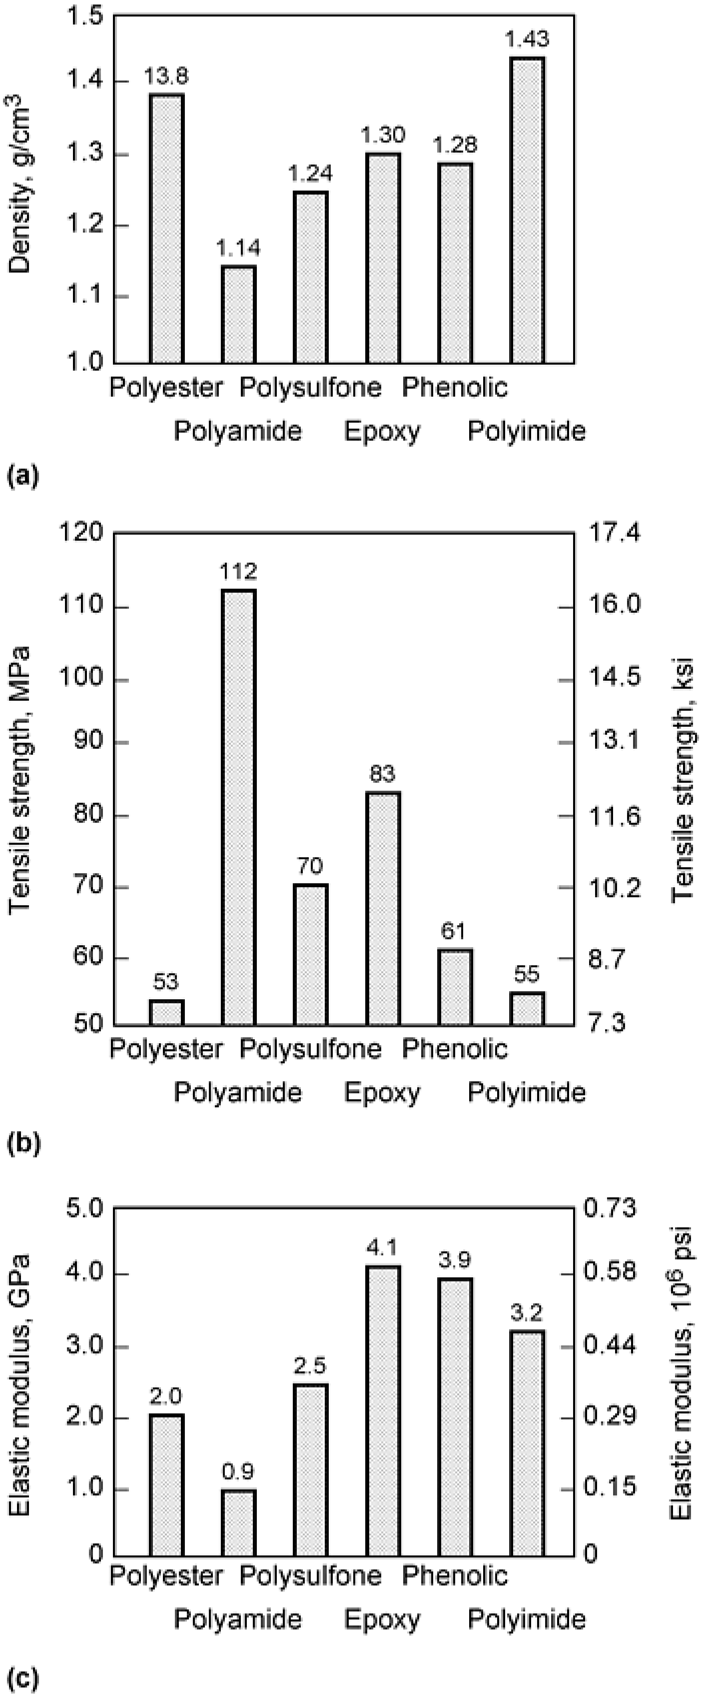

Fig. 3 Mechanical properties and service temperatures for selected matrix resins. Thermoplastics: polyester (unfilled; maximum temperature 140 °C, or 248 °F), polyamide (nylon 6/6, unfilled; maximum temperature 130 °C, or 266 °F), and polysulfone (standard; maximum temperature 160 °C, or 320 °F). Thermosets: epoxy (unfilled; maximum temperature 260 °C, or 500 °F), phenolic (unfilled; maximum temperature 230 °C, or 450 °F), and polyimide (unfilled; maximum temperature 370 °C, or 700 °F). (a) Density. (b) Tensile strength. (c)

Elastic modulus. Source: Ref 4

A common metal-matrix material is aluminum alloy, with properties that include low liquid temperature of 650 °C (1200 °F) (which aids fabrication), a low density (2.75 g/cm^3), a good elastic modulus (70.3 GPa, or 10.2 × 10^6 psi), and an excellent heat-treated yield strength (minimum 276 MPa, or 40 ksi).

For resin-matrix composites, most materials commonly used are preformulated at the supplier for the preimpregnated fiber, resin, curing agent, and coupling system. However, the manufacturer will often add small amounts of a filler to aid in the processing; change surface texture, color, and thermal and electrical conductivity; provide moisture resistance; and serve as an antioxidant. A short list of such fillers for resin matrices is given in Table 3. Modifications to the composition, however, must be tested for compatibility and successful cure processing to achieve properties tailored to meet specific product performance and service operation requirements.

Table 3 Common fillers for resin matrices

Category	Fillers
Lubricating fillers	Molybdenum disulfide, graphite, teflon
Magnetic fillers	Black iron oxide, powdered iron or shot, barium and strontium ferrites
Lower-density fillers	Microballoons: expanded perlite, glass nodules
Reinforcement, viscosity control, decorative fillers	Cotton flock, α-cellulose fibers
Lower compression, sound absorption fillers	Powdered cork, protein
Pigment, packing fillers	Carbon blacks, powdered bituminous coal
Electrical insulation	Fused silica
Lowers composite expansion	Beta encryptite (lithium aluminosilicate)
Electrical conduction	Carbon powder or fibers

Manufacturing of Composites

The manufacturing process shapes the composite laminate through a cure, or solidification, cycle consisting of pressure and temperature plus time at maximum temperature. Higher temperatures and pressures produce thinner parts with higher density and higher mechanical properties. In addition, the open or closed mold surface(s) defines the laminate shape, dimensional stability, and final fiber orientation. The range of part properties depends on the matrix material, the material and type of fiber reinforcement, and any fillers and coupling agents used.

Manufacturing processes include sixteen for fabricating resin-matrix composites in closed and open molds or dies (Tables 4, 5), six for metal-matrix composites (Table 6), and five for carbon-carbon matrix types (Table 7), for a minimum of 27 methods of manufacturing. Each table identifies the state of the fiber and matrix at the start of the process, the fiber orientation, cure or solidification process parameters, and the resin-, carbon-, or metal-matrix material used in the process.

Table 4 Resin-matrix composite closed-mold processing characteristics

Process	Resin	Reinforcement	Filler	Thermoplastics	Thermoset	Fiber orientation	Cure operation

Resin-Matrix Processing

Closed mold methods of fabrication are grouped into four families having similar characteristics (Ref 6, 7, 8, 9, 16).

Preform molding in transfer, compression, or resin-transfer molds uses a preform of fiber or fabric in a resin matrix. Fiber orientation is parallel to the mold surfaces.

Preform flow-die molding by injection, extrusion, or reaction injection uses a preform of fiber or fabric in a resin matrix that is forced through a forming die at high pressure and high temperature and then is cured. Fiber orientation is parallel to the mold centerline or to the mold surfaces.

Thin-shell molding by blow molding, rotational molding, or slip casting uses a liquid resin plus a preform of fiber in a resin matrix that is cured with a temperature, pressure, time cure cycle. Fiber orientation is parallel to the mold surfaces.

Miscellaneous molding processes such as foam, lost core, and thermoforming use short fibers in a resin matrix that is cured using a cure cycle. Fiber orientation is parallel to the mold surfaces.

Open-mold methods are grouped into the following three families by their characteristics (Ref 6, 7, 8, 9).

Moving-mold mandrel processes (filament winding, braiding, and fabric-tape wrapping) use a continuous fiber or fabric with a resin matrix that is wound on a moving mandrel and is subsequently cured. Fiber orientation is parallel to the mandrel surface.

Stationary-mold mandrel processes (fabric hand lay-up, chopped-fiber gun lay-up, fiber-tape lay-down, fiber pultrusion through a die, fabric structural-shape lamination) use a resin matrix that is cured after the required thickness is achieved. Fiber orientation is parallel to the mandrel surface.

Miscellaneous molding processes (such as casting and calendering) use a liquid resin, with or without a fiber reinforcement, shaped to the mold surface by the mold cavity or rollers and cured.

Whereas as the closed-mold tooling includes the capacity for pressure and temperature control over time, open-mold processes require additional equipment for the resin-cure cycle such as:

- Ovens
- Autoclaves (heated pressurized air chambers)
- Vacuum bags and bleeder/release materials
- Hydroclaves (heated pressurized water and component rubber bags)
- Furnaces and induction heaters
- Electron-beam or ultraviolet light resin-cure systems

The additional curing equipment ensures a uniform distribution of the resin matrix, a highly uniform density, and a high-quality component.

Metal-Matrix Processing

Metal-matrix processing involves higher temperatures and pressures for laminate metal-matrix solidification than resin-matrix processing does. Both open- and closed-mold presses are used in conjunction with plasma-arc metal-spray equipment. The family of processes used for metal-matrix composites are listed below (Ref 4, 12, 13).

Powder Metallurgy. Aluminum, titanium, or stainless steel powder plus fiber reinforcement is compacted at a pressure of 21 to 28 MPa (3 to 4 ksi) and sintered at temperatures up to 1760 °C (3200 °F) to form solid right-cylinder billets in closed molds. Subsequent forming to the final shape is by extrusion, rolling, or forging.

Rotating-mandrel processes are used to deposit the following material forms:

- Plasma-arc spraying of the metal matrix and gun-spraying of fiber reinforcement for hollow structural shapes
- Filament winding of continuous reinforcement fiber and plasma arc spraying of the metal matrix (aluminum, titanium, or stainless steel) for plates and shapes
- Filament winding of continuous fiber reinforcement that has been coated with molten metal matrix for plates and shapes

The material is processed on the open mandrel under a low pressure (up to 100 kPa, or 15 psi) and at low temperature (up to 165 °C, or 330 °F) for final solidification. The metal mandrel may or may not be removed, depending on the design concept.

Hot Pressing and Diffusion Bonding. A matrix of carbon, boron, silicon carbide, stainless steel, or titanium in the form of thin metal foil is reinforced with continuous fiber to form a flat sheet preform, which is subsequently densified by pressure and temperature diffusion bonding. High pressure (up to 100 MPa, or 15 ksi) and ultrahigh metal melt temperature (up to 2760 °C, or 5000 °F) is required for solidification to final shape. Shapes are then machined and final finished. The temperature used depends on the metal matrix and fiber types used.

Compressed Reinforcement Preform with Matrix Infiltrations. The preform reinforcement used is usually a metal or organic short fiber pressed into a sheet or solid billet preform, with infiltration of molten aluminum, titanium, or stainless steel by pressure impregnation or carbon infiltration by chemical vapor deposition (CVD). The pressure used may vary from low (0 to 100 kPa, or 0 to 15 psi) for CVD, to high (up to 100 MPa, or 15 ksi) for molten metal, and temperature is very high (up to 2760 °C, or 5000 °F). The temperature used again depends on the metal matrix and fiber types used.

Additional process equipment for the metal-matrix composite fabrication includes:

- CVD furnaces
- Closed molds with temperature, time, and pressure controls
- Hot-vacuum, closed-mold presses
- Plasma-arc metal spray and powder-gun equipment

This equipment ensures a matrix laminate having a uniform density with a minimum of subsurface discontinuities.

Carbon/Carbon Matrix Processing

Carbon/carbon processing methods involve the use of the highest temperature and pressure open molds and vacuum/inert heating chambers for the multiple-resin pressure-impregnation cycles and the subsequent multiple carbonization/graphitization of the resin and/or CVD densification cycles (Ref 2, 4, 15).

Rotating mandrels of bulk graphite are used to deposit a fiber (two- or three-dimensional) lay-down of a reinforcement preform that is subsequently pressure impregnated with a resin, cured, and carbonized. The resin/carbonization cycles may be repeated up to eight times to achieve the density goals. Chemical vapor deposited carbon may also be infiltrated into preform in the late densification cycles as a surface and subsurface strengthening agent and as an oxidation-resistant material.

Filament winding, braiding, or fabric-tape wrapping is used to produce two-dimensional fiber preforms or a three-dimensional fiber shape having radial in-wound or drilled/bonded-in-place radial-rod reinforcements. The fiber or fabric can be preimpregnated with resin or post-wind pressure impregnated with resin and then cured. The preform is

subsequently carbonized and/or carbon (CVD) densified. This cycle is repeated three to eight times and may be graphitized to a final density of 1.45 to 1.95 g/cm^3.

Static (Male/Female) Open/Closed Mold Mandrels. A fiber mat or a fabric-sheet pattern lay-up is resin transfer molded with resin or carbon CVD densification that is carbonized/graphitized and repeat cycled to the density goal.

Alternatively, a fiber preform is placed in a closed chamber and vacuum-pressure resin impregnated, cured, carbonized three to eight times, and graphitized. A variation of this second process is to carbon CVD infiltrate the preform after 2 to 4 cycles of resin char processing. The CVD process is continued for 2 to 3 cycles, with machining/cleaning of the outside surfaces after each cycle to open the preform-billet pores and void areas for further impregnation and densification.

Carbon-fiber/carbon-resin-char-matrix processing is accomplished first by a resin-cure cycle at 163 °C (325 °F) and a pressure of 1725 to 6900 kPa (250 to 1000 psi) in a vacuum-bag enclosure. Second, the cured resin is carbonized and graphitized in inert vacuum chambers. Carbonization requires a 1370 to 1930 °C (2500 to 3500 °F) temperature and a time of approximately one week, and graphitization requires a temperature of 2480 to 3040 °C (4500 to 5500 °F) and a one-week period. The reimpregnation of the pores and void cavities of the charred component, after machining the surfaces and cleaning, is at a pressure of 10.3 to 17.2 MPa (1500 to 2500 psi) in an inert vacuum chamber heated to 540 to 1095 °C (1000 to 2000 °F) for less than one week. An occasional carbon (CVD) infiltration into the carbonized preform is performed by processing in an inert vacuum furnace at 1370 to 1930 °C (2500 to 3500 °F) for less than one week.

Equipment in addition to the open graphite mandrels for carbon/carbon matrix processing includes carbonization and graphitization furnaces and carbon (CVD) infiltration chambers. In addition, resin-impregnation pots are used to fill the fiber preforms with a pitch or phenolic-resin system. Lathes or large turning machines are used after each densification cycle to prepare a fresh surface for the next resin-impregnation/char-densification cycle and to ensure final dimensional control. The open graphite mandrel is used for fabrication of the carbon/carbon fiber filament-wound preform, while closed chambers are used for the resin impregnation, carbonization, graphitization, and carbon (CVD) infiltration densification cycles.

Additional information about processing of composites is provided in the article "Design for Composite Manufacture" in this Volume.

Mechanical Properties of Composites

Within a composite laminate consisting of a reinforcing fiber/fabric, fillers, coupling agent and resin, metal, or carbon-matrix system, the greatest influence on mechanical properties is the reinforcement type and its percentage of the total constituents. That is, among composite components that have the same fiber orientation in the laminates and the same matrix material, the component having the highest-strength fiber and the greatest percentage (by weight) of fiber in the laminate will exhibit the greatest strength. Likewise, in the component, the highest strength exists in the planes with the highest percentage of fiber (Fig. 1). For a three-dimensional block, strength is greatest in the vertical and axial fiber directions. For a two-dimensional block, strength is greatest in the axial direction.

The decrease in laminate strength with an increase in temperature, as shown in Fig. 4 and 5 for glass and carbon fibers in an epoxy-resin matrix, is caused by the softening and a weight loss of water and solvent in the resin system. Resin weight loss begins at 120 to 175 °C (250 to 350 °F), and resin conversion to a porous char state begins at 315 to 760 °C (600 to 1400 °F). Resin matrix carbon retention for carbon matrix conversion at 760 °C (1400 °F) is 55% for phenolic, 17% for polyester, and 10% for epoxy (novolac). Fiber strength does not degrade significantly until the following temperatures are reached:

Fiber	Temperature	
	°C	**°F**
Kevlar	160	320
Glass	430	800
Al_2O_3	1200	2200
Boron	1650	3000
SiC	1650	3000

Resin-matrix composites (as well as metal- and carbon-matrix composites) are used in many aerospace and military applications at temperatures below -20 °C (0 °F) and above 760 °C (1400 °F). The resin-matrix composite having the best elevated-temperature properties is carbon fiber (highest degradation temperature) in phenolic resin (highest resin matrix carbon retention).

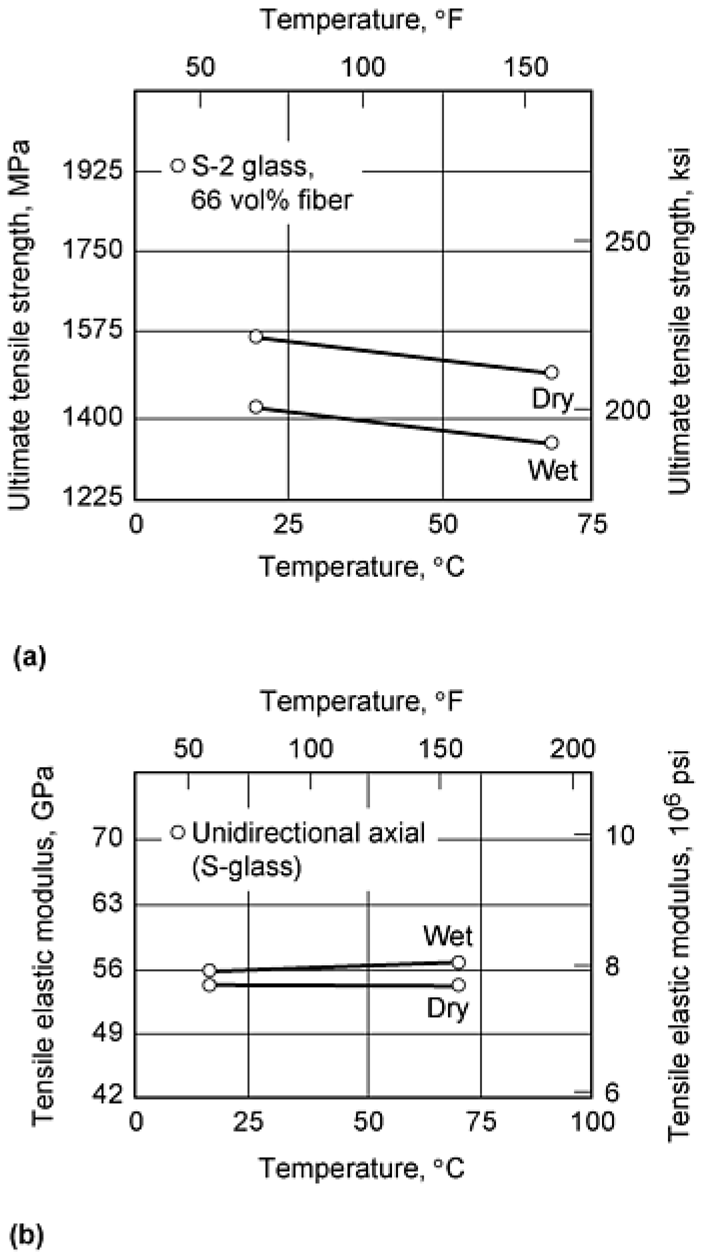

Fig. 4 Effect of temperature on the strength of S-glass-fiber/epoxy-matrix composites. (a) Tensile strength. (b) Elastic modulus. Source: Ref 4

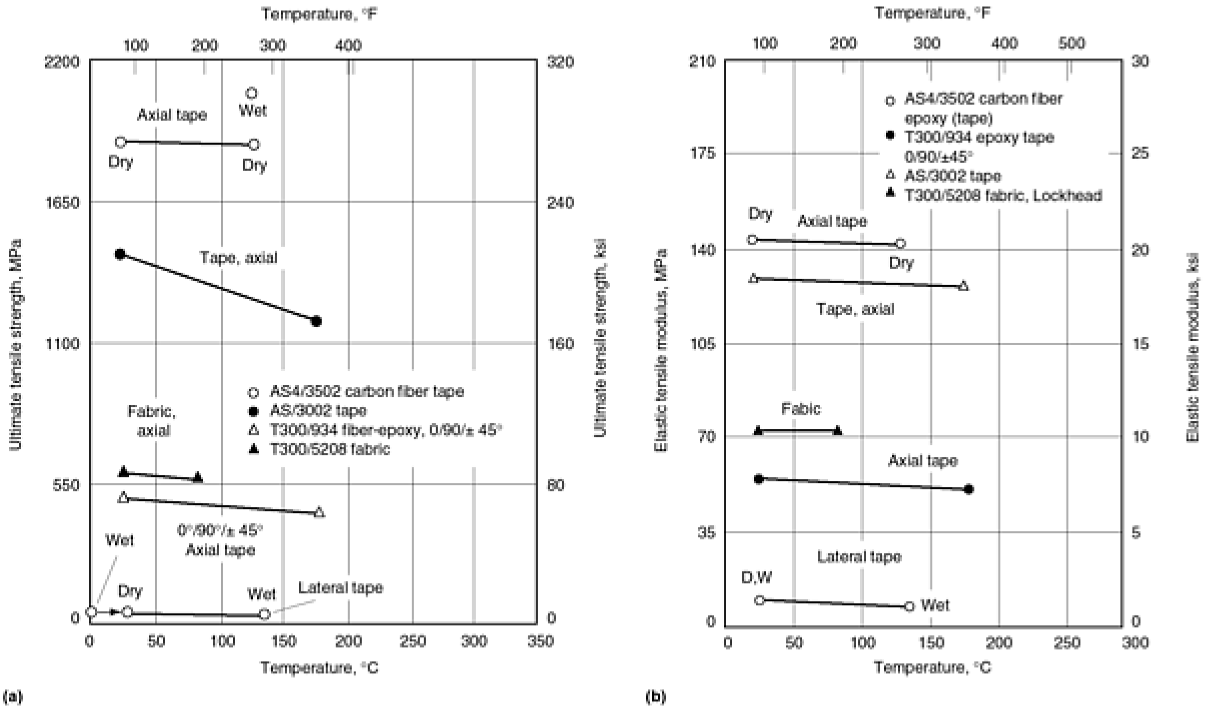

Fig. 5 Effect of temperature on the strength of carbon-fiber/epoxy-matrix composites. (a) Tensile strength. (b) Elastic modulus. Source: Ref 4

The strengths of metal-matrix composites using three different nonferrous alloys as the matrix materials are shown in Table 8. As can be seen, the titanium alloy provides higher strength and modulus (and higher density and cost) than the aluminum-alloy matrix. Of the available reinforcing fibers, boron, glass, and carbon provide the highest composite strengths, while graphite, silicon carbide (SiC), and aluminum oxide (Al_2O_3) provide the highest composite modulus.

Table 8 Typical mechanical properties of metal-matrix composites

Matrix material[(a)]	Reinforcement			Tensile strength[(b)]		Tensile modulus[(b)]

				340 (T)	49 (T)	. . .	. . .

Source: Ref 1

(a) Matrix material baseline is aluminum or titanium alloy in sheet, foil, melt, powder, or spray form and solidified with a temperature, pressure, and time cycle. Reinforcement fiber or powder is processed to higher temperatures than the metal matrix, thus the solidification cycles have little or no effect on the fiber.

(b) For fiber-reinforced materials, properties are reported in the direction of the fiber (L) or transverse to the fiber (T).

(c) Coated SiC fiber.

A variety of carbon-reinforcing-material types (fiber, fabric, felt, particles) can be bonded together with a carbon or graphite form of a phenolic or pitch resin-matrix system or a CVD carbon- or graphite-matrix system to form carbon/carbon composite shapes. At least six types (having specific gravities of 1.30 to 2.00) exist for the fabrication of laminates, rings, and cones by molding, tapewrapping, lay-up, or filament winding. Figure 6 shows the properties of eight such types. Of these, the material that uses a carbon fiber in a CVD carbon matrix has the highest tensile strength and percent strain, while the material that uses carbon fiber in a high-melt-temperature pitch-resin matrix exhibits the highest modulus.

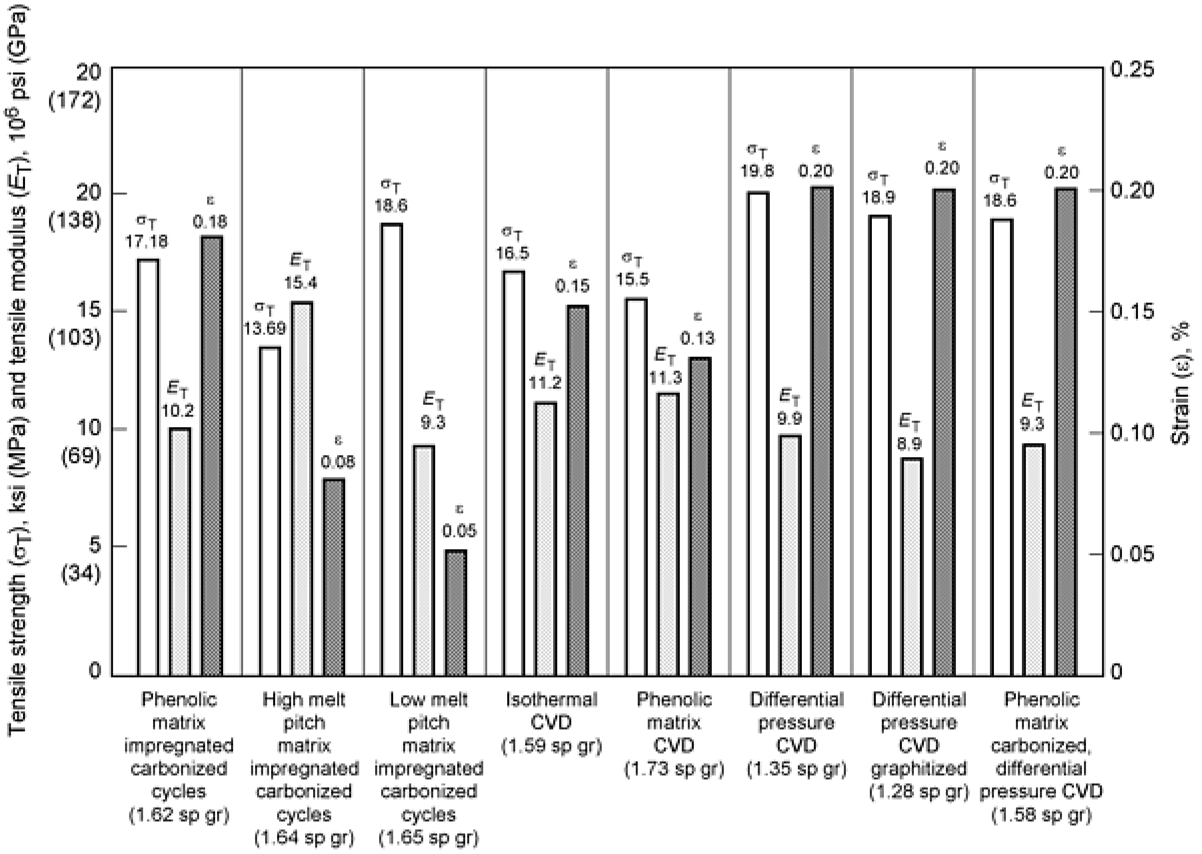

Fig. 6 Room-temperature mechanical properties of carbon-fiber/carbon-matrix (carbonized resin/CVD carbon) composites (tensile hoop rings). Source: Ref 15

Effects of Composition, Processing, and Structure on Properties of Composites

R. Laramee, Intermountain Design Inc.

Effects of Composition Variations on Properties

A composite material can be "tailored" to a product application by varying the composition and/or percentage of the total composition weight or volume of any or all parts of a composite composition, such as the matrix, fiber reinforcement, and coupling agent.

An S or E glass fiber reinforcement will give the highest strength at the least cost, while a graphite fiber provides the highest modulus at the highest cost. Fiber content in a matrix can vary from 33 to 66% by weight, can be a unidirectional continuous fiber or a two-directional woven fiber fabric, and the angle orientation between successive plys of material can be changed for further strengthening. A fiber/matrix coupling agent at 1 to 2% (by weight) on the fibers can help the laminate become stable, uniform, continuous, low in void content, and homogenous, thereby enhancing properties up to

25%. In addition, a filler can modify the modulus, strength, resin flow (viscosity), uniformity, ease of processing, and the density of a resin-matrix material. Hollow microspheres of carbon in the resin matrix can lower the composite density by 5 to 15% and decrease strength levels by 15 to 25% with an addition of only 1 to 10% by weight of spheres. Fillers in the resin matrix are usually kept to a low percentage (by weight), but may increase up to 20 to 30% when used in powder or whisker form.

It should be noted that two or more different fibers in a resin, metal, or carbon matrix can be formulated successfully as long as they are cure or bond-matrix compatible and their service performance is satisfactory.

Variations in composition can include the following significant factors:

- Fiber type
- Fiber content, %
- Fiber length
- Fiber orientation
- Laminate thickness
- Fiber/resin coupling agent
- Filler types

A primary composition decision is the fiber type to be selected. Among four of the common fibers--glass, aramid, carbon, and graphite--glass fiber offers high strength and impact resistance (see Fig. 7) with good damping characteristics and low cost but a high density (1.90-2.10 g/cm^3). Graphite offers lower strength and impact resistance; it also exhibits a high modulus, thermal stability, good oxidation resistance at temperature, and a light weight (1.32-1.90 g/cm^3), but at a higher cost. Density is an important factor in part-quality inspection and achieving system weight requirements.

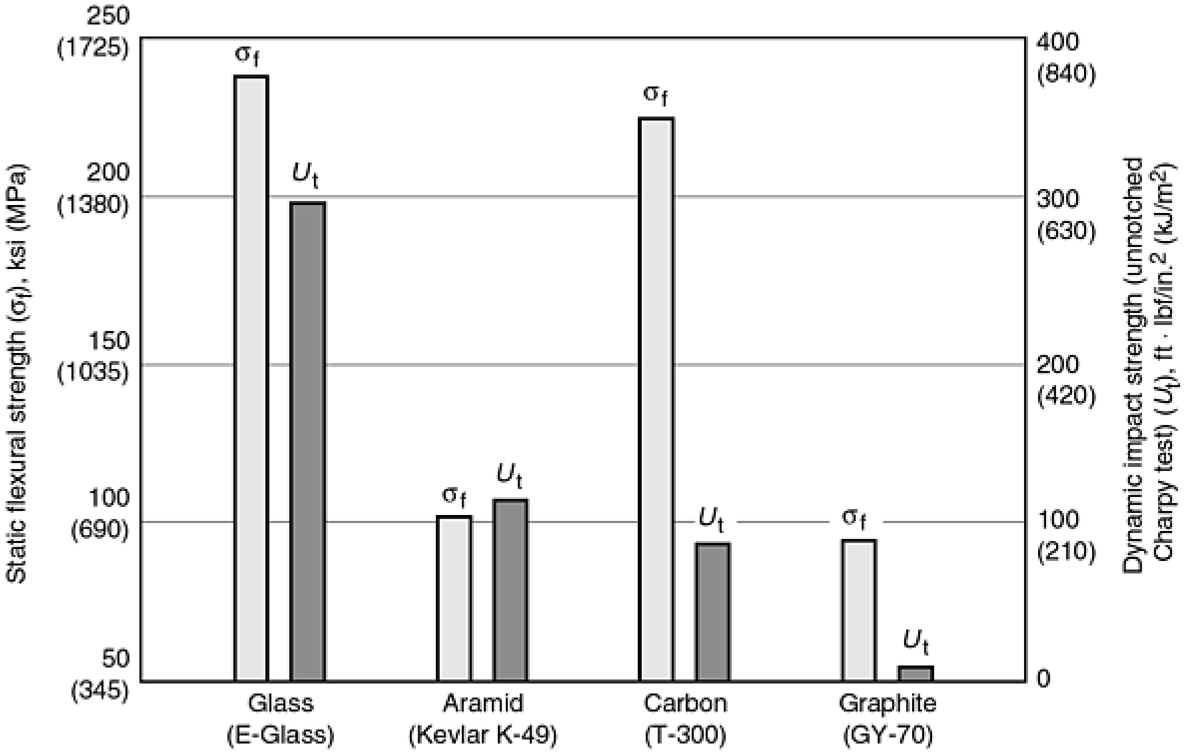

Fig. 7 Effect of fiber type on the flexure strength and impact strength of fiber/epoxy composites. Source: Ref 1

Figure 8 shows the increase in composite strength and modulus with an increase in the percent of glass fiber in a fiber/polyester laminate; this same trend also exists for carbon felt in a CVD carbon- or graphite-matrix material (Ref 12).

The use of longer-length reinforcing fibers in a resin-matrix composite also provides higher strength than shorter fibers (Table 9).

Table 9 Effect of chopped-fiber length on the mechanical and thermal properties of E-glass/phenolic composites

Fiber length		Notched izod impact strength		Tensile strength		Flexural strength		Flexural modulus		Compressive strength		Coefficient of thermal expansion (23-250 °C), 10^{-4} in./in./°C
mm	**in.**	**J/m**	**ft · lbf/in.**	**MPa**	**ksi**	**MPa**	**ksi**	**GPa**	**10^6 psi**	**MPa**	**ksi**	
<6	$<\frac{1}{4}$	30-65	0.6-1.2	55-83	8-12	69-103	10-15	13.8-24.1	2.0-3.5	241-276	35-40	1.5-2.5
6	$\frac{1}{4}$	320-426	6-8	83-103	12-15	103-138	15-20	13.8-17.2	2.0-2.5	241-276	35-40	1.5-2.5

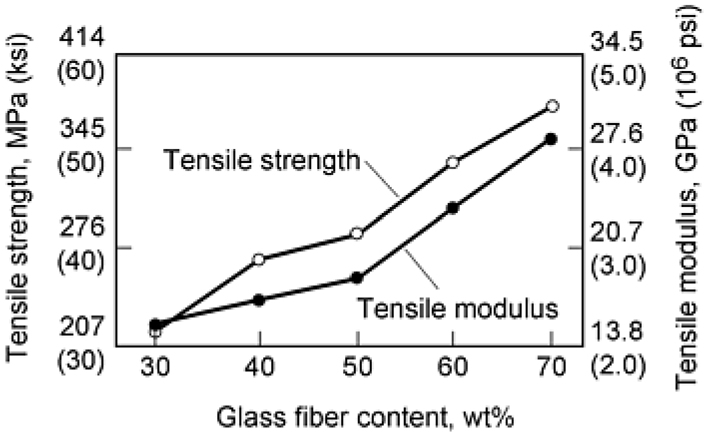

Fig. 8 Effect of glass fiber content on the longitudinal mechanical properties of pultruded E-glass/polyester composite sheets. Source: Ref 1

As shown in Fig. 9 (for a resin-matrix composite) and Fig. 10 (for two metal-matrix composites), strength of a composite is also highest when the fiber direction is parallel to the loading direction (0°) and the lowest when the fiber is oriented perpendicular to the loading direction (90°) (where strength is a measure of resin strength only).

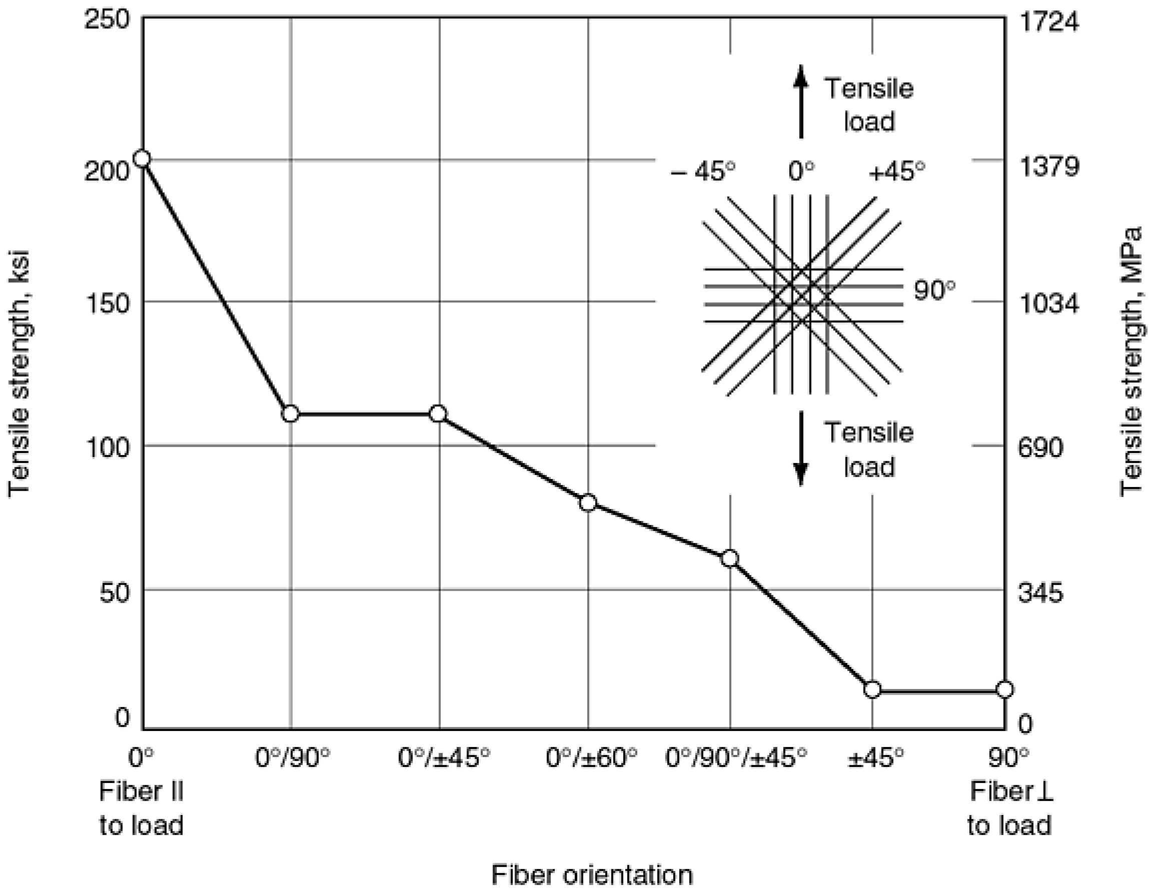

Fig. 9 Effect of fiber orientation on the strength of carbon-fiber/epoxy composites. Source: Ref 1

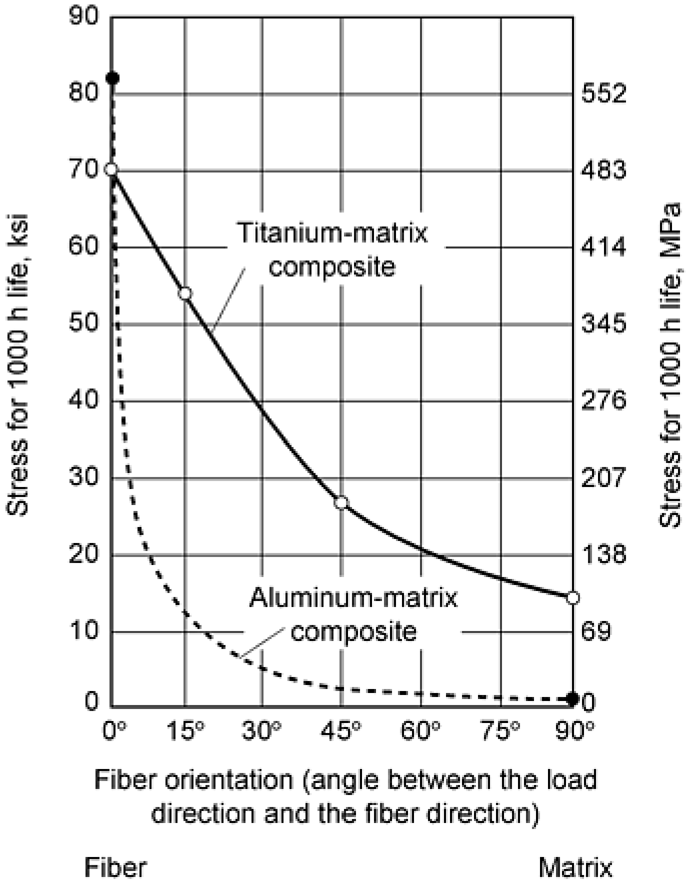

Fig. 10 Effect of fiber orientation on the creep strength of two metal-matrix composites reinforced with boron/SiC fiber. Titanium-matrix composite has matrix of Ti-6Al-4V; test temperature 425 °C (800 °F). Aluminum-matrix composite has matrix of 6061 aluminum; test temperature 300 °C (575 °F). Source: Ref 17

Another factor that affects mechanical properties is laminate thickness. As shown in Fig. 11, as the plate thickness of carbon/fiber epoxy resin-matrix composite increases from 12 to 18 plies (13 to 22 mm, or 0.5 to 1.0 in.), strength and modulus decrease as more void areas and/or resin-rich areas of lower local properties are introduced into the laminate.

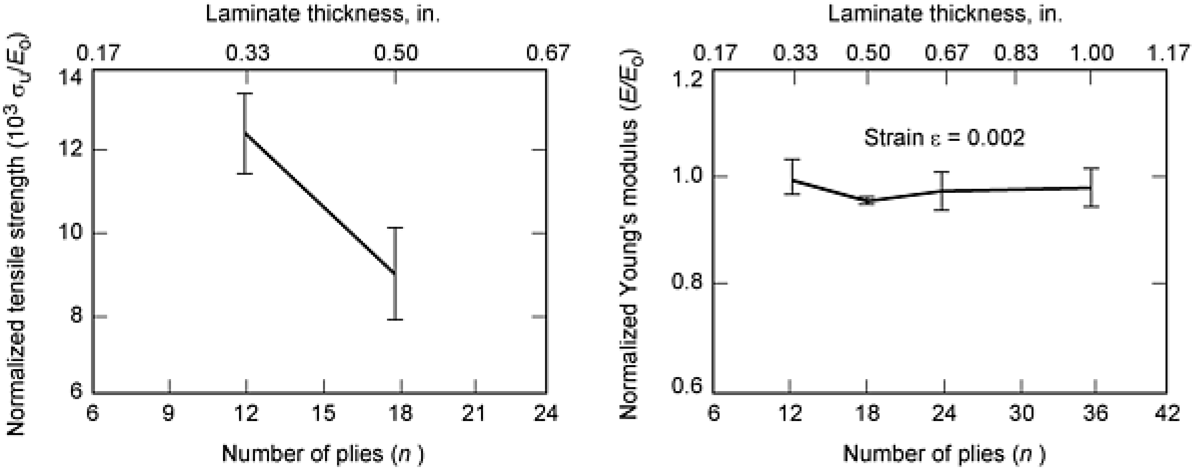

Fig. 11 Effect of laminate thickness on the mechanical properties of unidirectional AS4 carbon-tape/Epon 828 epoxy composites processed at 100 psi and 170 °C (275 °F) for 2 h. 1 ply = 0.7 mm (0.028 in.). Source: Ref 18

Coupling agents such as silane compounds placed on the reinforcing fiber prior to bonding to the resin matrix will mostly increase the tensile strength of the composite in wet or dry environmental conditions (Table 10). The strength increases will depend on the type of coupling agent and its compatibility with the resin system.

Table 10 Effect of silane coupling agents on the strength of E-glass fiber-reinforced polyester rods

Treatment	Dry strength		Wet strength[(a)]	
	MPa	**ksi**	**MPa**	**ksi**
No silane	916	133	240	35
Vinyl silane	740	107	285	41
Glycidyl silane	990	144	380	55
Methacryl silane	1100	160	720	104

Effects of Composition, Processing, and Structure on Properties of Composites

R. Laramee, Intermountain Design Inc.

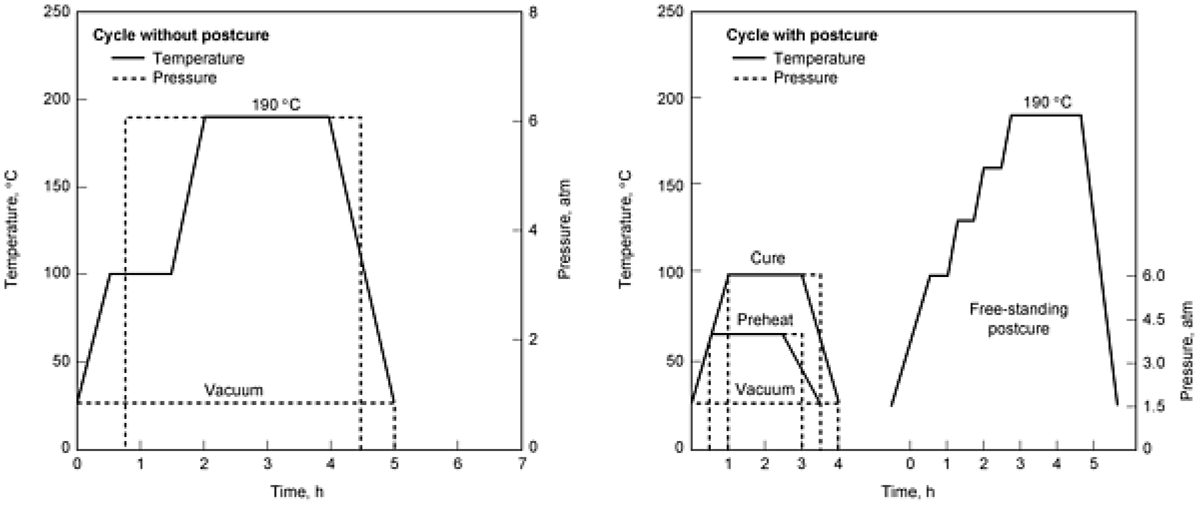
Effects of Processing on Properties

For resin-, metal-, and carbon-matrix composites, the basic parameters of temperature, time, and pressure are the key variables of the processing cure, the solidification bonding, or the conversion of resin to carbon char.

The cure process used for the resin matrix, with and without a post-cure cycle, can make a difference in the compressive strength and modulus of the matrix material. The conventional and optimized cure processes are listed in Table 11. A higher compressive strength and modulus result from the optimized process. This is caused by the higher cure pressure and preheat temperature used, plus the longer time used in the vacuum-bag application.

Table 11 Effect of processing-cure parameters on the compressive properties of graphite-fabric/epoxy composites

Cure process	Material preheat temperature		Cure cycle pressure		Vacuum pressure duration into cure cycle, h	Degassing/ bleeder plies	Prepreg mold stiffener plate, plies	Post cure	Compressive strength		Compressive modulus	
	°C	**°F**	**kPa**	**psi**					**MPa**	**ksi**	**GPa**	**10^6**
Conventional	None	None	607	88	1	2/none	None	Yes	270	39.3	42.7	6.2
Optimized	65	149	1014	147	2	None/2	4	No	290	42.2	48.3	7.0



Material: MXG 7620/2534 (Fiberite Corp.); 0° and 45° fabric orientation; 6.4 mm (0.25 in.) thickness (16 plies).

Generally, use of a post cure for laminates or structural shapes will lower the percent of residual volatiles and increase the properties (interlaminar shear strength), provided the temperature and time is optimized. Some post-cure temperatures and duration times can actually lower the properties of the original composite, if caution is not used, as shown in Fig. 12(a). The premise of a lower void content enhancing properties is shown in Fig. 12(b); plus, a higher autoclave pressure (150 psi) provides a higher shear strength at 0% void content.

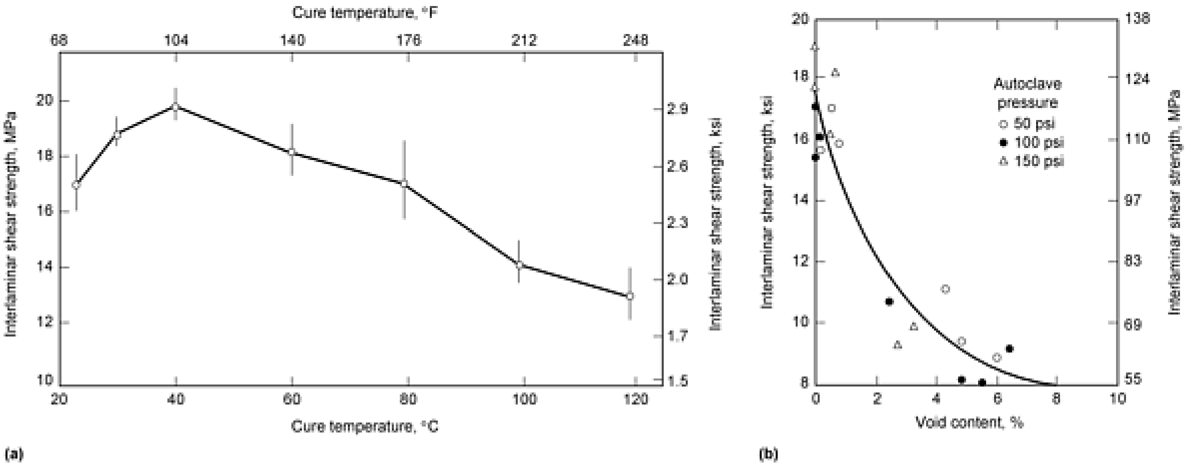


Fig. 12 Effect of interlaminar shear strength of (a) post-curing temperature for a glass/phenolic composite and (b) void content for a carbon/epoxy composite. Source: Ref 1, 7

In metal-matrix processing, the layers of reinforcing fiber in a metal matrix are diffusion bonded with pressure, temperature, and time until the bonding operation is complete. However, the right combination of diffusion-bond parameters, depending on the thickness, size, shape, and complexity, needs to be optimized (Fig. 13). In this example, $1\frac{1}{2}$ h at 425 °C (800 °F) and a 345 MPa (50 ksi) bond pressure provides an optimized tensile strength of 167 MPa (24.2 ksi).

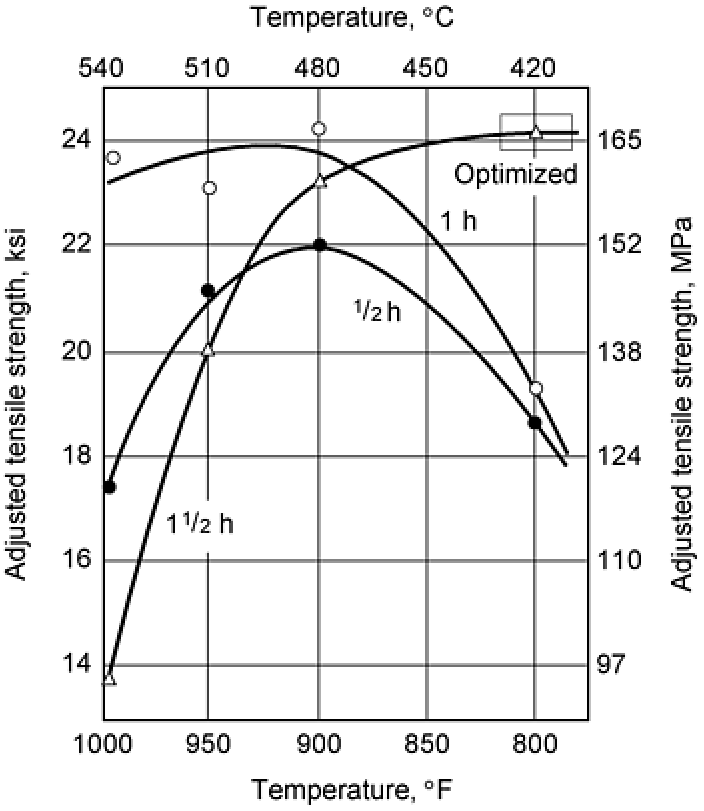

Fig. 13 Effect of bond time and temperature on the longitudinal strength of boron-fiber/aluminum-matrix composites. Fiber content, 3.3 vol%; bonding pressure, 345 MPa (50 ksi). Source: Ref 12

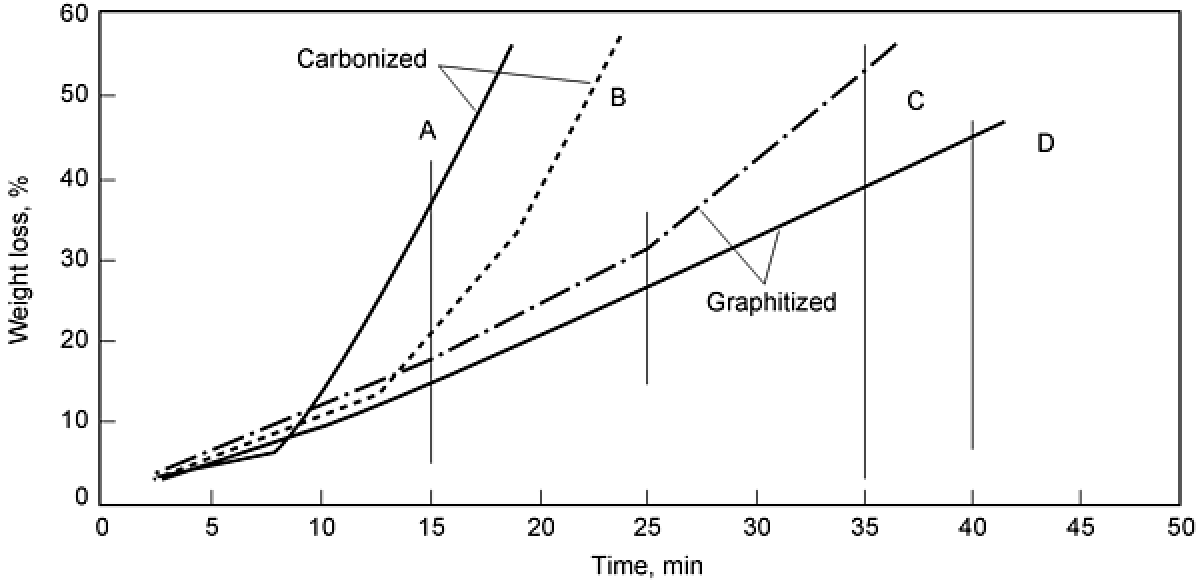
The matrix processing of carbon/carbon composites also involves temperature, pressure, and time parameters. In this instance, the parameters are those required to complete the conversion of the phenolic, pitch, or furane resin systems to a charred carbon matrix and its eventual densification through multiple impregnation and char conversion cycles. After final densification, the composite shape is brought to the full carbonization (1320 to 1870 °C, or 2400 to 3400 °F) or graphitization (1980 to 2980 °C, or 3600 to 5400 °F) temperature to finish the process. Carbonization provides a higher final strength, a higher density, and a higher weight loss due to oxidation than does graphitization.

A high graphitization temperature (2000 to 2400 °C, or 3630 to 4350 °F) provides a microstructure having a smaller separation (in angstrom units) between carbon platelets, resulting in a form of carbon/carbon composite that is more heat stable and exhibits a higher thermal conductivity, lower thermal expansion, lower density, and a higher oxidation resistance to weight loss. Thus, the A and B carbonization composites in Fig. 14 display a higher weight loss earlier than the graphitized composites, and the graphitized composites took 20 min longer to reach the same weight loss as the carbonized composites.



Material [(a)]	Heat treat temperature		Oxidation temperature	
	°C	**°F**	**°C**	**°F**
A	1500	2732	630	1166
B	1800	3272	698	1288
C	2000	3632	721	1330

Effects of Design Loadings and Environmental Conditions on Composite Properties

The types of loadings and environmental conditions existing for an applied composite product design must be considered in advance for the composite to successfully meet the required performance life and operating conditions of the system.

Adequate bonding of joints between composites or between a composite and a metal requires a minimum of 1 in. or more lap to develop a usable strength level for single- and double-lap joints and from 1.5 to 2.0 in. for strap, step, and scarf joints (Fig. 15).

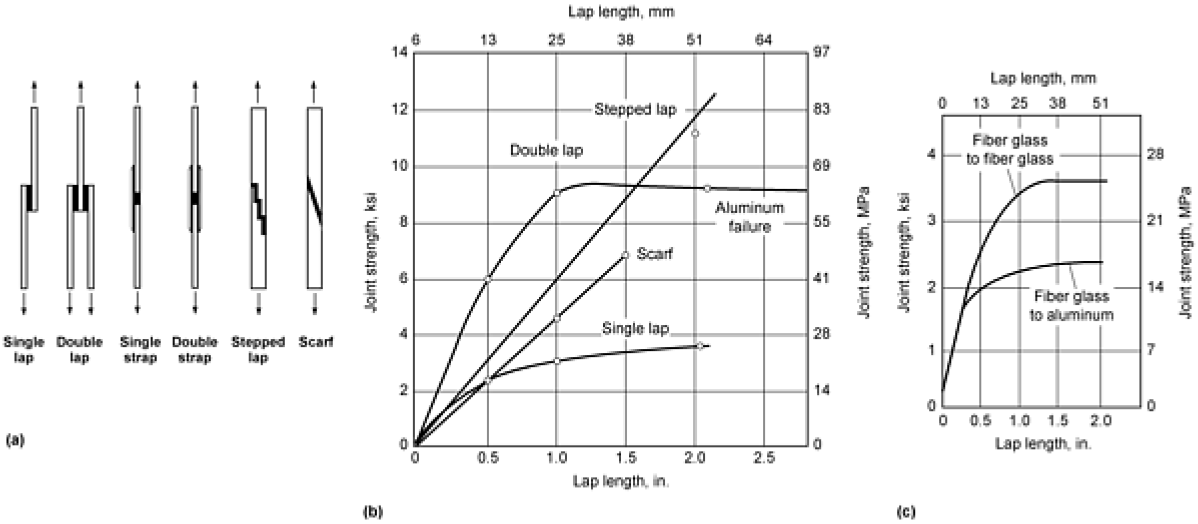

Fig. 15 Effect of lap length on strength of the adhesive bond. (a) Joint configurations. (b) Boron/epoxy composites epoxy bonded to aluminum. (c) Fiber glass bonded to fiberglass and to aluminum (single-lap bonds; epoxy adhesive). Source: Ref 1

The presence of a hole in a flat laminate will lower the failure stress by an average factor of three to five, due to the stress concentration caused by the hole. This is shown in Fig. 16, which also shows the effect of fiber angle in respect to the load.

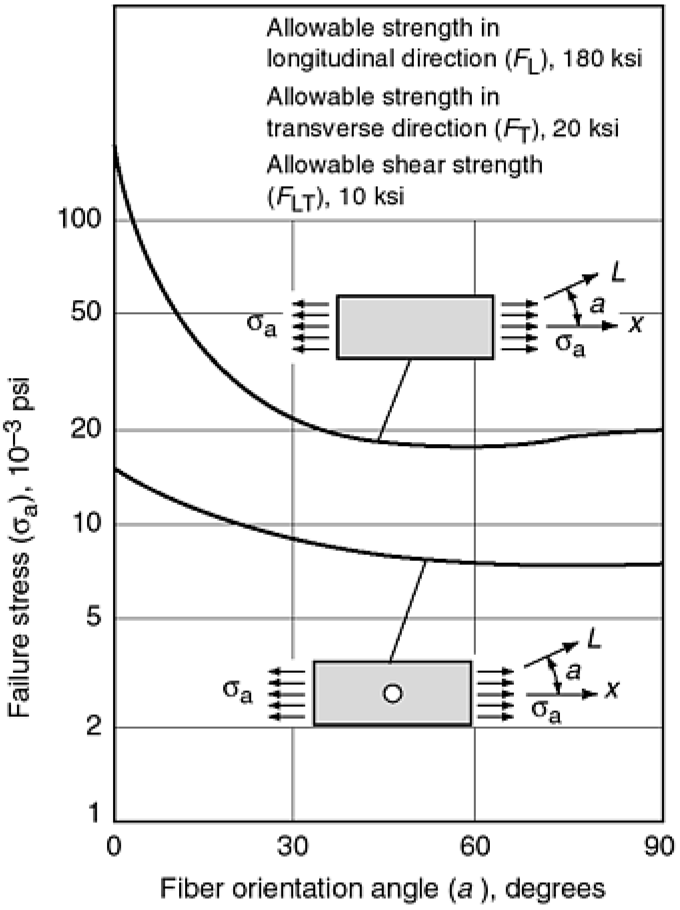

Fig. 16 Effects of fiber orientation and cut-out on the failure stress of boron/epoxy composite plates. Source: Ref 20

Environmental conditions also affect the mechanical properties of composites. Repeated tension, flexural, or compression dynamic loadings (fatigue) will lower the allowable strength levels for resin-matrix composites. Reduction factors from 2 to 4 are common between static (no cycles) and dynamic (10 million cycles) allowable stresses (Fig. 17, 18, 19). The same pattern for allowable strength versus fatigue number of cycles also holds true for carbon- and metal-matrix composites.

A glass/phenolic exterior panel stored, weathered, or stress weathered in Florida could lose 15% or more in strength after 3 years (Table 12). Table 10 indicates the tensile strength of dry and wet glass/polyester composites. The effects of exposure to room-temperature water, boiling water, salt, and acid are given in Table 13 and 14 and Fig. 20 and 21. As the resin-matrix composite gains weight in boiling water, it experiences a corresponding loss of properties.

Table 12 Weather serviceability data for a glass/phenolic composite

Property	Original	Stored 3 yr	Weathered 3 yr Florida	Stress weathered 3 yr Florida
Tensile strength, MPa (ksi)	408 (59.2)	401 (58.2)	367 (53.2)	349 (50.6)
Compression strength, MPa (ksi)	278 (40.3)	291 (42.2)	254 (36.8)	201 (29.1)
Flexure strength, MPa (ksi)	421 (61.0)	408 (59.2)	356 (51.6)	333 (48.3)
Modulus of elasticity, GPa (10^6 psi)	24.8 (3.6)	24.7 (3.58)	22.1 (3.2)	18.6 (2.7)

Conclusions

Composite material development design concepts should be tested for confirmation of material supplier test properties and design loaded with test fixture criteria for subscale and full-scale application. Existing materials and fabrication methods for composite design should be used wherever possible to control the unknown factors involved in advanced-concept applications.

It is important to have a thorough understanding of the following factors for composite material applications:

- The material composition and the percentage (by weight) of all constituents and the storing, shipping, and handling requirements.
- The cure/forming cycle suggested by the material supplier and the preferred machining, surface treating, and finishing operations (including the bands of acceptability for expected variations).
- The cured properties of the composite for the range of operating loads and environments to be expected in the performance service life.

If changes to the baseline composition, cure/forming cycle, and properties are required, it is important to stay in close contact with the material supplier's technical representatives and laboratory scientists and their corresponding equivalents within your company and your industry. The first few components fabricated should be expected to change in material composition, processing, properties, shape, fabrication step sequencing, and specification criteria. However, with a sound engineering approach over the life of the program, the necessary adjustments usually can be made to produce a high-quality product.

Effects of Surface Treatments on Materials Performance

Arnold R. Marder, Lehigh University

Introduction

SURFACE ENGINEERING is a multidisciplinary activity intended to tailor the properties of the surfaces of engineering components so that their function and serviceability can be improved. The *ASM Handbook* defines surface engineering as "treatment of the surface and near-surface regions of a material to allow the surface to perform functions that are distinct from those functions demanded from the bulk of the material" (Ref 1). Of concern to the design engineer is the availability of surface-specific properties for the component that can provide:

- Protection in a desired environment
- Improved mechanical properties
- Electronic or electrical properties
- Desired appearance

Of further concern to the designer is the availability of economical processes to produce the required properties. These processes include solidification treatments such as hot dip coatings, weld-overlay coatings, and thermal spray surfaces; deposition surface treatments such as electrodeposition, chemical vapor deposition (CVD), and physical vapor deposition (PVD); and heat treatment coatings such as diffusion coatings and surface hardening.

Surface treatments are used in a variety of ways to improve the material properties of the component. Coating mechanical properties, for example, hardness, strength, and toughness, can improve the component wear, fatigue, and erosion properties, respectively. Electrical properties in circuit design are dependent on the surface-deposition processes. Similarly, environmental properties such as resistance to aqueous corrosion and high-temperature oxidation and sulfidation can be improved by selective surface treatments.

The bulk of the material or substrate cannot be considered totally independent of the surface treatment. Most surface processes are not limited to the immediate region of the surface, but can involve the substrate by exposure to either a thermal cycle or a mechanical stress. For example, diffusion coatings often have high-temperature thermal cycles that may subject the substrate to temperatures that can cause phase transformations and thus property changes, or shot-peening treatments that deliberately strain the substrate surface to induce improved fatigue properties. It is the purpose of this

article to review information on surface treatments that improve service performance so that the design engineer may consider surface-engineered components as an alternative to more costly materials.

Related information is provided in the article "Design for Surface Finishing" in this Volume. More detailed information about the processes described in this article can be found in *Surface Engineering,* Volume 5 of *ASM Handbook* (Ref 1).

Solidification Surface Treatments

Solidification surface treatments include hot dip coatings, weld overlays, and thermal spray coatings.

Hot Dip Coatings

Hot dip coatings are predominantly used to improve the aqueous corrosion of steel. Processing of hot dip coatings involve either batch or continuous processing. The continuous process is more advantageous for sheet steels, whereas the batch process is normally used for individual parts. Details of the processing techniques are outlined in Ref 1. In the batch galvanizing process, the two types of conventional practices used at the present time are the wet process and the dry process (Ref 2). The wet process involves a flux blanket on the top of the molten zinc bath to remove impurities from the surface of the steel and also to keep that portion of the surface of the zinc bath, through which the steel is immersed, free from oxides. In the dry process the steel is usually cleaned, treated with an aqueous solution, dried, and then dipped in the molten zinc bath. The molten zinc bath is maintained at temperatures between 445 and 455 °C (830 and 850 °F) and times in the range of 3 to 6 min. The time of immersion is used to control the thickness of the coating, which consists of iron-zinc alloy phases at the interface along with a top coat of pure zinc. Good cooling control is necessary because the zinc can continue to react with the substrate to produce further alloying and detrimentally affect the properties of the coating such as the spangle finish (or grain size).

In continuous hot dip processing, welded coils of steel are coated at speeds of 200 m/min. The flux or Cook-Norteman line is similar to the batch process in that the sheet is cleaned and fluxed in line prior to immersion. The hot-processed continuous line is more complex in that the steel sheet is first cleaned at temperature in a reducing environment, annealed above the recrystallization temperature of about 700 °C (1290 °F) and then immersed in the molten bath. As the strip exits the bath, the thickness of the molten metal film is controlled by gas wiping dies that remove excess coating metal. After coating, the sheet is either cooled by forced air or subjected to an in-line heat treatment, called galvannealing, before being rewound into coil or sheared into cut lengths at the exit of the line.

In general, the coating microstructure consists of the substrate, the interfacial alloy layer, and the overlay cast structure. Depending on the type of coating, the microstructure and composition of these constituents changes. As expected, the substrate plays a major role in the type of coating obtained, and substrate composition can affect growth kinetics of the phases formed. For example, if the substrate contains silicon the well-known Sandelin Effect can influence the iron-zinc phase reaction and consequently the thickness of the coating (Ref 3). Similarly, alloy additions to the steel to improve sheet formability, for example, interstitial-free (IF) steels with titanium, titanium/niobium, and phosphorus, can influence the microstructure of the iron-zinc phases in galvanized and galvannealed steel (Ref 4). Substrate grain size has also been shown to greatly affect the nucleation of the iron-zinc phases. In aluminum-containing baths, the structure formed first is an inhibition layer that is dependent on bath composition and prevents further alloying for a certain short time before the inhibition layer becomes unstable (Ref 5).

When the zinc galvanizing bath contains only a trace of aluminum, zinc attack of the substrate is uniform and the phases that form are governed by the iron-zinc binary phase diagram. In zinc baths containing aluminum, the stability of the

inhibition layer governs the amount of iron-zinc phases formed. Once the inhibition layer is no longer stable, outbursts or rapid growth of iron-zinc phases occur during hot dipping (Ref 6). During the thermal cycle of the galvannealed process, the inhibition layer dissolves and iron-zinc phase layer growth occurs in a controlled manner until the entire coating is made up of iron-zinc phases (Ref 7). Both galvanized and galvannealed alloy phase growth are determined by Fe-Al-Zn ternary diffusion, and the overlay cast microstructure greatly depends on aluminum content of the bath. The pure-zinc and low-aluminum coatings form an overlay of pure Zn (η) phase. Zn-5wt% Al (Galfan) solidifies as eutectic microstructure, and the Zn-55 wt% Al (Galvalume and Zincalume) solidifies as aluminum dendrites with zinc-rich interdendritic regions. The aluminum coatings (Type I and Type II) either form overlays of aluminum-silicon or aluminum alloy, respectively.

Galvanized coatings are commonly characterized by surface spangles. In cross section, an Fe_2Al_5(Zn) inhibition layer develops first, preventing any iron-zinc intermetallic phase formation. The overlay layer is made up of dendrites of pure Zn (η) phase and appears as a polycrystalline structure. The three surface finishes commonly produced are:

- Regular spangle, where the coating solidifies from the dipping temperature by air cooling
- Minimum spangle, where the coating is quenched using water, steam, chemical solutions, or by zinc powder spraying
- Extra-smooth temper roll finish carried out as an additional operation with regular and minimum spangle material

Aluminum is probably the most important alloying element added to the hot dip galvanizing bath, with different levels required to produce different properties in the bath (Ref 8). Aluminum levels of 0.005 to 0.02 wt% are added to brighten the initial coating surface. The effect is related to the formation of a continuous alumina (Al_2O_3) layer on the coating surface that inhibits further oxidation by acting as a protective barrier layer. This effect is also responsible for the reduced atmospheric oxidation of the zinc bath. In addition, aluminum in the range of 0.1 to 0.3 wt% is added to the zinc bath to suppress the growth of brittle iron-zinc intermetallic phases at the steel coating interface by forming the Fe_2Al_5 (Zn) inhibition layer. The end of this incubation period is marked by the disruption of the initial layer, followed by rapid attack of the substrate steel. An increase in the incubation period depends on increased aluminum bath composition using a low bath temperature, having low bath iron content, agitation, and the presence of solute additions in the steel. Thus, during commercial production, the immersion time is kept below the incubation period in order to obtain a highly ductile product.

Zinc coatings add corrosion resistance to steel in several ways. As a barrier layer, a continuous zinc coating separates the steel from the corrosive environment. By galvanic protection, zinc acts as a sacrificial anode to protect the underlying steel at voids, scratches, and cut edges of the sheet. The sacrificial properties of zinc can be seen in a galvanic series where the potential of zinc is less noble than steel in most environments at ambient temperatures. In addition, after dissolution of the zinc metal, zinc hydroxide can precipitate at the cathodic areas of the exposed steel, forming a secondary barrier layer. Zinc corrodes at a slower rate than the steel substrate, although the corrosion rate of zinc varies depending on the atmosphere to which it is exposed (Ref 9), as shown in Fig. 1.

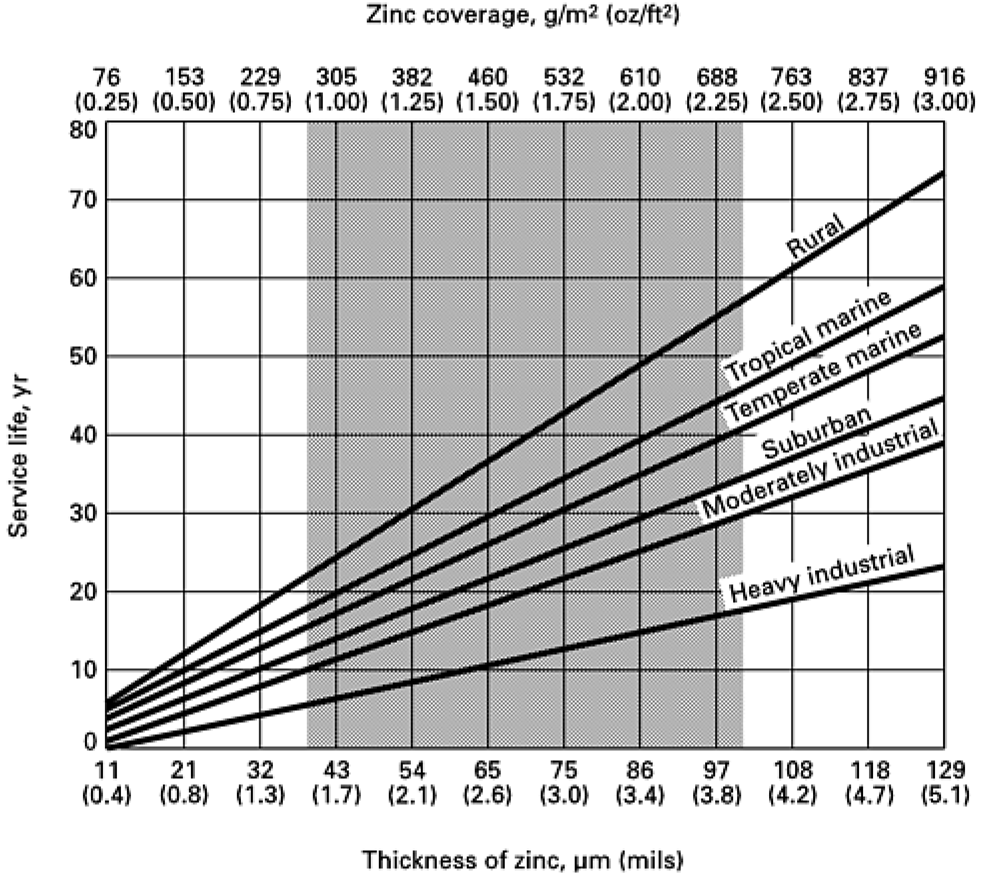

Fig. 1 Service life (time to 5% rusting of steel surface) versus thickness of zinc for selected atmospheres. Shaded area is thickness range based on minimum thicknesses for all grades, classes, and so forth, encompassed by ASTM A 123 and A 153. Source: Ref 10

During forming, especially stretch-forming operations, increased friction of the zinc can result in less total stretch before fracture. In severe forming operations, galling and coating pickoff can also occur. Furthermore, coating particulate buildup on die surfaces can lead to poor surface appearance of formed parts. Proper lubrication is essential in the design of any forming process, especially when forming zinc-coated parts. Weldability of zinc coatings is also an important property of the coating. Spot weldability properties are particularly important because most galvanized product is joined in this manner. Zinc coatings reduce the life of welding electrodes because of the copper electrode alloys with zinc. This effect leads to higher resistance, localized heating, and increased pitting and erosion of the electrode tip. As a result, manufacturing costs increase because lower tip life reduces productivity due to frequent downtime in the welding operation to redress tips.

Although zinc coatings are often used in the as-coated state, some applications call for a painted surface, and therefore paintability is an important design property of the coating. It has been shown that large-spangle material is difficult to paint; therefore, most painted products are either minimum spangle or temper rolled. It is usually necessary to pretreat a hot dip galvanized coating with a zinc phosphate or complex oxide thin coating before prepainting. In the automobile industry, following the pretreatment most automobile bodies are primed with an electrophoretic paint (e-coat), and, as a result, resistance to e-coat cratering is an important property. At high e-coat voltages, sparking as a result of exceeding the dielectric properties of the deposited paint film cases localized heat generation, film disruption, and premature curing of the paint. After paint curing, these sparked areas form pinpoint craters that result in a paint surface with a detrimental appearance. Therefore, resistance to e-coat cratering, expressed in cratering threshold voltage, is an essential paintability property (Table 1).

Table 1 Effects of hot dip coatings on threshold voltages for cratering of cathodic electrophoretic primer

Type of surface	Cratering threshold, V
Uncoated bare steel	>400
Zinc	275
Zinc-iron	225
Zn-55Al	375
Aluminum	>400

Galvanneal coatings are essentially diffusion coatings that expose the zinc galvanized steel to an annealing temperature around 500 °C (930 °F) to produce a fully alloyed coating containing iron-zinc intermetallic phases. This is accomplished by inserting heating and cooling capacity above the liquid zinc pot in order for the galvannealing process to be continuous. Good process control requires that the effects of heating rate, hold temperature and time, and cooling rate on the iron-zinc reaction kinetics be well understood. Galvanneal coatings have been classified as (Ref 7):

- *Type 0:* Underalloyed coating containing predominantly ζ-phase.
- *Type 1:* Optimal alloyed coating with less than a 1 μm interfacial γ-layer and a top layer containing δ-phase interspersed with a small amount of ζ-phase
- *Type 2:* Overalloyed coating with a γ-layer more than 1 μm thick and an overlay of δ-phase containing basal plane cracks.

Formability is an important property in galvanneal coatings because iron-zinc intermetallic phases are considered brittle. As a result, powdering and flaking of the coating can occur during the forming operation, resulting in reduced corrosion resistance and impaired paintability. The type 1 coating was found to have the best formability properties (Ref 12), but as in most forming operations lubrication to improve metal flow is essential. Spot weldability of galvanneal coatings are improved over galvanized coatings because it is more difficult for these iron-zinc phases to alloy with the copper electrode. Paintability is also better than that of galvanized coatings because of the microscopically rough surface formed as a result of the iron-zinc alloy phases throughout the coating. However, galvanneal coatings are more prone to cratering during e-coating (Table 1). Conversely, corrosion resistance can be slightly reduced because of the increased iron in the coating from the iron-zinc phases; the galvanic potential is not as great as it is for pure zinc.

Zn-5Al alloy coating (Galfan) is near the eutectic point in the aluminum-zinc equilibrium phase diagram. Two compositions have been reported based on additions to the eutectic composition: small (up to about 0.5%) mischmetal additions containing lanthanum and cerium and additions of 0.5% Mg. These additions are made to improve the wettability and suppress bare spot formation as well as to produce a typical "minimized spangle" structure. The microstructure of Galfan is characterized by a two-phase structure, a zinc-rich proeutectoid η-phase surrounded by eutectic phase consisting of lamellae of α-aluminum and zinc-rich η-phase. However, the microstructure can be varied depending on the cooling rate. In the range of normal bath temperatures, 420 to 440 °C (790 to 825 °F) there is no visible intermetallic layer or at least an extremely thin layer (<0.5 μm) at the interface between the steel substrate and the overlay coating. Thus, Galfan coatings have excellent formability and cut-edge corrosion protection.

Zn-55Al alloy coating (marketed under the tradename Galvalume) contains about 1.5% Si added for the purpose of preventing an exothermic reaction at the coating overlay/substrate steel interface. As a result, the coating contains α-

aluminum dendrites, zinc-rich interdendritic regions, and a fine dispersion of silicon particles, along with a prominent Fe-Al-Zn intermetallic alloy layer at the interface between the steel substrate and the overlay coating. The surface of the coating contains characteristic spangles that consist of aluminum dendrites with a clearly measurable dendrite arm spacing. Cooling rate after dipping can significantly refine the microstructure of the coating, increasing the number of silicon particles and constraining the growth of aluminum dendrites.

Initially, the atmospheric corrosion of the Zn-55Al coating takes place in the zinc-rich interdendritic regions, enabling the coating to exhibit galvanic protection. As the coating continues to corrode, the zinc corrosion products become trapped in the interdendritic regions and act as a further barrier to corrosion. Eventually, the aluminum dendrites, which also acted as a barrier layer, add to the corrosion protection, as does the Fe-Al-Zn intermetallic alloy layer. This results in a parabolic type of corrosion as evidenced in Fig. 2. Although its galvanic protection is less than that provided by galvanized coatings, Zn-55Al is generally adequate to protect against rust staining at scratches and cut edges of the steel sheet.

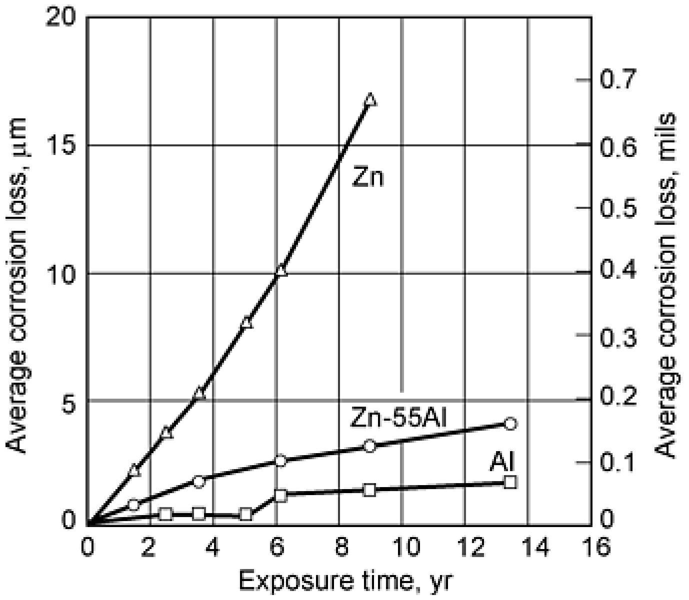

Fig. 2 Corrosion losses of hot dip coatings in the industrial environment of Bethlehem, PA. Source: Ref 13

Aluminum coatings are produced as type 1 coating, a thin (20 to 25 μm) aluminum-silicon alloy coating, and type 2, a thicker (30 to 50 μm) pure aluminum coating. Silicon is present in type 1 coatings in the range of 5 to 11 wt% to prevent formation of a thick iron-aluminum intermetallic layer at the coating/steel substrate interface. Instead, a thin Fe-Al-Si intermetallic layer is formed, allowing for good formability and coating adherence. These coatings are intended primarily for applications requiring improved appearance, good formability, and resistance to high temperatures, as in automobile exhaust components. The type 2 coating has a microstructure containing a pure aluminum overlay and a thick iron-aluminum intermetallic alloy layer. Thus, the formability and adhesion of this coating is limited by the poor ductility of the alloy layer. Nevertheless, the coating is used for outdoor construction applications (e.g., roofs, culverts, etc.) that require resistance to atmospheric corrosion (Table 2). The aluminum outerlayer offers excellent corrosion resistance because of the good barrier properties provided by the increased thickness of the coating (Fig. 2).

Table 2 Coating thickness losses for galvanized steel and type 2 aluminized steel in atmospheric exposure

(a) G90 galvanized steel has a coating weight of 0.90 oz/ft^2 (270 g/m^2).

Weld-Overlay Coatings

Welding is a solidification method for applying coatings with corrosion, wear, and erosion resistance. Weld-overlay coatings, sometimes referred to as hardfacing, offer unique advantages over other coating systems in that the overlay/substrate weld provides a metallurgical bond that is not susceptible to spallation and can easily be applied free of porosity or other defects. Welded deposits of surface alloys can be applied in thicknesses greater than most other techniques, typically in the range of 3 to 10 mm. Most welding processes are used for application of surface coatings and on-site deposition can be more easily carried out, particularly for repair purposes. Weld overlays are very versatile because a large number of commercially available alloys can be selected to provide protection from a wide range of environmental degradation mechanisms.

During weld-overlay surfacing, the coating material is raised to its melting point and then solidified on the surface of the substrate, which means that metals and alloys used for this purpose must have melting points similar to or less than the substrate material. The effectiveness of the weld-overlay coating depends mainly on the welding process and the overlay alloy composition. The welding process must be selected and optimized to apply protective overlays at high deposition rates and thermal efficiency, with good control over the overlay/substrate dilution and coating thickness. The overlay alloy composition must be selected to provide the required properties to prevent coating degradation, and the alloy composition must be readily weldable.

A number of welding processes are available for applying protective weld overlays, and many welding parameters must be considered when attempting to optimize a particular process for a given application. The process principles and their characteristics for some processes are summarized for comparison purposes in Table 3 and are described in Ref 15 and 16. The processes can be grouped as torch processes, arc welding processes, and high-energy-beam techniques. The torch process, oxyacetylene welding (OAW), is the oldest and simplest hardfacing process and involves simply heating the substrate with the flame and then melting the filler rod to get the hardfacing to melt. High-energy-beam techniques use

laser beam welding (LBW) or electron beam welding (EBW) to alloy the surface by adding alloy powders to the weld pool.

Table 3 Weld surfacing processes

Process	Approximate deposit thickness (min), mm	Deposition rate, kg/h	Dilution, single layer, %	Typical uses
Oxyacetylene (OAW)	1.5	≤ 1	1-5	Small area deposits on light sections
Powder weld (PW)	0.1	0.2-1		Small area deposits on light sections
Shielded metal arc (SMAW)	3	1-4	15-30	Multilayers on heavier sections
Gas tungsten arc (GTAW)	1.5	≤ 2	5-10	High-quality low-dilution work
Plasma transferred arc (PAW)	2	≤ 10	2-10	High-quality lowest-dilution work
Gas metal arc (GMAW)	2	3-6	10-30	Faster than SMAW, no stub-end loss; positional work possible
Flux-cored arc (FCAW)	2	3-6	15-30	Similar to GMAW. Mainly for iron-base alloys for high abrasion resistance
Submerged arc (SAW)				
Wire	3	10-30	15-30	Heavy section work; higher-quality deposits than FCAW
Strip	4	10-40	10-25	Corrosion-resistant cladding of large areas
Bulk	. . .	. . .	. . .	Similar to SAW wire but other alloys possible
Electroslag (ESW)	4	15-35	5-20	High-quality deposits at higher deposit rates than SAW. Limited alloy range

Source: Ref 16

In arc welding, the heat is generated by an arc between an electrode and the workpiece. Arc welding processes can be grouped into nonconsumable electrode processes and consumable electrode processes. Nonconsumable electrode processes, gas tungsten arc welding (GTAW) and plasma arc welding (PAW), both involve a tungsten electrode and the introduction of the filler metal (in the form of rod or wire in GTAW and powder in PAW). The arc melts the filler metal to form a molten pool that is protected from the atmosphere by an inert gas shield. In plasma arc welding, an additional inert gas flows through a constricted electric arc in the welding torch to form the plasma. In general, for consumable electrode processes, the arc is maintained between the consumable electrode and the workpiece. In shielded metal arc welding (SMAW), the electrode consists of a core wire surrounded by a flux covering, that upon melting forms a liquid

slag and gas to protect the molten metal pool. In flux core arc welding (FCAW), the flux is contained in the core of the metallic tubular electrode, whereas in gas metal arc welding (GMAW) the consumable wire electrode and substrate metal is protected from the atmosphere by a gas fed axially with the wire through the welding gun nozzle. In submerged arc welding (SAW), the arc, which is submerged beneath a covering of flux dispensed from a hopper, melts the electrode, the surface of the workpiece, and some of the flux that protects the molten pool from oxidation. Electroslag welding (ESW) uses equipment similar to SAW for strip cladding.

There are a large number of processing parameters that must be considered when attempting to optimize welding processes for surface application:

All processes
Voltage across the arc Current through the arc Current polarity Current pulsing parameters Travel speed of heat source Shielding gas type (except SAW)
Consumable processes
Filler metal feed rate Electrode diameter Electrode extension ("stick-out" length)
Nonconsumable processes
GTAW electrode tip angle (vertex angle) PAW plasma gas flow rate

However, the important factors considered in terms of arc welding overlay parameter optimization and process performance include arc efficiency, melting efficiency, deposition rate, dilution, and coating thickness (Ref 17). Arc efficiency is only a function of the arc welding process; melting efficiency increases with increasing arc power and travel speed, and the maximum deposition rate is directly related to both the arc and melting efficiency. During the deposition of the weld-overlay coating, the base metal and the filler metal are melted and mixed in the liquid state to form a fusion bond. Depending on the weld-overlay coating thickness, if a large portion of the substrate is melted and allowed to mix appreciably with the weld overlay, dilution can cause the overall alloy content of the coating to be significantly reduced. The level of mixing is quantified as the dilution ratio and is one of the most important parameters in a surface application because the original filler metal mechanical and corrosion properties can be altered. The extent to which dilution occurs depends on the surfacing and substrate materials used, the welding process chosen, and the parameters employed. Table 3 indicates the range for dilution expected for the various processes employed. Figure 3 is a surfacing diagram that relates dilution for various arc welding processes according to filler metal feed rate and melting power (a function of arc and melting efficiency) and can be used to facilitate process selection and parameter optimization in weld-overlay applications (Ref 18).

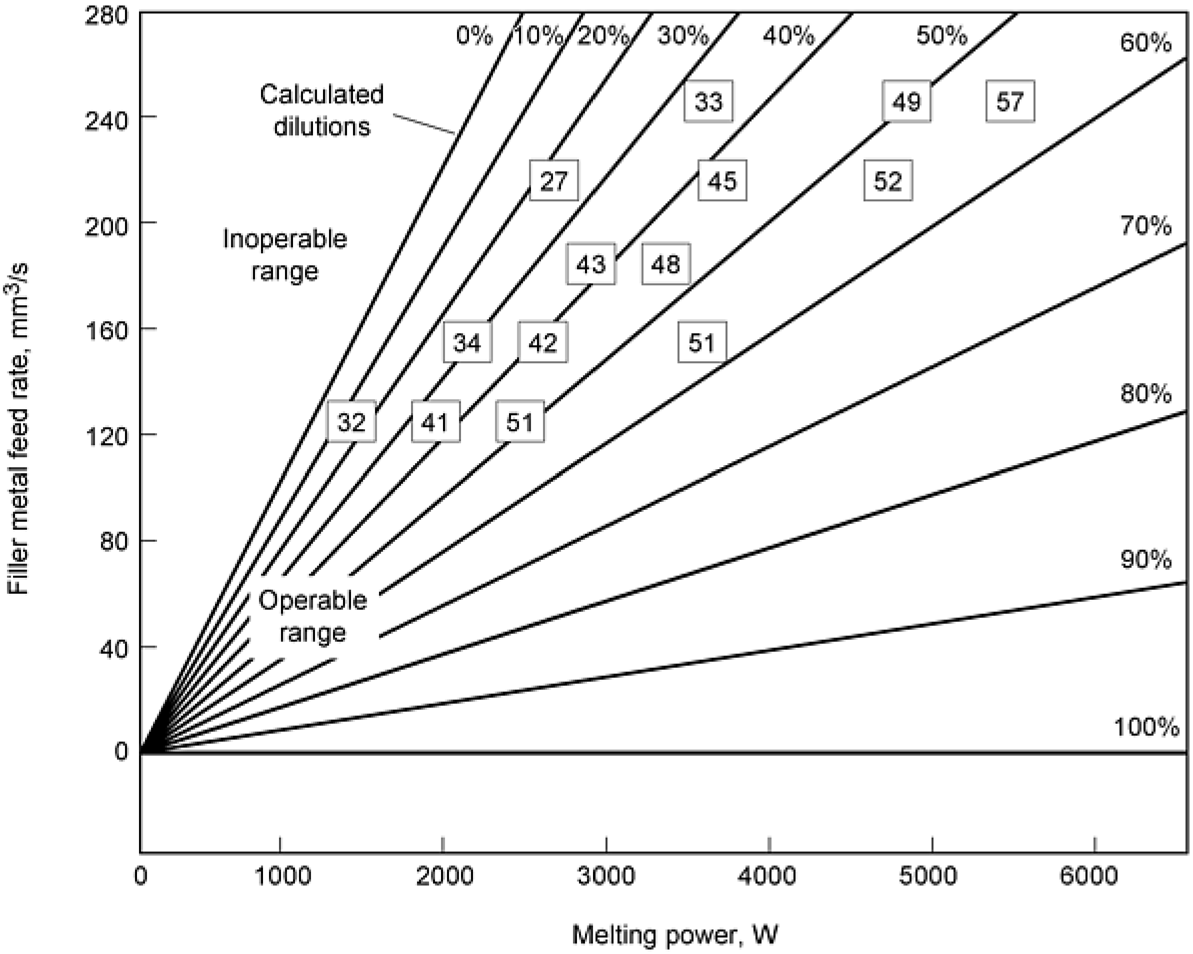

Fig. 3 Effect of processing parameters on dilution with experimental data plotted for SAW process. Source: Ref 18

During welding, the base metal is subjected to peak temperatures that are at least as high as the melting temperature of the substrate. The properties of the weld and the adjacent heat-affected zone (HAZ) strongly depend on the thermal history as dictated by the heat input. Preheating the part may be a necessary step in reducing the residual stress and distortion associated with welding. Preheat and maintenance of a specific minimum temperature during the welding cycle can also reduce the cooling rate to prevent the formation of a detrimental transformation region in the HAZ of ferrous alloys. Interpass temperature is another important factor needed to be controlled in order to prevent increased dilution and HAZ grain growth at high temperatures. Postweld heat treatment can take many forms, depending on whether the weld-overlay coating needs to be stress-relief annealed or must be heat treated for specified properties.

Excellent reviews of hardfacing metallurgy and the application of weld-overlay consumables are found in Ref 16 and 19. For overlay coatings, components are designed to provide resistance to various forms of wear, erosion, and corrosion over a large temperature range. Thus, properties such as hardness, microstructure, and corrosion resistance are more important for the coating than tensile strength and elongation, which are usually provided by the substrate material.

Generally, coatings selected for wear resistance require high hardness as a characteristic, thus the term "hardfacing." It is believed that most hardfacing alloys develop their wear resistance by virtue of wear-resistance carbides (Ref 20). Almost all hardfacing alloys can be separated into two major groups based on chemical compositions of the primary solidified hard phases:

- *Carbide hardening alloys,* including cobalt-base/carbide (WC-Co) and some iron-base superalloys
- *Intermetallic hardening alloys,* for example, nickel-base superalloys, austenitic stainless steels, and iron-aluminides

However, although increased hardness generally increases wear resistance, different microstructures containing the same carbide type can also have significant effect on wear resistance (Fig. 4).

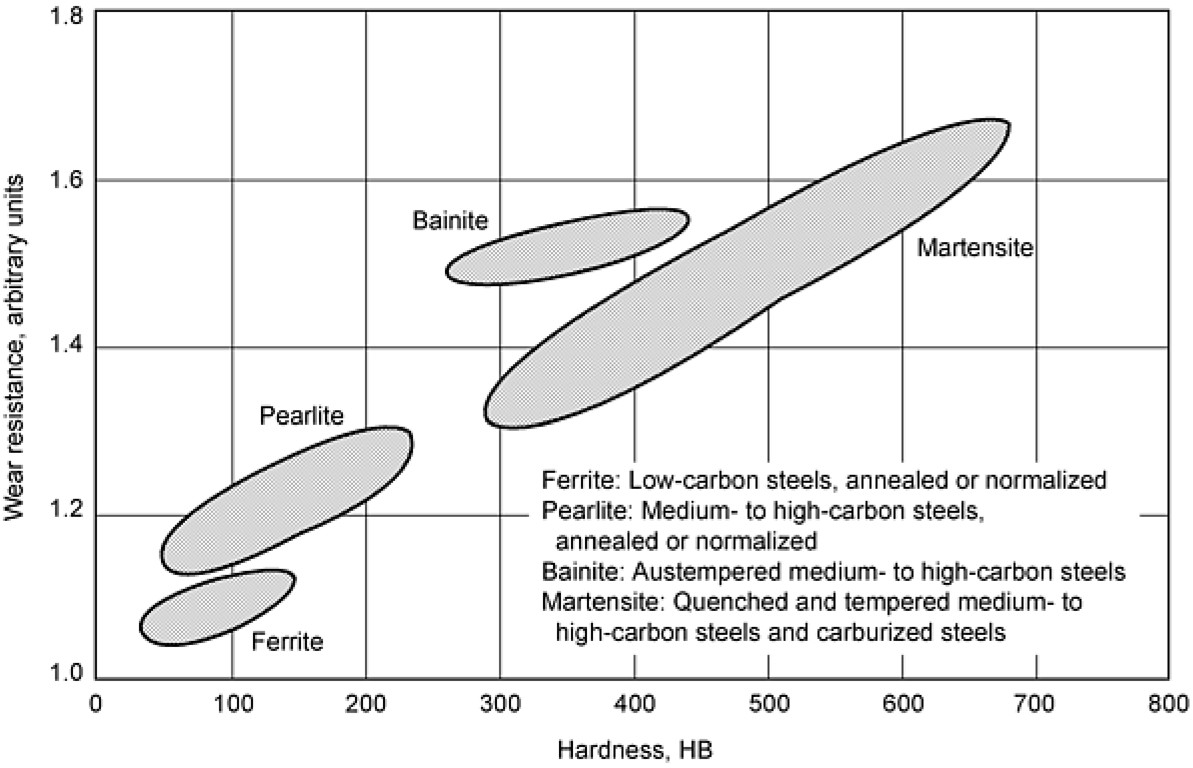

Fig. 4 Effect of structure and hardness on abrasion resistance. Source: adapted from Ref 21

Erosion resistance of materials is very dependent on the erosion conditions, the effects of which are dominated by a number of variables including particle size, shape, composition, and velocity; angle of incidence; and temperature. Unlike wear properties, the erosion rate of weld-overlay coatings generally increases with increasing hardness (Fig. 5). However, the erosion resistance of weld-overlay alloys depends on whether the coating can be classified as a brittle or ductile material (Ref 22). Those materials that can be deformed plastically (ductile) produce a large plastic zone beneath the eroded surface, and the increased plastic zone size can be directly correlated to an improved steady-state erosion resistance. For those materials that cannot deform plastically (brittle), an increase in coating hardness sometimes may lead to a decrease in volumetric erosion rate. Thus, materials that can dissipate particle impact energy through plastic deformation (plastic zone) exhibit low erosion rates. However, for materials that do not deform plastically (no plastic zone) and do not undergo plastic deformation, the ability to resist brittle fracture (i.e., cracking) becomes a major factor that can control the erosion resistance.

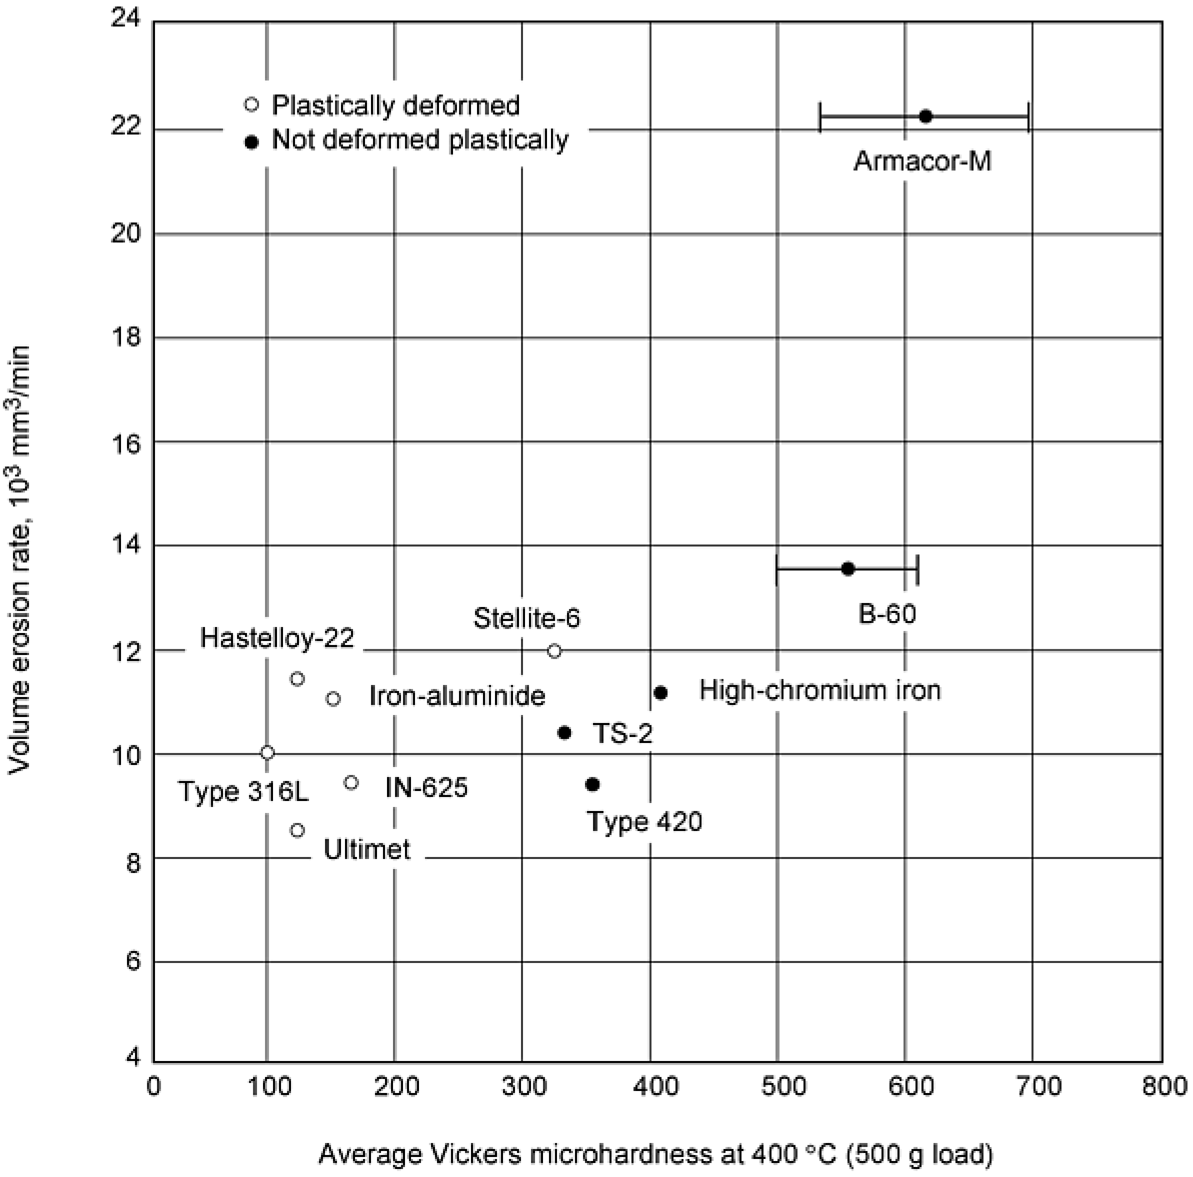

Fig. 5 Volume steady-state erosion rates of weld-overlay coatings at 400 °C (750 °F) as a function of average microhardness at 400 °C (90° impact angle; alumina erodent). Source: Ref 22

The corrosion resistance of weld-overlay coatings follows the corrosion-resistant properties of the bulk materials and is also dependent on the corrosive environment. Weld-overlay coatings provide resistance to oxidation and sulfidation. Dilution, as discussed previously, can be expected to modify the behavior of the coating alloy from the properties quoted for the undiluted bulk materials. In weld-overlay coatings such as austenitic steels, dilution can affect corrosion resistance because of a reduction in the effective chromium content or an increase in carbon content through carbon pickup from the substrate steel. Iron aluminides appear to be potentially important weld-overlay coatings for sulfidation environments. Figure 6 shows isothermal weight gain studies for a number of weld-overlay coatings exposed to H_2S-H_2-H_2O-Ar gas mixtures at 800 °C (1470 °F) (Ref 23). This work showed that compositions containing at least 30% Al and $\geq$2% Cr had excellent sulfidation resistance and, at increased chromium levels, corrosion rates increased but were still superior to other alloy classes such as stainless steels.

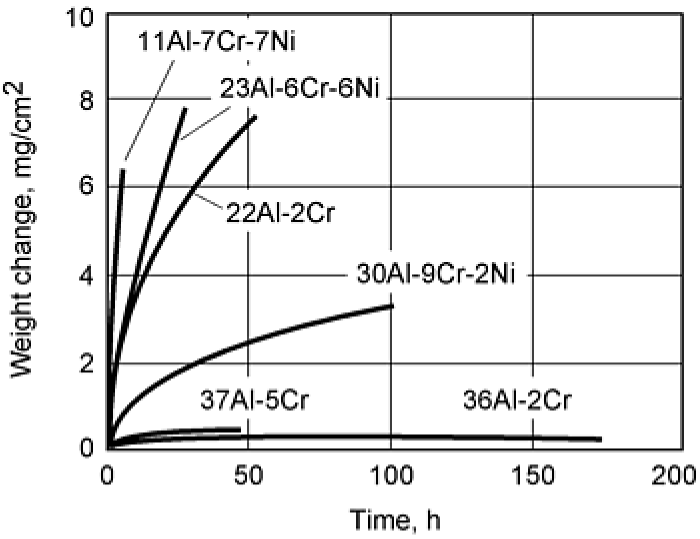

Fig. 6 Weight change versus time for specimens cut from iron-aluminide weld overlays and isothermally exposed to H_2S-H_2-H_2O-Ar at 800 °C (1470 °F). The elemental concentrations shown are in at.%; the balance is iron. Source: Ref 23

Detailed information about weld overlay coatings is available in the article "Hardfacing, Weld Cladding, and Dissimilar Metal Joining," in *Welding, Brazing, and Soldering,* Volume 6 of *ASM Handbook* (Ref 24).

Thermal Spray Coatings

Thermal spraying is a generic term for a group of processes that apply a consumable in the form of a spray of finely divided molten or semimolten droplets to produce a coating. A number of extensive reviews of the topic can be found in Ref 25, 26, 27, 28, and 29. The characteristics that distinguish thermal spray processes from weld-overlay coatings are indicated as follows (Ref 29):

- Substrate adhesion, or bond strength, is dependent on the materials and their properties and generally is characterized as a mechanical bond between the coating and the substrate, unlike the metallurgical bond found in weld-overlay coatings.
- Spray deposits can be applied in thinner layers than welded coating, but thick deposits are also possible.
- Provided there is a stable phase, almost all material compositions can be deposited, including metals, cermets, ceramics, and plastics.
- Thermal spray processes are usually used on cold substrates, preventing distortion, dilution, or metallurgical degradation of the substrate.
- Thermal spray processes are line-of-sight limited, but the spray plume often can be manipulated for complete coverage of the substrate.

Processes for thermal spray coatings can be classified into two categories, arc processes and gas combustion processes, depending on the means of achieving the heat for melting of the consumable material during the spraying operation.

In the lower-energy electric arc (wire arc) spray process, heating and melting occur when two electrically opposed charged wires, comprising the spray material, are fed together to produce a controlled arc at the intersection. The molten material on the wire tips is atomized and propelled onto the substrate by a stream of gas (usually air) from a high-pressure gas jet. The highest spray rates are obtained with this process, allowing for cost-effective spraying of aluminum and zinc for the marine industry. In the higher-energy plasma arc spray process, injected gas is heated in an electric arc and converted into a high-temperature plasma that propels the coating powder onto the substrate at very high velocities. This process can take place in air with air plasma spraying (APS), or in a vacuum with vacuum plasma spray (VPS) or low-pressure plasma spraying (LPPS).

For gas combustion processes, the lower-energy flame spray process uses oxyfuel combustible gas as a heat source to melt the coating material, which may be in the form of rod, wire, or powder. In the higher-energy, high-velocity, oxyfuel combustion spray (HVOF) technique, internal combustion of oxygen and fuel gas occurs to produce a high-velocity plume capable of accelerating powders at supersonic speeds and lower temperatures than the plasma processes. Continuous combustion occurs in most commercial processes, whereas the proprietary detonation gun (D-gun) process uses a spark discharge to propel powder in a repeated operating cycle to produce a continuous deposit.

In the lower-energy processes, electric arc (wire arc) spray and flame spray processes, adhesion to the substrate is predominantly mechanical and is dependent on the workpiece being perfectly clean and suitably rough. Some porosity is always present in these coatings, which may present problems in both corrosion and erosion. The higher-energy processes--APS, VPS, LPPS, and HVOF processes--were developed to reduce porosity and improve adhesion to the substrate. In addition, these processes are capable of spraying materials with higher melting points, thus widening the range of applications to include high-temperature coatings and thermal and mechanical shock-resistant coatings. With these higher-energy processes, bond strengths are higher because of the possible breakup of any oxide films present on the particles or the workpiece surface, allowing for some diffusion bonding to take place (Ref 29). Typical design features of the various thermal spray processes are listed in Table 4.

Table 4 Typical design characteristics of thermal spray processes

Process	Gas temperature, °C	Particle velocity, m/s	Adhesion, MPa	Oxide content, %	Porosity, %	Spray rate, kg/h	Relative cost, low = 1	Typical deposit thickness, mm
Flame	3,000	40	8	10-15	10-15	2-6	1	0.1-15
Arc wire	NA	100	12	10-20	10	12	2	0.1 to >50

NA, not applicable. Source: Ref 29

The variations in oxide content and porosity, as well as the chemical composition of the coating, greatly affect the properties of the deposit and, in the case of corrosion, the underlying substrate. The splat morphology and, more importantly, the splat/splat and splat/substrate interface are critical to properties such as bond strength, wear, erosion, and corrosion. The mechanical properties of thermal spray coatings are not well documented except for their hardness and bond strength. Table 5 contains typical mechanical properties data for a large range of plasma sprayed materials; however, the sensitivity of the properties of the coatings to specific deposition parameters makes universal cataloging of properties by process and composition "virtually meaningless" (Ref 26).

One of the most extensive uses for thermal spray coatings is in wear applications. Generally, the wear resistance of coatings increases with their density and cohesive strength, so that HVOF coatings provide the best wear resistance in contrast to plasma spray coatings (Table 6). Carbide cermets were found to be good for both wear and erosion environments, and the optimal amount of hard phase (oxide and carbide) has been determined for erosion resistance. A comparison between the presprayed powder and the actual coating microstructure showed that the retention of the FeCrAlY matrix is much better than the chromium carbide particles, which can form oxides during HVOF thermal spraying (Ref 30). Erosion tests show that both carbides and oxides increase the erosion rate of the coating (Fig. 7) and that low amounts of hard constituents are preferable for erosion resistance.

Thermal spray zinc, aluminum, and zinc-aluminum alloys are used for sacrificial galvanic protection for corrosion resistance on bridges, ships, and other large structures. Other corrosion-resistant applications for thermal spray coatings include oxidation and sulfidation resistance in power boilers and other high-temperature uses. In a comparison of several different thermal spray techniques, it was found that high-temperature corrosion-resistant coatings must have compositions that promote the formation of protective oxides at splat boundaries, be dense enough so that protective oxides can form within and fill voids, and be thick enough to postpone the diffusion of corrosive species to the substrate material along the fast diffusion paths of the coating (Ref 31). It has been found that corrosion attack of the substrate generally decreases as the free path to the substrate (that is, the diffusion path the corrosive species takes to the substrate) increases. Thus, as in erosion and wear, the splat/splat and splat/substrate boundaries are critical to properties of the thermal spray coatings.

Effects of Surface Treatments on Materials Performance

Arnold R. Marder, Lehigh University

Deposition Surface Treatments

Deposition surface treatments include electrochemical plating, chemical vapor deposition, and physical vapor deposition processes.

Electrochemical Deposition

Electrochemical methods are well-established processes for applying metal coatings for improved surface properties of materials. Electrodeposition or electroplating is defined as the deposition of a coating by electrolysis, that is, depositing a

substance on an electrode immersed in an electrolyte by passing electric current through the electrolyte. The process can take place in an aqueous electrolyte near ambient temperatures (called aqueous solution electroplating) or in a fused metal salt at high temperatures (called metalliding or fused salt electroplating). Modifications of the electroplating process include occlusion or composite deposition plating. Excellent reviews of electroplating can be found in Ref 32 and 33. Wear- and corrosion-resistance data for selected electrochemical coating methods are summarized in Table 7.

Table 7 Characteristics of wear- and corrosion-resistant electrochemical finishes for engineering components

Characteristic	Copper	Electroplated nickel	Electroless nickel	Chromium	Electroless nickel + chromium	Electroplated nickel + chromium	Comment
Maximum working temperature, °C	50	650	550	650	550	650	Short times at higher temperatures possible
Nontoxicity	Excellent	Very good	Very good	Very good	Very good	Very good	. . .
Covering complex shapes	Medium	Medium	Excellent	Very poor	Very good	Medium	. . .
Thickness range, μm	12.5-500	12.5-500	12.5-500	12.5-500	12.5-500 + 25-50	12.5-500 + 25-50	Grinding needed over 200 μm

Aqueous solution electroplating provides decorative and protective finishes for use at ambient temperatures and in a variety of environments. A main drawback in electroplating is the inability of achieving uniform deposition, which is related to the throwing power of the electrolyte. Throwing power is substrate-shape dependent and also depends on the anode/cathode configuration and the current density, as well as on the composition and conductivity of the electrolyte. A second difficulty is that not all metallic elements can be deposited. Another problem with electroplating is evolution of hydrogen at the electrodes when the cathode efficiency is less than 100%. If a ferrous substrate is to be plated, absorbed atomic hydrogen can cause embrittlement of the part. Unless the parts are heat treated to remove the absorbed hydrogen, they will be brittle and unusable for any application involving elastic strain.

Substrate preparation for plating is critical to ensure good adhesion and surface quality. Maximum adhesion depends on both the elimination of surface contaminants in order to induce a metallurgical bond and the generation of a completely active surface to initiate plating on all areas. The cleaning steps for steel substrates usually involve precleaning, intermediate alkaline cleaning, electrocleaning, acid treatments, and anodic desmutting (Ref 35). Electrodeposited metals can have a very good bond to the substrate, but that bond will never be the same as a fusion bond, and poor bonds can go undetected unless techniques are used to test the actual bond strength. The electrodeposited coating usually ends up with a surface texture that is the same as the starting substrate surface texture, unless an intermediate leveling coating (such as copper) is used.

Nevertheless, the electroplating process produces a coating with distinct advantages (Ref 36):

- The workpiece will not undergo distortion or metallurgical changes because the operating temperature of the bath does not exceed 100 °C (212 °F).
- Plating conditions can be adjusted to modify hardness, internal stress, and metallurgical characteristics of the coating.
- Coatings are dense and adherent to the substrate.
- The thickness of the coating is proportional to the current density and length of time of the deposition.
- Although deposition rate seldom exceeds 75 μm/h (3 mils/h), it can be accelerated by forced circulation of the electrolyte, and can be as high as 150 or 200 μm/min (6 or 8 mils/h) for some metals in high-speed plating.
- There is no technical limit to the thickness of electrodeposits.
- Application of coatings is not confined to the line of sight. Although throwing power may be limited, the freedom of anode design and location is helpful.
- Areas not requiring deposition can be masked.
- Only the tank size of the bath limits the dimensions of the part, although large parts such as gun barrels can be the tank itself; as another alternative, brush plating can be used.
- The process is suitable for automation and has economic advantages over other coating processes.

In general, aqueous electroplating has minimal effect on substrate properties (apart from hydrogen embrittlement). Coated substrates can also be heat treated to promote interdiffusion, although this may result in concentration of elements at grain boundaries, causing embrittlement. Specific elemental electrodeposition processes and properties are reviewed in Ref 37; some examples are given here.

Nickel plating is widely used for a corrosion- and wear-resistant finish. Typical applications, with a thin top coat of electrodeposited chromium, are decorative trim for automotive and consumer products and office furniture. Nickel deposits are also used for nondecorative purposes for improved wear resistance, for example, on pistons, cylinder walls, ball studs, and so forth.

Chromium electroplating is also used as decorative and hard coatings. Colored and tarnish-resistant chromium decorative coatings are produced over a base deposit of copper and/or nickel for applications such as those noted above for nickel. Hard chromium coatings are used for hydraulic pistons and cylinders, piston rings, aircraft engine parts, and plastic molds, where resistance to wear, heat abrasion, and/or corrosion are required.

Cadmium and zinc electroplating provides galvanic corrosion protection when coated on steel. Deposit thickness can vary between 5 and 25 μm (0.2 to 1 mil), and typical applications for both coatings are found in Table 8. Cadmium is preferred for the protection of steel in marine environments, whereas zinc is preferred in industrial environments. Cadmium is also preferred for fastening hardware and connectors because its coefficient of friction is less than zinc. Cadmium is toxic and should not be used in parts that will have contact with food. Precautions for minimizing hydrogen embrittlement should be taken because cadmium plating is more susceptible to such embrittlement than any other plated metal. The development of continuous electrogalvanizing lines has produced a thin, formable coating that is ideal for deep drawing or painting. Automotive body panels are typically new applications for electrogalvanized zinc, zinc-nickel, and zinc-iron alloys. Processing details applicable to electrogalvanizing can be found in Ref 39.

Table 8 Recommended minimum thicknesses and typical applications for zinc and cadmium coatings electrodeposited on iron and steel

Service conditions	Coating thickness[a]		Chromate finish	Time to white corrosion on salt spray, h	Typical applications

(a) Thickness specified is after chromate coating, if used.

(b) There are some applications for cadmium coatings in this environment; however, these are normally satisfied by hot dipped or sprayed coatings.

Tinplate is another continuous electrolytic plating process that has been used for the past 200 years to make containers for the long-term storage of food (Ref 40). The typical tinplate product consists of five layers: an innermost layer of steel sheet, a tin-iron intermetallic compound layer, a free-tin layer, a thin passivation layer based on chromium oxide, and a top layer of oil film for lubrication. The corrosion characteristics of tinplate are documented in the literature (Ref 41).

Metalliding, or fused-salt electroplating, is a process for surface modification and surface hardening by electrodeposition from fused-salt electrolytes. Two unique aspects of this electrodeposition process are: (1) elements that cannot be plated by conventional processes may plate by fused-salt electrodeposition and (2) if the deposition rate is controlled to match the diffusion rate of the deposition species in the substrate at the fused-salt temperatures 400 to 900 °C (750 to 1650 °F), the substrate will develop a diffusion coating, termed metalliding. In electroplating (Ref 42), the molten-salt medium in which the anode and cathode are immersed, consists of a soluble form of the metal to be plated dissolved in a molten-salt solvent, such as an alkali metal halide, that does not participate in the plating process. Coating thickness is determined by the electrical charge, and a sharp interface between the coating and substrate is maintained. At the higher-temperature plating range of the bath, some coating/substrate interdiffusion can occur. In metalliding (Ref 43), the element to be diffused is made the anode of the molten-salt electrochemical cell (usually fluoride) and the substrate is the cathode. A more electrochemically active anode diffuses into the cathode when the electrodes are connected. Because the process is diffusion controlled, a sharp coating/substrate interface does not exist; instead a diffusion gradient in the substrate occurs.

Although fused-salt electroplating has only found limited application for refractory metals and ceramic coatings, some success has been obtained with the platinum-group metals. The process conditions for this technology are too stringent and economically unfeasible. Nevertheless, the process requirements for the electrodes, the melt, and cell operation have been outlined (Ref 42). On the other hand, metalliding is a unique electrodeposition process for applying elements that are difficult to electrodeposit on substrates that usually cannot be plated. It is an important process for improving the surface hardness and corrosion resistance of metals without producing significant dimensional changes. Small-scale, small-size, specialized or strategically important components can be considered for technological development for coating by metalliding if the cost justification can be made, in view of the fact that a one-step diffusion process can be achieved more easily.

Precious Metal Plating. Silver, gold, and the platinum metal groups are electroplated by either aqueous solution electroplating or fused-salt electrodeposition. Both silver and gold are used for decorative purposes as well as industrial uses; the aqueous plating process is reviewed in Ref 44 and 45. Decorative applications of both elements still predominate, but silver has been successfully substituted for gold in some functional uses in electronics. Silver is used on metallic leadframes, the device that supports the majority of silicon chips. New silicon-to-silver bonding techniques have been used to replace the more expensive gold. However, in electrical contact applications, where long-term surface

integrity is important, silver has not been able to replace gold because of its tendency to oxidize or sulfidize on the surface, increasing the contact resistance of the component.

Both aqueous and fused-salt electrolytes have been used for plating the platinum group elements. Platinum has been used as a diffusion barrier layer in aluminiding nickel-base alloys and MCrAlY coatings. Platinum from the aqueous electrolyte is highly stressed unlike the fused-salt deposit. Substances particularly considered for platinum-group metal coating are the refractory group alloys of molybdenum, tungsten, tantalum, niobium, and vanadium, which tend to form volatile oxides at high temperatures thus reducing their usefulness as corrosion-resistant materials. However, cost is still a major factor, and these metals can be used for diffusion barrier layers only if components are small and strategically important.

Electroless plating baths have been developed for copper, nickel, silver, and a number of other materials, but the system with the most importance for corrosion and wear applications is the nickel/phosphorus system. Electroless nickel plating is used to deposit nickel without the use of an electric current; thus it is sometimes called autocatalytic plating. In this process the part is immersed in a aqueous solution containing metal salts, a reducing agent, and other chemicals that control the pH and reaction rates. The part acts as a catalyst for the reduction of the nickel ions by the reducing agent. The reducing agent causes the metal ion reduction and the nickel coating on the part continues to act as a catalyst as the plating process continues, unlike in electroplating where the ions pick up electrons from the cathode. When the process takes place using a hypophosphite-reducing agent, the finished nickel coating is not pure nickel, but contains phosphorus inclusions. Phosphorus content can be as high as 13% (Ref 46).

As applied, nickel-phosphorus coatings are uniform, hard, relatively brittle, lubricious, easily solderable, and highly corrosion resistant (Ref 47). Wear resistance equivalent to hard chromium coatings can be obtained when the coating is heat treated at low temperatures to produce a very hard precipitation-hardened structure. As applied, most of these coatings are amorphous metal glasses that when heated first form nickel phosphite (Ni_3P) particles; at temperatures above 320 °C (610 °F), the deposit crystallizes. Internal stresses are primarily a function of coating composition, and coating thickness uniformity can be easily controlled. Adhesion to most metals is excellent, and frictional properties are also excellent and similar to chromium.

As deposited, the microhardness of electroless nickel coating is about 500 to 600 HVN (48 to 50 HRC), equivalent to many hardened steels. After precipitation hardening, hardness values as high as 110 HVN are reported, which is equivalent to commercial hard-chromium coatings. Because of their high hardness, electroless nickel coatings have excellent wear and abrasion resistance in both the as-deposited and hardened condition.

Electroless nickel coatings can be easily soldered and are used in electronic applications to facilitate soldering of light metals such as aluminum. Electroless nickel is often used as a barrier coating; to be effective, the deposit must be free of pores and defects. In the as-deposited amorphous state, the coating corrosion resistance is excellent (Table 9), and in many environments is superior to that of pure nickel or chromium alloys. However, after heat treatment the corrosion resistance can deteriorate.

Composite deposition plating is a further extension of aqueous solution electroplating or electroless coatings in that particles or fibers are suspended in the electrolyte, then occluded in the deposit. Oxides, carbides, silicides, refractory powder, metallic powder, and organic powder can be introduced into the electrolyte. The most widely used electrodeposited composites are cermet coatings, with alumina (Al_2O_3), zirconia (ZrO_2), titania (TiO_2), and silicon carbide (SiC) added to increase strength, hardness, and wear resistance (Table 10). The amount of ceramic particles incorporated in the coating depends on the current density and the bath loading, that is, the amount of particulate in the suspension. It has been shown that coatings up to 40 vol% Al_2O_3 were produced at 0.5 A/dm^2 and 5.3 vol% bath loading. The amount of Al_2O_3 incorporated into the coating was seen to decrease with increasing current density and decreasing bath loading (Ref 48). Hardness values ranged from approximately 250 to 580 HVN, depending on the amount of Al_2O_3 incorporated.

Metallic particles such as chromium can be introduced into a metal plating electrolyte (for example, nickel and cobalt), and the deposited composite can be subsequently heat treated to form high-temperature oxidation-resistant alloys. MCrAlY composites have been made by depositing 10 μm CrAlY powder in a cobalt or nickel matrix. Heat treatment bonds the coating to the substrate and interdiffuses the cobalt and nickel with the CrAlY particles. The CoCrAlY coatings produced have been shown to be superior to some plasma sprayed CoCrAlY and pack aluminized coatings (Ref 34). Aluminum particles have been codeposited in a nickel matrix and subsequently heat treated to produce a nickel-aluminum intermetallic coating with exceptional oxidation resistance (Ref 49) (Fig. 8).

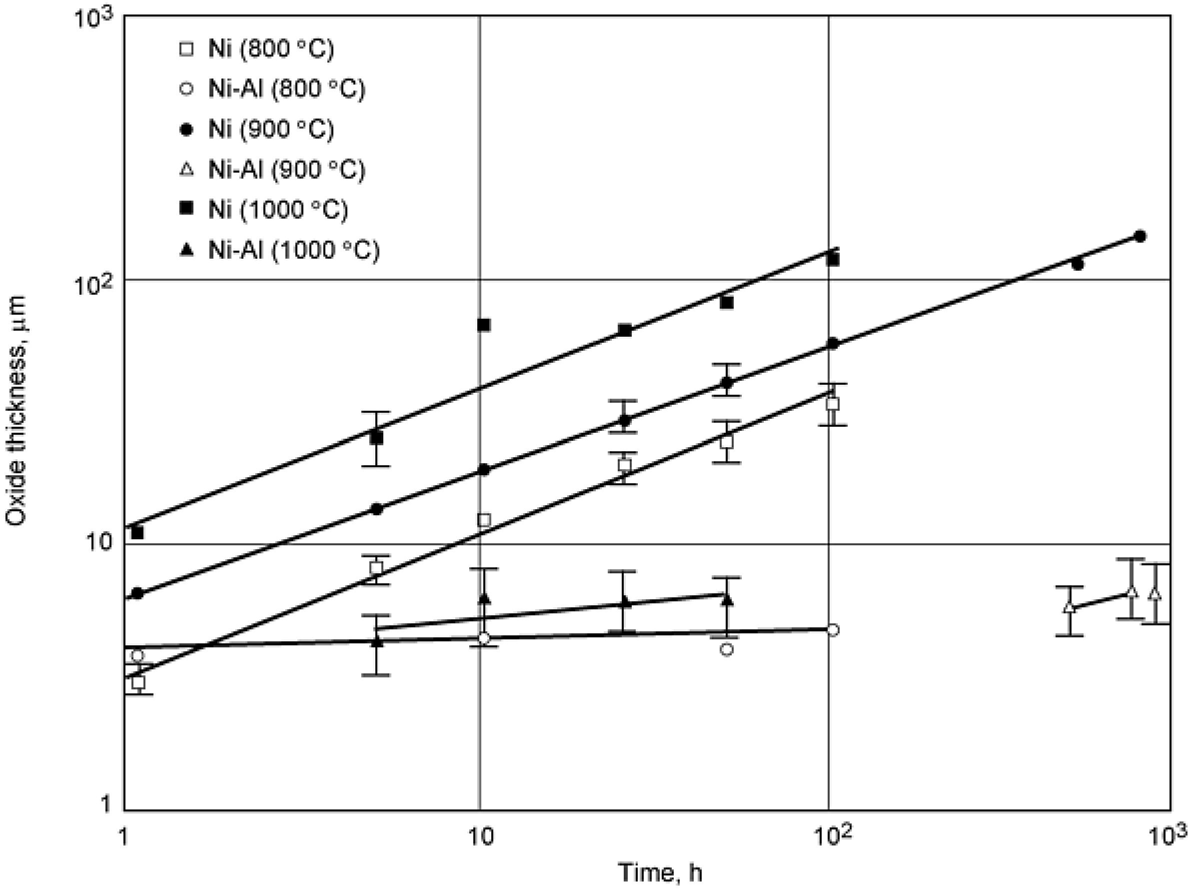

Fig. 8 Oxide depth versus time plotted on log-log scale for pure nickel and nickel-alloy coatings exposed in air at 800, 900, and 1000 °C. Source: Ref 49

Polytetrafluoroethylene (PTFE), diamond, and SiC particles can also be incorporated into a nickel electroless plating for improved properties. Diamond and silicon carbide are used to enhance abrasion resistance; the surface hardness of these composites is reported to be 1300 HVN. Polytetrafluoroethylene is added to the electroless nickel bath to provide a composite coating with enhanced lubrication. Almost any particulate material can be deposited in a metallic matrix, provided the particles are sufficiently small to remain suspended in the bath and that the particles do not react chemically with the bath during electrodeposition.

Chemical Vapor Deposition and Related Processes

Chemical vapor deposition (CVD) involves the formation of a coating by the reaction of the coating substance with the substrate. The coating species can come from a gas or gases or from contact with a solid as in the pack cementation process. The process is more precisely defined as the deposition of a solid on a heated surface by a chemical reaction from the vapor or gas phase (Ref 50). In general, three processing steps are involved in any CVD reaction: (1) the production of a volatile carrier compound, (2) the transport of the gas to the deposition site without decomposition, and (3) the chemical reaction necessary to produce the coating on the substrate. The numerous chemical reactions used in CVD include thermal decomposition (pyrolysis), reduction, hydrolysis, disproportionation, oxidation, carburization, and nitridation. These reactions take place singly or in combination and are controlled by thermodynamics, kinetics, mass transport, chemistry of the reaction, and processing parameters of temperature, pressure, and chemical activity.

Chemical vapor deposition processes can be classified as either open reactor systems, including thermal CVD and plasma CVD, or as a closed-reactor system, as in pack cementation. In thermal CVD, reactions usually take place above 900 °C (1650 °F), whereas plasma CVD usually operates at temperature between 300 and 700 °C (570 and 1290 °F) (Table 11). Using the lower-reaction-temperature plasma CVD enables coatings to be produced on substrates with low melting points or that otherwise would undergo solid-state transformations over the range of deposition temperatures. Furthermore, the

low deposition temperature of plasma CVD coatings limits the stresses due to the large mismatches in thermal expansion that can lead to cracking and delamination of the coating.

Table 11 Typical deposition temperatures for thermal and plasma CVD

Material	Deposition temperature			
	Thermal CVD		**Plasma CVD**	
	°C	**°F**	**°C**	**°F**
Silicon nitride	900	1650	300	570
Silicon dioxide	800-1100	1470-2010	300	570
Titanium carbide	900-1100	1650-2010	500	930
Titanium nitride	900-1100	1650-2010	500	930
Tungsten carbide	1000	1830	325-525	615-975

Materials that cannot ordinarily be deposited by electrodeposition--for example, the refractory metals tungsten, molybdenum, rhenium, niobium, tantalum, zirconium, hafnium, and so forth--are deposited using CVD processes. Typical products produced are crucibles, rocket nozzles, and other high-temperature components; linings for chemical vessels; and coatings for electronic components. These refractory metals are deposited at temperatures far below their melting points or sintering temperatures, and coatings can be produced with a preferred grain size and grain orientation. For example, tungsten that is deposited by the hydrogen reduction of the halide and deposition at a lower temperature (500 °C, or 930 °F) gives a finer grain size with higher strength (83 MPa, or 12 ksi) than deposition at a higher temperature (700 °C, or 1290 °F) (Ref 50).

The deposition of ceramics involves many different compounds, for example, titanium carbide (TiC), titanium nitride (TiN), Al_2O_3, diamond, and so forth. Table 12 lists the properties of typical CVD coating materials for wear and corrosion resistance. Coatings for the cutting tool industry utilize CVD processes, particularly TiC coatings for cemented tungsten carbide tools and TiN and carbonitride coatings for high-speed tool steels and cemented carbide tools (Ref 50). Nearly all coatings are multilayer systems that combine TiN for lubricity and galling resistance, Al_2O_3 for chemical inertness and thermal insulation, and TiC and carbonitride for abrasion resistance. A comparison of coatings for cutting tools is given in Table 13.

Table 12 Selected wear and corrosion properties of CVD coating materials

Material	Hardness		Thermal conductivity, W/m · K	Coefficient of thermal expansion at 25 °C (77 °F) 10^{-6}/K	Remarks
	GPa	**10^6psi**			
Titanium carbide	31.4	4.5	17	7.6	High wear and abrasion resistance, low friction
Titanium nitride	20.6	3.0	33	9.5	High lubricity; stable and inert
Titanium carbonitride	24.5-29.4	3.5-4.3	20-30	8	Stable lubricant
Chromium carbide	22.1	3.2	11	10	Resists oxidation to 900 °C (1650 °F)
Silicon carbide	27.4	4.0	125	3.9	High conductivity, shock resistant
Titanium diboride	33.0	4.7	25	6.6	High hardness, high wear resistance
Alumina	18.8	2.7	34	8.3	Oxidation resistant, very stable
Diamondlike carbon	29-49	4.2-7.1	200	. . .	Very hard, high thermal conductivity
Diamond	98	14.2	180	2.9	Extreme hardness and high thermal conductivity

(a) For each property, best material is identified first.

Diamond films grown by CVD exhibit outstanding properties approaching natural diamond, such as high electrical resistivity, high optical transparency, extreme hardness, high refractive index, and chemical inertness. Different film deposition techniques and system configurations result in films with different characteristics. Diamond films can be grown using processing variables of different concentrations of methane in methane-hydrogen gas mixtures and flow rates (Ref 52). The CVD of diamond requires the presence of atomic hydrogen, which selectively removes graphite and activates and stabilizes the diamond structure. The basic reaction involves the decomposition of methane, which can be activated by microwave plasma, thermal means (hot filament), plasma arc, or laser.

The pack cementation process originally involved pack carburizing, which is the process of diffusing carbon into the surface of iron or low-carbon steel by heating in a closed container filled with activated charcoal. The simplest and oldest carburizing process involves filling a welded sheet metal or plate box with granular charcoal that is activated with chemicals such as barium carbonate to assist the formation of carbon monoxide (CO). In the heated box, charcoal forms carbon dioxide (CO_2), which converts to CO in an environment with an excess of carbon. The CO then forms atomic carbon at the component surface and diffuses into the part. The pack carburization process is of little commercial importance, although it is still done occasionally. It has given rise to other CVD pack diffusion processes including aluminizing, siliconizing, chromizing, and boronizing.

Pack cementation is a modified CVD deposition batch process that involves heating a closed/vented pack to an elevated temperature (e.g., 1050 °C, or 1920 °F) for a given time (e.g., 16 h) during which a diffusional coating is produced (Ref 53). The traditional pack consists of four components: the substrate or part to be coated, the master alloy (i.e., a powder of the element or elements to be deposited on the surface of the part), a halide salt activator, and relatively inert filler powder. The master alloy, the filler, and halide activator are thoroughly mixed together, and the part to be coated is buried in this mixture in a retort (Ref 54). When the mixture is heated, the activator reacts to produce an atmosphere of source element(s) halides that diffuse into the pack and transfer the source element(s) to the substrate on which the coating is formed (Ref 55). A summary of CVD pack diffusion process characteristics is given in Table 14.

Table 14 Typical characteristics of pack cementation processes

Process	Nature of case	Process temperature, °C (°F)	Typical case depth	Case hardness, HRC	Typical base metals	Process characteristics
Aluminizing (pack)	Diffused aluminum	870-980 (1600-1800)	25 μm-1 mm (1-40 mils)	<20	Low-carbon steels	Diffused coating for oxidation resistance at elevated temperatures
Siliconizing by chemical vapor deposition	Diffused silicon	925-1040 (1700-1900)	25 μm-1 mm (1-40 mils)	30-50	Low-carbon steels	For corrosion and wear resistance, atmosphere control is critical
Chromizing by chemical vapor deposition	Diffused chromium	980-1090 (1800-2000)	25-50 μm (1-2 mils)	Low-carbon steel, <30; high-carbon steel, 50-60	High- and low-carbon steels	Chromized low-carbon steels yield a low-cost stainless steel; high-carbon steels develop a hard corrosion-resistant case
Titanium carbide	Diffused carbon and titanium, TiC compound	900-1010 (1650-1850)	2.5-12.5 μm (0.1-0.5 mil)	>70[(a)]	Alloy steels, tools steels	Produces a thin carbide (TiC) case for high resistance wear; temperature may cause distortion

Boriding	Diffused boron, boron compounds	400-1150 (750-2100)	12.5-50 μm (0.5-2 mils)	40-70	Alloy steels, tool steels, cobalt and nickel alloys	Produces a hard compound layer, mostly applied over hardened tool steels; high process temperature can cause distortion

(a) Requires quench from austenizing temperature.

Aluminizing. An aluminizing pack cementation process is commercially practiced for a range of alloys, including nickel- and cobalt-base superalloys, steels, and copper. Simple aluminide coatings resist high-temperature oxidation by the formation of an alumina protective layer and can be used up to about 1150 °C (2100 °F), but the coating can degrade by spallation of the oxide during thermal cycling. For extended periods of time at temperatures in excess of 1000 °C (1830 °F), interdiffusion of the coating will cause further degradation, and therefore practical coating life is limited to operating temperatures of 870 to 980 °C (1600 to 1800 °F). Pack compositions, process temperatures, and process times depend on the type of base material to be aluminized and fall into the following classifications (Ref 57):

Class	Alloy
I	Carbon and low-alloy steels
II	Ferritic and martensitic stainless steels
III	Austenitic stainless steels with 21-40% Ni and iron-base superalloys
IV	Nickel- and cobalt-base superalloys

As a general rule, overall aluminum diffusion is slowed as the nickel, chromium, and cobalt contents increase. Thus, higher temperatures and longer processing times are required to produce greater aluminum diffusion thicknesses as the base material increases in alloy content.

Stainless steels are oxidation resistant as a result of the formation of a thin chromium-rich oxide on the component surface. A similar reaction occurs in aluminized steels in which a thin slower-growing aluminum-rich oxide forms. Unlike chromium oxide, Al_2O_3 does not exhibit volatility in the presence of oxygen above 927 °C (1700 °F). Figure 9 compares an aluminized carbon steel with several alloys at a temperature in which scaling remains less than 10 mg/cm^2 for oxidation in air. In sulfidizing environments, pack aluminized coatings have excellent resistance to corrosive attack. In contrast to stainless steels, the aluminum-rich surface (50% Al) and diffusion zone (20% Al min) of the coating is far more resistant than chromium to sulfidation corrosion. Figure 10 compares the corrosion rates of bare and aluminized 9Cr-1Mo steel in a hydrogen sulfide (H_2S) environment.

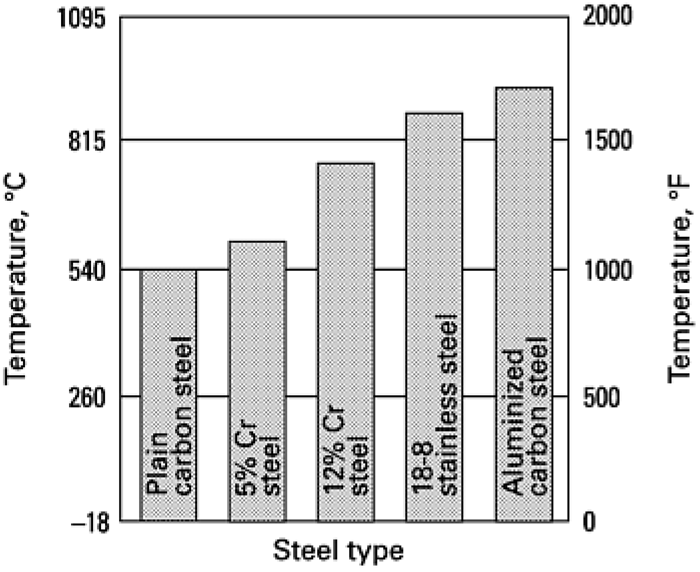

Fig. 9 Oxidation of steels in air at the temperature at which scaling is less than 10 mg/cm^2. Source: Ref 58

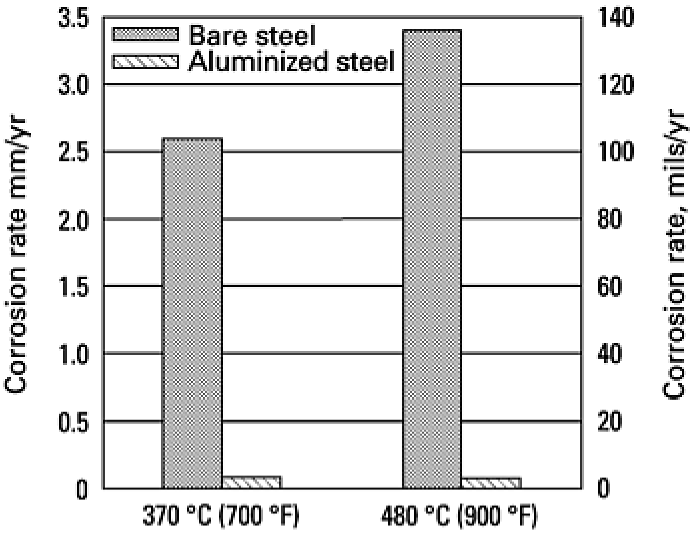

Fig. 10 Relative corrosion rates of 9Cr-1Mo alloy steel in 5 mol% H_2S at 3550 kPa (515 psi) for 300 h. Source: Ref 59

Siliconizing, the diffusion of silicon into steel, occurs similarly to aluminizing. There are pack and retort processes in which parts are subjected to gas atmospheres that react with the heated part surface to produce nascent silicon that diffuses into the substrate to be coated. In a pure silicon pack that is activated with NH_4Cl, $SiCl_4$ and $SiHCl_3$ gases form, which are reduced by hydrogen gas to deposit elemental silicon on the surface of the part (Ref 55). Another process involves tumbling parts in a retort with SiC. When a temperature of 1010 °C (1850 °F) is reached, silicon tetrachloride gas is introduced, which reacts with the part and the SiC particles to produce a concentration gradient of silicon on the part surface as the silicon diffuses into the substrate. The process normally takes place on low-carbon steels, and these steels develop case depths up to 1 mm (0.040 in.) with a silicon content of 13 wt% (Ref 60). Case depths developed on these siliconized steels have hardnesses of about 50 HRC and therefore can be used for wear resistance. The presence of silicon on the surface allows for the formation of a stable silicon dioxide (SiO_2) phase in oxidizing environments and excellent corrosion resistance.

Chromizing. Chromium can be applied in the same manner as aluminum and silicon to produce a chromium-rich coating, and many of the same principles of aluminizing packs apply to chromizing packs. Parts are packed in chromium

powder with an inert filler such as aluminum oxide. A halide salt activator is added that changes to the vapor phase at the processing temperature and serves as a carrier gas to bring chromium to the surface of the part. Diffusion coatings can be formed on nickel-base superalloys by pack cementation using ammonium chloride as a chromium-alumina activator. These coatings usually contain 20 to 25 wt% Cr at the outer surface and involve approximately equal rates of interdiffusion of chromium and nickel. Significant depletion of aluminum and titanium from the alloy surface occurs, thus producing a coating that is a solid solution of the chromium in the remaining nickel-base superalloy. The deposited coating is usually overlaid with a thin layer of α-chromium, which must be removed chemically (Ref 55).

In low-alloy steels, it has been shown that chromizing is much more complex, leading to microstructures that may behave detrimentally in some environments (Ref 61). In a chromized 2.25Cr-1Mo alloy, the coating contains a thin outer layer ($\sim$5 μm) of mostly chromium (>80 wt%), which is essential for corrosion protection. Large columnar ferritic grains, containing between 30 and 15 wt% Cr, are found beneath the outer layer. The columnar grain boundaries, as well as the boundary between the outer chromium-rich layer and the columnar grains, are decorated with chromium carbides that were found to contribute to coating degradation. A layer of Kirkendall voids (also decorated by carbides), iron carbides at the coating/substrate interface, and a large decarburized zone in the substrate are also produced by the process.

Evaluation of samples exposed to a fossil-fired boiler up to two years revealed two degradation mechanisms: cracking and sulfidation corrosion. Cracking of the outer coating layer allowed ingress of sulfur, resulting in intergranular sulfidation corrosion attack. Once the outer protective chromium layer has been breached, the columnar grain boundary orientation promotes crack initiation and propagation along the carbides when the tube is subjected to axial thermal loading. However, it should be noted that chromized coatings have been used up to 10 years in some fossil-fired boilers. Therefore, stress and environmental conditions are critical to the successful use of these pack cementation coatings, as long as the effect of the processing thermal cycle on the coating and substrate morphology is understood.

Boriding, or boronizing, is a thermochemical surface-hardening process that can be applied to a wide variety of ferrous, nonferrous, and cermet materials. The boronizing pack process is similar to pack carburizing with the parts to be coated being packed with a boron-containing compound such as boron powder or ferroboron. Activators such as chlorine and fluorine compounds are added to enhance the production of the boron-rich gas at the part surface. Processing of high-speed tool steels that were previously quenched hardened is accomplished at 540 °C (1000 °F). Boronizing at higher temperatures up to 1090 °C (2000 °F) causes diffusion rates to increase, thus reducing the process time. The boron case does not have to be quenched to obtain its high hardness, but tool steels processed in the austenitizing temperature range need to be quenched from the coating temperature to harden the substrate.

Boronizing is most often applied to tool steels or other substrates that are already hardened by heat treatment. The thin (12 to 15 μm) boride compound surfaces provide even greater hardness, improving wear service life. Distortion from the high processing temperatures is a major problem for boronized coatings. Finished parts that are able to tolerate a few thousandths of an inch (75 μm) distortion are better suited for this process sequence because the thin coating cannot be finish ground (Ref 60).

Multicomponent Coatings. Multicomponent pack cementation coatings have been developed from chromium/aluminum and chromium/silicon processing for high-temperature corrosion resistance. In general, simple binary alloys--for example, iron-chromium, nickel-aluminum, and so forth--are not as effective for oxidation resistance as a ternary alloy using the interaction of two oxidation-resistant elements. Considering an Fe-20Cr-5Al alloy exposed to a high-temperature environment, a continuous adherent chromia (Cr_2O_3) scale initially is formed, which prevents the rapid oxidation of the iron (Ref 62). The Cr_2O_3 scale also prevents inward diffusion of the oxygen, negating internal oxidation of aluminum, and allows for the formation of a much more stable but slower-growing and protective Al_2O_3. Similar results were found for an Fe-30Cr-3Si alloy in which a Cr_2O_3 scale formed initially during exposure to an oxidizing environment, preventing the rapid oxidation of iron and the internal oxidation of silicon and allowing a very slow protective SiO_2 film to form beneath the Cr_2O_3 (Ref 62).

The codeposition of two or more elements in a halide-activated cementation pack is inherently difficult because of the large differences in the thermodynamic stabilities of their volatile halides. A variety of alloys have been coated with chromium/aluminum (low-carbon and alloy steels; types 410, 304, and 316 stainless steels; and nickel-base superalloys) and chromium/silicon (low-carbon and low-alloy steels, types 304 and 409 stainless steels, Incoloy 800). Each alloy requires a specific pack chemistry to obtain optimal coating composition for superior oxidation resistance. Details of the required pack compositions for each coating/alloy combination are reviewed in Ref 63.

During chromizing/aluminizing of low-alloy steels, a ferrite layer is initially formed on the steel allowing for subsequent diffusion of chromium and aluminum into the ferrite matrix substrate. Rejection of carbon into the ferrite/austenite

interface at the reaction temperature minimized decarburization and prevents the formation of chromium carbides at the surface. The resulting chromium/aluminum coating provides excellent isothermal and cyclic oxidation resistance at 700 °C (1290 °F) by the formation of an Al_2O_3 scale. Similar results were found for a chromizing/silicon process in which improvement over an uncoated steel was significant (Fig. 11). Even in austenitic stainless steels and superalloys the key element in the reduction of oxidation kinetics is the presence of ferrite at the surface, with its higher diffusion coefficients. The high diffusivity for ferrite promotes the early formation and retention of the thermodynamically more stable oxide scales in chromium/silicon coatings, that is, chromia rather than iron oxide at an early stage of oxidation and silica rather than chromia at steady state.

Physical Vapor Deposition Processes

Physical vapor deposition (PVD) processes involve the formation of a coating on a substrate by physical deposition of atoms, ions, or molecules of the coating species (Ref 64). There are three main techniques for applying PVD coatings: thermal evaporation, sputtering, and ion plating. Thermal evaporation involves heating of the material until it forms a vapor that condenses on a substrate to form a coating. Sputtering involves the electrical generation of a plasma between the coating species and the substrate. Ion plating is essentially a combination of these two processes. A fourth type of process is ion implantation, which does not produce a coating; instead, high energy ions are made to penetrate into and modify the substrate surface. A comparison of the process characteristics is provided in Table 15. Reviews of these processes can be found in the literature (for example, Ref 64, 66, and 67).

Table 15 Comparison of PVD process characteristics

Process	Processing temperature, °C	Throwing power	Coating materials	Coating applications and special features
Vacuum evaporation	RT-700, usually <200	Line of sight	Chiefly metal, especially Al (a few simple alloys/a few simple compounds)	Electronic, optical, decorative, simple masking

Ion implantation	200-400, best <250 for N	Line of sight	Usually N (B, C)	Wear resistance for tools, dies, etc. Effect much deeper than original implantation depth. Precise area treatment, excellent process control
Ion plating, ARE	RT-0.7 T_m of coating. Best at elevated temperatures	Moderate to good	Ion plating: Al, other metals (few alloys) ARE: TiN and other compounds	Electronic, optical, decorative. Corrosion and wear resistance. Dry lubricants. Thicker engineering coatings
Sputtering	RT-0.7 T_m of metal coatings. Best >200 for nonmetals	Line of sight	Metals, alloys, glasses, oxides. TiN and other compounds[(a)]	Electronic, optical, wear resistance. Architectural (decorative). Generally thin coatings. Excellent process control
CVD	300-2000, usually 600-1200	Very good	Metals, especially refractory TiN and other compounds[(a)], pyrolytic BN	Thin, wear-resistant films on metal and carbide dies, tools, etc. Free-standing bodies of refractory metals and pyrolytic C or BN

RT, room temperature; ARE, activated reactive evaporation; T_m, absolute melting temperature.

(a) Compounds: oxides, nitrides, carbides, silicides, and borides of Al, B, Cr, Hf, Mo, Nb, Ni, Re, Si, Ta, Ti, V, W, Zr.

Originally PVD was used to deposit single metal elements by transport of a vapor in a vacuum without involving a chemical reaction. Today, PVD technology has evolved so that a wide array of inorganic materials (including metals, alloys, compounds, or their mixtures) and organic compounds can be deposited. The PVD process occurs in a vacuum chamber and involves a vapor source and the substrate on which deposition occurs. Different techniques arise because of variations in atmospheres, vapor source heating method, and electrical voltage of the substrate, all of which contribute to the structure, properties, and deposition rate of the coating (Ref 67). The steps in deposition occur as follows:

1. Synthesis of the material deposited (transition from a condensed state, solid or liquid, to the vapor phase, or, for deposition of compounds, reaction between the components of the compound, some of which may be introduced into the chamber as a gas or vapor)
2. Vapor transport from the source to the substrate
3. Condensation of the vapors followed by film nucleation and growth

The PVD process produces coatings for a range of applications including electronics, optics, decoration, and corrosion and wear prevention. Only engineering uses, that is, corrosion- and-wear-resistant coatings, are discussed below. The coatings used for wear applications are usually hard compounds, and, from the designers point of view, thin-film wear coatings can be used for the same type of applications as chromium electroplate. Physical vapor deposition coatings have hardnesses greater than any metal and are used in systems that cannot tolerate even microscopic wear losses. Most processes are operated on a batch basis, and the component size is limited by the size of the vacuum chamber. Provided that the substrate can be manipulated to face the coating source, the size and shape of objects are limited by the capital and operating expenditures involved rather than by the fundamental characteristics of the process. Furthermore, cleanliness of the substrate is critical and far exceeds surface preparation requirements for other coatings.

Thermal evaporation is the oldest and probably the most widely used PVD technique. It accounts for the major proportion of both the equipment in use and the area coated. Thermal evaporation occurs in a hard vacuum of 0.1 to 10 mPa, at which pressures the mean free path of a gas atom, that is, the average distance the atom travels before colliding with another atom, is greater than the chamber dimensions. An atom evaporating from a source travels in a straight line; thus the process is line-of-sight limited, and coating around corners or reentrant angles is not possible without substrate manipulation. A description of the process and the equipment is found in Ref 68.

Aluminum and chromium coatings for automotive trim are probably the largest application of this process. Hard coatings of chromium and Al_2O_3 are sometimes deposited on steel or tungsten carbide tools, but this application has been replaced by sputter coatings. Aerospace applications use aluminum and nickel-chromium for corrosion protection and aluminum and silver as solid lubricants. Electron beam/physical vapor deposition (EB/PVD) is widely used in the gas turbine industry for applying MCrAlY metallic coatings on turbine blades and vanes for oxidation and corrosion protection (Ref 69). Zirconia thermal barrier coatings (TBCs) can also be deposited using this technique. Bond coats for EB/PVD TBCs are normally MCrAlY type coatings, similarly processed. The major advantage of EB/PVD TBCs is the columnar outer structure of the ZrO_2 (Fig. 12), which reduces the stress buildup within the body of the coating. These TBCs have superior degradation resistance that has been confirmed in gas turbine flight tests. For example, EB/PVD zirconia was found to be better than plasma sprayed zirconia or metallic MCrAlY after 4200 h tests of first-stage blades.

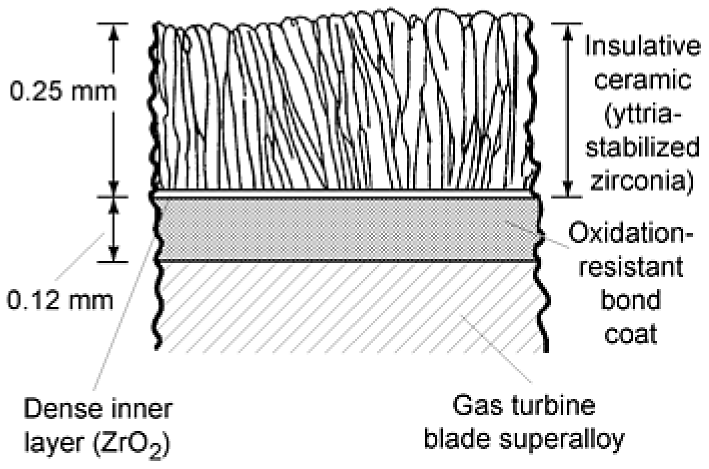

Fig. 12 Cross section illustrating the strain-tolerant columnar ZrO_2 microstructure of EB/PVD zirconia thermal barrier coatings. Source: Ref 69

Sputter coating is a vacuum process that involves the use of ions from a gas-generated plasma to dislodge coating atoms or molecules from a target made of the material that will become the coating. The plasma is established between the target and the substrate by the application of a direct current potential or an alternating potential (radio frequency). An inert gas is introduced into the chamber to form the glow discharge plasma between the electrodes. The materials that can be sputter coated are pure metals, alloys, inorganic compounds, and some polymeric materials. A major restriction to be considered for the substrate material is the temperature of the process, which can range from 260 to 540 °C (500 to 1000 °F). Details of the process and equipment have been reviewed (Ref 70). Sputtering is often used for depositing compounds and materials that are difficult to coat by thermal evaporation techniques. Engineering applications of sputter coatings include:

- Corrosion and oxidation resistance, for example, nickel-chromium, MCrAlY, and polymers
- Lubrication, for example, silver, indium, MoS_2, PTFE, selenides, silicides, and tellurides
- Wear resistance, for example, TiN, other nitrides, tungsten, molybdenum, carbides, borides, and diamondlike carbon

Titanium nitride coatings are generally used for wear resistance, and Fig. 13 shows that TiN coatings increase the abrasion resistance of a hardened steel (Ref 64).

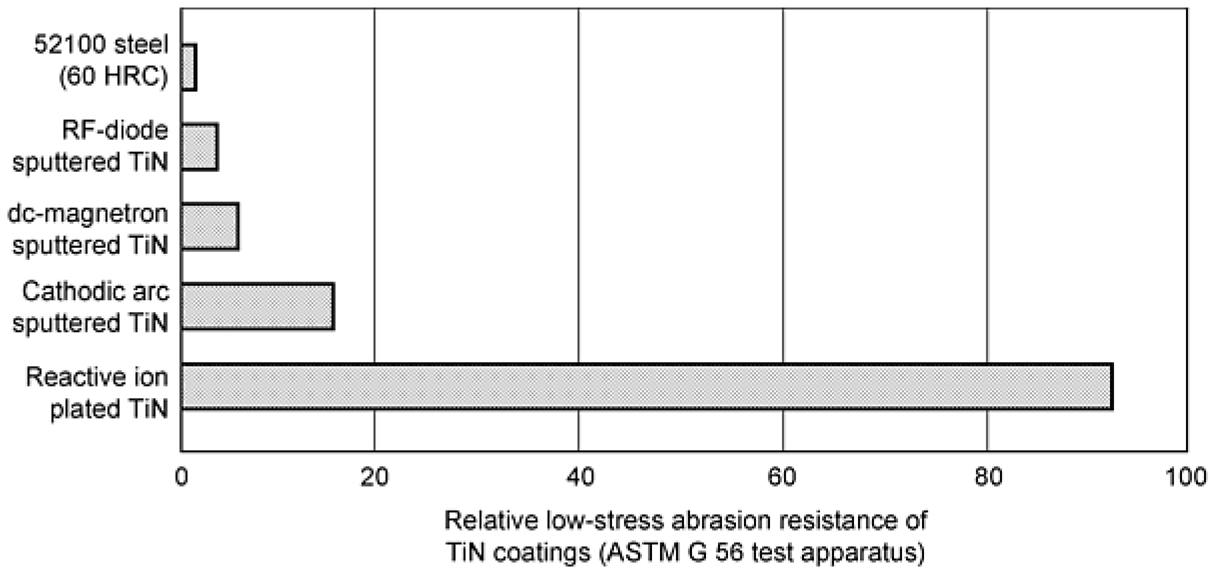

Fig. 13 Effect of coating technique on the relative abrasion resistance of TiN on hardened steel applied by various processes. Source: Ref 71

Ion plating is a vacuum coating process in which a portion of the coating species impinges on the substrate in ionic form (Ref 64). The process is a hybrid of the thermal evaporation process and sputtering with the evaporation rate being maintained at a higher rate than the atoms that can be sputtered from the substrate. Some evaporant atoms pass through the plasma in atomic form, while some atoms collide with electrons from the substrate and become ions. They impinge on the substrate in ionic form, pick up electrons and return to the atomic state, forming the coating. A detailed description of the process and equipment is provided in Ref 72.

A variant process is reactive ion plating in which the metallic constituent (titanium) of the compound (TiN) is evaporated into the reactive gas mixture of argon and nitrogen that is enhanced by the glow discharge, depositing a golden-colored TiN coating on the substrate. Films of TiN are applied to a wide range of tools such as bits, punches, dies, taps, and so forth, to improve tool life by three to ten times (Ref 69). Figure 13 shows the improvement in abrasion resistance of reactive ion plating over other PVD sputtering processes. The results show that the higher-energy reactive ion plating process had more than an order of magnitude improvement over the radio-frequency diode sputtered coatings (Ref 64). These results indicate that application technique should be made a coating selection factor.

Ion implantation involves the bombardment of a solid material with medium- to-high-energy ionized atoms and offers the ability to alloy virtually any elemental species into the near-surface region of any substrate (Ref 73). The advantage of such a process is that it produces improved surface properties without the limitations of dimensional changes or delamination found in conventional coatings. During implantation, ions come to rest beneath the surface in less than 10 to 12 s, producing a very fast quench rate and allowing the development of nonequilibrium surface alloys or compounds. Details of the process and associated equipment are documented in Ref 73. Ion implantation is commercially applied to various steels, tungsten carbide/cobalt materials, and alloys of titanium, nickel, cobalt, aluminum and chromium, although applications are restricted to temperatures below 250 °C (480 °F) for steels and 450 °C (840 °F) for carbides.

Table 16 lists some of the applications for the ion-implantation process. Ion-implantation surfaces produce exceptional results in reducing wear, friction, and corrosion. Commercial applications involve tooling, bearings, and biomedical components. Nitrogen implantation, especially in alloy surfaces containing elements forming stable nitrides, has found use in tools and dies such as cobalt-cemented tungsten carbide wire drawing inserts. Nitrogen implantation has been especially successful in increasing the life (up to 20 times) of tools and parts used in the manufacture of injection-molded plastics. Titanium and cobalt-chromium alloy orthopedic prostheses for hip and knee joints are among the most successful commercial applications for ion-implantation components for wear resistance.

Table 16 Research and development applications for ion implantation

Surface properties modified	Substrates studied	Ions species used	Comments
Wear	Steels, WC, Ti, Co/Cr alloys, TiN coatings, electroplated Cr	N, C 10-20 at.% $\geq 10^{17}$ ions/cm^2	Ti,Co/Cr alloys largest use commercially in orthopedic devices
Friction	Steels	Ti plus C implants $\geq 10^{17}$ ions/cm^2	Dual implants give amorphous surface layer
Fatigue	Ti alloys, steels	N, C $\geq 10^{17}$ ions/cm^2	Implantation effective for surface initiated fatigue
Fracture toughness	Ceramics: Al_2O_3, TiN	Ar 10^{15}-10^{17} ions/cm^2	Radiation damage critical; ion-induced compressive stress helpful
Aqueous corrosion catalysis	Steels, Ti alloys, Pt	Cr, Ta, Cr+P $\geq 10^{17}$ ions/cm^2	Ion implant can mimic "normal" alloys; amorphous and unique surface alloys possible
Oxidation	Superalloys	Y, Ce $\geq 10^{15}$ ions/cm^2	Low effective doses; implanted species stay at metal-oxide interface
Electrical conductivity	Polymers	Ar, F 10^{15}-10^{17} ions/cm^2	Permits chain scissoning, doping; conductivity approaches disordered metal levels
Optical: refractive index	Glasses, electrooptics	Li, Ar 10^{15}-10^{17} ions/cm^2	Chemical doping and lattice disorder both important

Effects of Surface Treatments on Materials Performance

Arnold R. Marder, Lehigh University

Heat Treatment Coatings

Several types of coatings involve a heat treatment either after processing or as part of the coating process. These processes involve (1) surface hardening in steels, where localized heat treatment of the surface component occurs, and (2) diffusion coatings, in which the surface composition is modified. These composition modifications can be produced in processes involving carburizing and/or nitriding of steel component surfaces when interstitial atoms of carbon or nitrogen are diffused into the steel surface at high temperature in order to increase the surface hardness, strength, and fatigue resistance.

Surface Hardening

Surface hardening in a general sense involves many processes that improve the wear resistance of parts while utilizing the tough interior properties of the steel component. In this case, surface hardening is limited to localized heat-treating processes that produce a hard quenched surface without introducing additional alloying species. This approach consists of hardening the surface by flame, induction, laser beam, or electron beam heating. More detailed information on surface hardening of steels can be found in Ref 74.

Flame hardening consists of austenitizing the surface of steel by heating with an oxyacetylene or oxyhydrogen torch and immediately quenching with water (Ref 74). After quenching, the microstructure of the surface layer consists of hard martensite over a lower-strength interior core of other steel morphologies such as ferrite and pearlite. A prerequisite for proper flame hardening is that the steel must have adequate carbon and other alloy additions to produce the desired hardness, because there is no change in composition. Flame-hardening equipment utilizes direct impingement of a high-temperature flame or high-velocity combustion product gases to austenitize the component surface and quickly cool the surface faster than the critical cooling rate to produce martensite in the steel. This is necessary because the hardenability of the component is fixed by the original composition of the steel. Thus, equipment design is critical to success of the operation. Flame-heating equipment may be a single torch with a specially designed head or an elaborate apparatus that automatically indexes, heats, and quenches parts. With improvements in gas-mixing equipment, infrared temperature measurement and control, and burner rig design, flame hardening has been accepted as a reliable heat-treating process that is adaptable to general or localized surface hardening for small or medium-to-high production requirements (Ref 35).

The flame-hardening process is used for a wide variety of applications (Ref 74). These include (1) parts that are so large that conventional furnace treatments are impractical or uneconomical, (2) prevention of detrimental treatment of the entire component when only small segments of the part require heat treatment, and (3) use of less costly material to obtain the desired surface properties where alloyed steels would be normally applied. Flame hardening is limited to hardenable steels (wrought or cast) and cast iron. Typical hardnesses obtained for the flame-hardened grades depend on the quench

media (Table 17). The practical level of minimum surface hardness attainable with water quenching for various carbon contents is shown in Fig. 14.

Table 17 Response of steels and cast irons to flame hardening

(a) To obtain the hardness results indicated, those areas not directly heated must be kept relatively cool during the heating process.

(b) Thin sections are susceptible to cracking when quenched with oil or water.

(c) Hardness is slightly lower for material heated by spinning or combination progressive-spinning methods than it is for material heated by progressive or stationary methods.

(d) Hardness values of carburized cases containing 0.90 to 1.10% C.

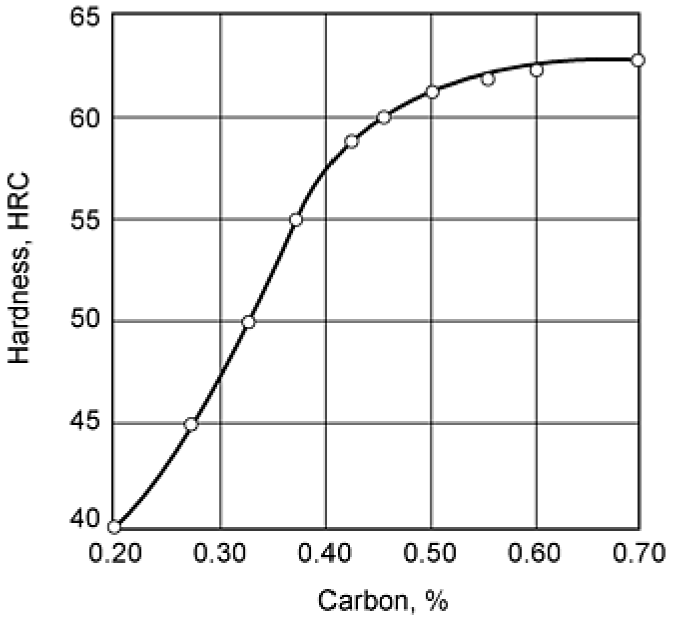

Fig. 14 Relationship of carbon content to minimum surface hardness attainable by flame or induction heating and water quenching. Practical minimum carbon contents can be determined from this curve. Source: Ref 75

Induction hardening is a versatile heating method that involves placing a steel part in the magnetic field generated by high-frequency alternating current passing through an inductor, usually a water-cooled copper coil. The depth of hardening increases as the frequency of the alternating current decreases. Other variables important to the process include the coil current, heating time, and the coil design (Ref 76). The specific ferrous alloys that are commonly used in

induction surface hardening are the same as those used in flame hardening (Table 17). The minimum carbon contents to obtain specific surface hardness are also shown in Fig. 14. Electrical properties of the alloy are an important consideration when selecting induction treatment as a surface-hardening technique. In induction hardening the electrical resistivity and magnetic properties of the alloy can produce significant differences in heating characteristics. Thus, different steels require differing induction-heating parameters. Table 18 compares the flame- and induction-hardening processes.

Table 18 Comparison of flame- and induction-hardening processes

Characteristic	Flame	Induction
Equipment	Oxyfuel torch, special head quench system	Power supply, inductor, quench system
Applicable material	Ferrous alloys, carbon steels, alloy steels, cast irons	Same
Speed of heating	Few seconds to few minutes	1 to 10 s
Depth of hardening	1.2 to 6.2 mm (0.050 to 0.250 in.)	0.4 to 1.5 mm (0.015 to 0.060 in.); 0.1 mm (0.004 in.) for impulse
Processing	One part at a time	Same
Part size	No limit	Must fit in coil
Tempering	Required	Same
Can be automated	Yes	Yes
Operator skills	Significant skill required	Little skill required after setup
Control of process	Attention required	Very precise
Operator comfort	Hot, eye protection required	Can be done in suit
Cost		
Equipment	Low	High
Per piece	Best for large work	Best for small work

Source: Ref 76

Electron- and laser-beam methods use high-energy beams to heat treat the surface of hardenable steel. The EB heat treating process uses a concentrated beam of high-velocity electrons as an energy source to heat selected parts of the steel component. In laser heat treatment a laser beam is used to harden localized areas of ferrous parts. These processes are

similar to flame and induction hardening, except that the need for quenchants is eliminated as long as a sufficient size workpiece is being used.

Electron-Beam Hardening. In electron-beam (EB) hardening, the surface of the hardenable steel is heated rapidly to the austenitizing temperature, usually with a defocused electron beam to prevent melting. The mass of the workpiece conducts the heat away from the treated surface at a rate that is rapid enough to produce hardening. Materials for application of EB hardening must contain sufficient carbon and alloy content to produce martensite. With the rapid heating associated with this process, the carbon and alloy content should be in a form that will quickly allow complete solid solution in the austenite at the temperatures produced by the electron beam. In addition, the mass of the workpiece should be sufficient to allow proper quenching; for example, the part thickness must be at least ten times the depth of hardening, and hardened areas must be properly spaced to prevent tempering of previously hardened areas. The most suitable materials for EB hardening are the same steels used in flame hardening (Ref 76):

- 1045 to 1080 carbon steels
- Medium- to high-carbon alloy steels (4140, 4340, 8645, 52100, and so forth)
- Pearlitic matrix cast irons
- W1, W2, O1, O2, L2, L6, S1, S2 tool steels

There are two basic types of EB systems: stationary or movable. In the movable process, the workpiece is fixed and the gun is moved to produce heating for the hardening. Stationary guns require manipulation of the workpiece under the beam. However, in both cases the area to be hardened on the workpiece must be in a line of sight with the beam. Gun movement or workpiece manipulation is accomplished by computer control to produce any desired pattern, and the beam can be oscillated or pulsed by standard controls. To produce an electron beam, a high vacuum of 10^{-5} torr (10^{-3} Pa) is required in the region where the electrons are emitted and accelerated. This vacuum environment protects the emitter from oxidizing and avoids scattering of the electrons while they are still traveling at a relatively low velocity. Electron-beam hardening in hard vacuum units require that the part be placed in a chamber that is sufficiently large to manipulate the gun or the workpiece. Out-of-vacuum units usually involve shrouding the workpiece; a partial vacuum (10^{-2} torr, or 13 Pa) is obtained in the work area by mechanical pumps.

Laser-Beam Hardening. Lasers can be used to perform selective hardening with hardening depths and material constraints similar to those of EB hardening. Laser heat treatment produces thin surface zones, which are heated and cooled rapidly, resulting in very fine martensitic microstructures, even in steels with relatively low hardenability. This process produces typical case depths for steel ranging from 0.75 to 1.3 mm (0.030 to 0.050 in.) depending on the laser power range, and hardness values as high as 60 HRC (Ref 35). Laser processing has advantages over EB hardening in that laser hardening does not require a vacuum, wider hardening profiles are possible, and there can be greater accessibility to hard-to-get areas with the flexibility of optical manipulation of light energy. A major disadvantage of lasers is the need to use surface treatments to prevent reflectivity of the laser beam.

Diffusion Coating (Carburizing/Nitriding)

Diffusion coatings (Table 19) involve heat treating processes that cause some elemental species to diffuse into the surface of the part to alter the surface properties. These coatings are developed by either heating the component in a gaseous atmosphere of the coating material (carburizing, nitriding, etc.) or by two processes discussed earlier: metalliding and pack cementation. Diffusion processes depend on the concentration gradient of the diffusing species, the diffusivity of the atomic species in the host material, and the time and temperature at which the process takes place.

Table 19 Typical characteristics of carburizing, nitriding, and carbonitriding diffusion treatments

Process	Name of case	Process temperature, °C (°F)	Case hardness, Typical case depth	Hardness, HRC	Typical base metals	Process characteristics
Carburizing						
Pack	Diffused carbon	815-1090 (1500-2000)	125 μm-1.5 mm (5-60 mils)	50-63[a]	Low-carbon steels, low-carbon alloy steels	Low equipment costs, difficult to control case depth accurately
Gas	Diffused carbon	815-980 (1500-1800)	75 μm-1.5 mm (3-60 mils)	50-63[a]	Low-carbon steels, low-carbon alloy steels	Good control of case depth, suitable for continuous operation, good gas controls required, can be dangerous
Liquid	Diffused carbon and possibly nitrogen	815-980 (1500-1800)	50 μm-1.5 mm (2-60 mils)	50-65[a]	Low-carbon steels, low-carbon alloy steels	Faster than pack and gas processes, can pose salt disposal problem, salt baths require frequent maintenance
Vacuum	Diffused carbon	815-1090 (1500-2000)	75 μm-1.5 mm (3-60 mils)	50-63[a]	Low-carbon steels, low-carbon alloy steels	Excellent process control, bright parts, faster than gas carburizing, high equipment costs
Nitriding						
Gas	Diffused nitrogen, nitrogen compounds	480-590 (900-1100)	125 μm-0.75 mm (5-30 mils)	50-70	Alloy steels, nitriding steels, stainless steels	Hardest cases from nitriding steels, quenching not required, low distortion, process is slow, is usually a batch process
Salt	Diffused nitrogen, nitrogen compounds	510-565 (950-1050)	2.5 μm-0.75 mm (0.1-30 mils)	50-70	Most ferrous metals including cast iron	Usually used for thin hard cases <25 μm (<1 mil), no white layer, most are proprietary processes
Ion	Diffused nitrogen, nitrogen compounds	340-565 (650-1050)	75 μm-0.75 mm (3-30 mils)	50-70	Alloy steels, nitriding steels, stainless steels	Faster than gas nitriding, no white layer, high equipment costs, close case control
Carbonitriding						
Gas	Diffused carbon and nitrogen	760-870 (1400-1600)	75 μm-0.75 mm (3-30 mils)	50-65[a]	Low-carbon steels, low-carbon alloy steels, stainless steels	Lower temperature than carburizing (less distortion), slightly harder case than carburizing, gas control critical

Liquid (cyaniding)	Diffused carbon and nitrogen	760-870 (1400-1600)	2.5-125 μm (0.1-5 mils)	50-65[(a)]	Low-carbon steels	Good for thin cases on noncritical parts, batch process, salt disposal problems
Ferritic nitrocarburizing	Diffused carbon and nitrogen	480-590 (900-1090)	2.5-25 μm (0.1-1 mil)	40-60[(a)]	Low-carbon steels	Low-distortion process for thin case on low-carbon steel, most processes are proprietary

Source: Ref 56

(a) Requires quench from austenitizing temperature.

All carburizing and nitriding processes increase the surface carbon or nitrogen content of the alloy to allow the surface to respond to quench hardening. The heat treater usually relies on empirical data to determine how long to expose the part to achieve the desired carbon or nitrogen diffusion. The term used for the entire field of surface-hardening processes is case hardening, and the case indicates the depth of hardening below the surface. Although the depth of hardening decreases gradually because the diffused species does not stop abruptly, the effective case depth is considered to be the depth at which the hardness falls below 50 HRC.

Carburizing is the addition of carbon to the surface of low-carbon steels at temperatures (generally between 850 and 950 °C, or 1560 and 1740 °F) at which austenite, with its high solubility for carbon, is the stable crystal structure (Ref 74). Hardening of the component is accomplished by removing the part and quenching or allowing the part to slowly cool and then reheating to the austenitizing temperature to maintain the very hard surface property. On quenching, a good wear- and fatigue-resistant high-carbon martensitic case is superimposed on a tough, low-carbon steel core. Carburized steels used in case hardening usually have base carbon contents of about 0.2 wt%, with the carbon content of the carburized layer being fixed between 0.8 and 1.0 wt% (Ref 77). Carburizing methods include gas carburizing, vacuum carburizing, plasma carburizing, salt bath carburizing, and pack carburizing. These methods introduce carbon by use of an atmosphere (atmospheric gas, plasma, and vacuum), liquids (salt bath), or solid compounds (pack). The vast majority of carburized parts are processed by gas carburizing, using natural gas, propane, or butane. Vacuum and plasma carburizing are useful because of the absence of oxygen in the furnace atmosphere. Salt bath and pack carburizing have little commercial importance, but are still done occasionally.

Gas carburizing can be run as a batch or a continuous process. Furnace atmospheres consist of a carrier gas and an enriching gas. The carrier gas is supplied at a high flow rate to ensure a positive furnace pressure, minimizing air entry into the furnace. The type of carrier gas affects the rate of carburization. Carburization by methane is slower than by the decomposition of CO. The enriching gas provides the source of carbon and is supplied at a rate necessary to satisfy the carbon demand of the work load. Most gas carburizing is done under conditions of controlled carbon potential by measurement of the CO and CO_2 content. The objective of the control is to maintain a constant carbon potential by matching the loss in carbon to the workpiece with the supply of enriching gas. The carburization process is complex, and a comprehensive model of carburization requires algorithms that describe the various steps in the process, including carbon diffusion, kinetics of the surface reaction, kinetics of the reaction between the endogas and enriching gas, purging (for batch processes), and the atmospheric control system. Possible models of each of these steps have been outlined (Ref 78).

Vacuum carburizing is a nonequilibrium, boost-diffusion-type carburizing process in which austenizing takes place in a rough vacuum, followed by carburization in a partial pressure of hydrocarbon gas, diffusion in a rough vacuum, and then quenching in either oil or gas (Ref 79). Vacuum carburizing offers the advantages of excellent uniformity and reproducibility because of the improved process control with vacuum furnaces, improved mechanical properties due to the lack of intergranular oxidation, and reduced cycle time. The disadvantages of vacuum carburizing are predominantly related to equipment costs and throughput.

Plasma carburizing is basically a vacuum process utilizing glow-discharge technology to introduce carbon-bearing ions to the steel surface for subsequent diffusion (Ref 80). This process is effective in increasing carburization rates because the process bypasses several dissociation steps that produce active soluble carbon. For example, because of the ionizing effect of the plasmas, active carbon for adsorption can be formed directly from methane (CH_4) gas. High

temperatures can be used in plasma carburizing because the process takes place in an oxygen-free vacuum, thus producing a greater carburized case than both atmospheric gas and vacuum carburizing (Fig. 15).

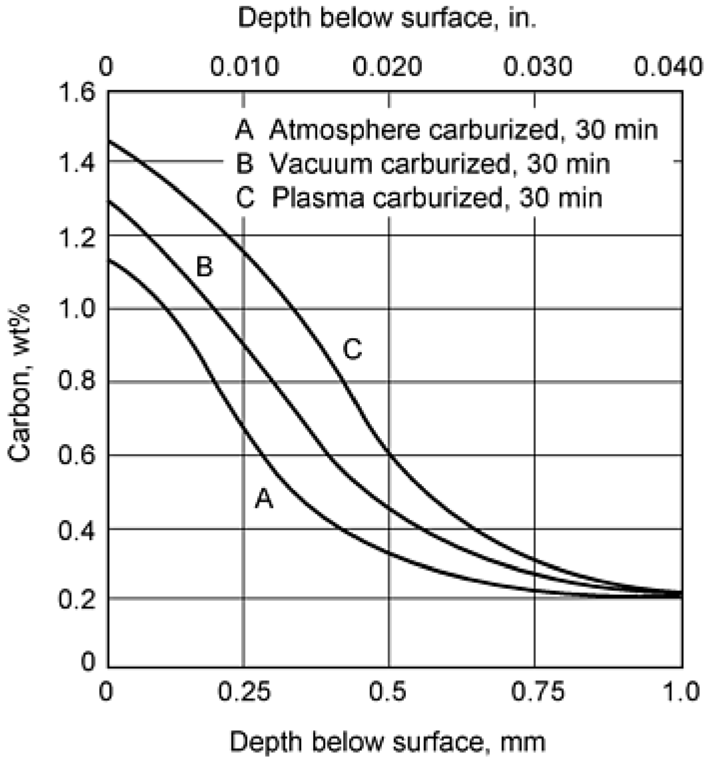

Fig. 15 Carbon gradient profile of atmosphere, vacuum, and plasma carburizing of AISI 8620 steel at 980 °C (1800 °F) saturation conditions for 30 min and followed by direct oil quenching. Source: Ref 81

Nitriding is a process similar to carburizing, in which nitrogen is diffused into the surface of a ferrous product to produce a hard case. Unlike carburizing, nitrogen is introduced between 500 and 550 °C (930 and 1020 °F), which is below the austenite formation temperature (Ac_1) for ferritic steels, and quenching is not required. As a result of not austenitizing and quenching to form martensite, nitriding results in minimum distortion and excellent control. The various nitriding processes (Table 19) include: gas nitriding, liquid nitriding, and plasma (ion) nitriding.

All hardenable steels must be quenched and tempered prior to nitriding. The nitriding process is used to obtain a high surface hardness, improve wear resistance, increase fatigue resistance, and improve corrosion resistance (except for stainless steel). The case structure of a nitrided steel, containing a diffusion zone with or without a compound zone (Fig. 16), depends on the type and concentration of alloying elements and the time-temperature exposure of a particular nitriding treatment (Ref 82). The diffusion zone is the original core microstructure with the addition of nitride precipitates and nitrogen solid solution. The compound zone is the region where γ' (Fe_4N) and ε($Fe_{2-3}N$) intermetallics are formed. Commercial steels containing aluminum, chromium, vanadium, tungsten, and molybdenum are most suitable for nitriding because they readily form nitrides that are stable at the nitriding temperatures (Ref 83). The following steels can be nitrided for specific applications:

- Aluminum-containing low-alloy steels: Nitralloys
- Medium-carbon, chromium-containing low-alloy steels: 4100, 4300, 5100, 6100, 8600, 8700, and 9800 series
- Low-carbon, chromium-containing low-alloy steels: 3300, 8600, and 9300 series
- Hot-working die steels containing 5% Cr: H11, H12, and H13
- Air-hardenable tool steels: A2, A6, D2, D3, and S7
- High-speed tool steels: M2 and M4
- Nitronic stainless steels: 30, 40, 50, and 60
- Ferritic and martensitic stainless steels: 400 and 500 series

- Austenitic stainless steels: 200 and 300 series
- Precipitation-hardened stainless steels: 13-8 PH, 15-5 PH, 17-4 PH, 17-7 PH, A-286, AM 350 (Ref 83), and AM 355

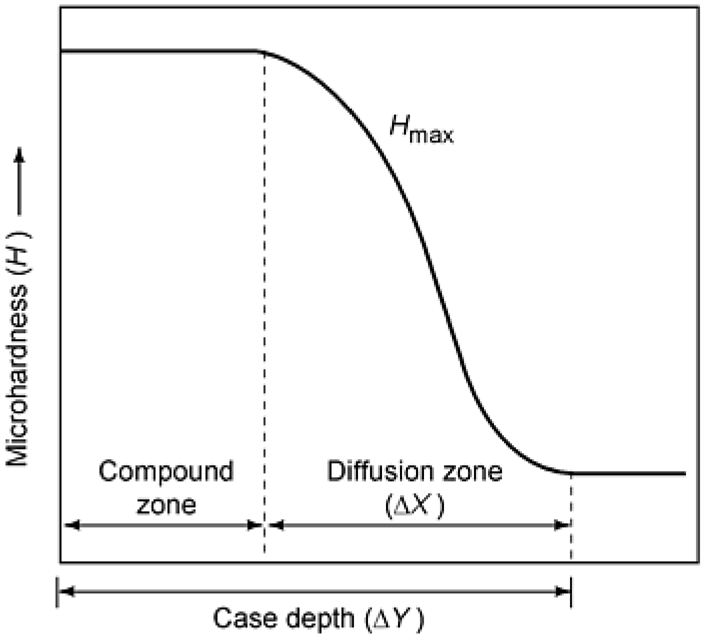

Fig. 16 Factors affecting the microhardness profile of a nitrided steel. The hardness of the compound zone is unaffected by alloy content, while the hardness of the diffusion zone is determined by nitride-forming elements (Al, Cr, Mo, Ti, V, Mn,). ΔX is influenced by the type and concentration of alloying elements; ΔY increases with temperature and decreases with alloy concentration. Source: Ref 82

Gas nitriding (Ref 83) is a case-hardening process that takes place in the presence of ammonia gas. Either a single-stage or a double-stage process can be used when nitriding with anhydrous ammonia. The single-stage process, in which a temperature of 495 to 525 °C (925 to 975 °F) is used, produces the brittle nitrogen-rich compound zone known as the white nitride layer at the surface of the nitrided case. The double-stage process, or Floe process, has the advantage of reducing the white nitrided layer thickness. After the first stage, a second stage is added which either by continuing at the first-stage temperature or increasing the temperature to 550 to 565 °C (1025 to 1050 °F). The use of the higher-temperature second stage lowers the case hardness and increases the case depth.

Liquid nitriding (nitriding in a molten salt bath) uses similar temperatures as in gas nitriding and a case-hardening medium of molten, nitrogen-bearing, fused-salt bath containing either cyanides or cyanates (Ref 84). Similar to salt bath carburizing, liquid nitriding has the advantage of processing finished parts because dimensional stability can be maintained due to the subcritical temperatures used in the process. Furthermore, at the lower nitriding temperatures, liquid nitriding adds more nitrogen and less carbon to ferrous materials than that obtained with high-temperature treatments because ferrite has a much greater solubility for nitrogen (0.4% max) than carbon (0.02% max).

Plasma (ion) nitriding is a method of surface hardening using glow-discharge technology to introduce nascent (elemental) nitrogen to the surface of a metal part for subsequent diffusion into the material (Ref 82). The process is similar to plasma carburizing in that a plasma is formed in a vacuum using high-voltage electrical energy and the nitrogen ions are accelerated toward the workpiece. The ion bombardment heats the part, cleans the surface, and provides active nitrogen. The process provides better control of case chemistry, case uniformity, and lower part distortion than gas nitriding.

Carbonitriding introduces both carbon and nitrogen into the austenite of the steel. The process is similar to carburizing in that the austenite composition is enhanced and the high surface hardness is produced by quenching to form martensite. This process is a modified form of gas carburizing in which ammonia is introduced into the gas carburizing atmosphere (Ref 85). As in gas nitriding, elemental nitrogen forms at the workpiece surface and diffuses along with carbon into the

steel. Typically, carbonitriding takes place at a lower temperature and a shorter time than gas carburizing, producing a shallower case. Steels with carbon contents up to 0.25% are commonly carbonitrided; these include 1000, 1100, 1200, 1300, 1500, 4000, 4100, 4600, 5100, 6100, 8600, and 8700 series.

Ferritic nitrocarburizing is a subcritical heat treatment process, carried out by either gaseous or plasma techniques, and involves the diffusion of carbon and nitrogen into the ferritic phase. The process results in the formation of a thin white layer or compound layer, with an underlying diffusion zone of dissolved nitrogen in iron, or alloy nitrides (Ref 86). The white layer improves surface resistance to wear, and the diffusion zone increases the fatigue endurance limit, especially in carbon and low-alloy steels. Alloy steels, cast irons, and some stainless steels can be treated. The process is used to produce a thin, hard skin, usually less than 25 μm (0.001 in.) thick, on low-carbon steels in the form of sheet metal parts, powder metallurgy parts, small shaft sprockets, and so forth.

Sources of Materials Property Data and Information

Jack H. Westbrook, Brookline Technologies

Introduction

ONLY TWO GENERATIONS AGO the information needs of a materials engineer were rather simply served. In the first place, because there was little intersubstitution among the major classes of materials and because the interdisciplinary field of materials science was not yet born, the engineer was, most likely, a metallurgist with little concern for materials other than metals. For such an individual the one-volume *Metals Handbook* largely filled his needs for data and tutorial reviews.

How different is the world of today! There are now of the order of 100,000 different commercially available materials from which to choose. Increasingly, in many applications, plastics, ceramics, and glasses compete directly with metals; processing techniques once regarded as unique to a certain materials class are being adapted to other quite different classes (e.g., slip casting or vacuum forming of metals); and the development and proliferation of composites further blur the boundaries between the subfields of materials. Thus, the scope of materials for which information is required has been greatly broadened.

In addition, the sheer volume of information has increased exponentially. Not only has there been a general explosion in the primary journal publications, but another exponentially growing collection (more difficult to be aware of and to access) has developed in the report literature. The *ASM Handbook* has now grown to twenty volumes and yet is still challenged to do as complete a job of summarizing current knowledge as did its one-volume predecessor of the 1940s. Furthermore, an increasing proportion of materials data is not in hard-copy print form but in electronic formats, available on floppy disks, tapes, CD-ROMs, or on-line. Finally, new social and environmental concerns and increased world trade have demanded the availability of new types of materials information. Health, safety, and environmental issues require--for the application, storage, and disposal of materials--types of information unheard of a few decades ago. Worldwide sourcing of materials, multinational operations of many companies, and proliferation of the use of the Système International d'Unités (SI) (the "metric system") place new demands on the searcher, compiler, and disseminator of materials information.

It is also important to emphasize that the materials information needs of engineers in industry are more demanding and difficult to satisfy than those of materials scientists. Engineers must not only have accessible the best existing value for the property in question, but they must also know the limits of uncertainty for the value in order to estimate the reliability of a design. Rather than working solely with elemental metals or individual chemical compounds, engineers are frequently confronted with complex alloys, clads, and other composites whose properties and behavior must also be known or reliably estimated. Furthermore, as noted above, many properties of commercial materials are not fixed values, but depend on processing history and resulting structure and effect of external variables. In addition, engineers frequently require data that cannot be expressed in terms of a single property or combination of properties, but must be related to a performance test or service application.

Fewer sources of compiled and evaluated data cater to the needs of industry as compared to scientists, and, under business pressures, engineers in industry have less time available to search for answers to their questions or to reconcile conflicting data from diverse sources. Furthermore, existing materials data compilations, both print and electronic, display a disconcerting variety of terminologies, test methods, property units, and so forth, making integration difficult at best, a situation exacerbated by the great disparity of materials classes to be considered. The available data compilations may be from a publisher, from a materials supplier, or result from an in-house testing program. Endorsement of reliability of the information may be keyed to the individual editor/compiler, a professional association, a trade association, the data generator, or the distribution agency. Examples of each are presented later in this article.

Property data and information are needed at each stage in the sequence: design, manufacture, application and recycling of industrial or consumer goods. The number and diversity of the specific data required are staggering. Not only do each of

these functional needs subsume a variety of specific types of data, but also within each type there may be a multiplicity of individual parameters or information units to characterize the attribute in question. The main features of this taxonomy are shown in Fig. 1. Only selected items have been expanded for illustration; the reader may readily detail others appropriate to individual cases. It must also be remarked that most of the parameters listed at the far right in Fig. 1 are not fixed values determined solely by the composition of the materials selected, but will vary as a function of structure, processing, or the effect of external variables such as temperature, section size, or surface finish. The particular property and materials classes important for application vary among industrial groups as indicated in Table 1, but the materials information needs for each are always quite broad.

Table 1 Materials information needs by industrial groupings

Industry	Material classes									Properties group					
	Ferrous metals	**Nonferrous metals**	**Refractory metals and superalloys**	**Ceramics and glasses**	**Composites**	**Inorganic compounds**	**Plastics**	**Semiconductors**	**Wood**	**Mechanical**	**Thermal**	**Electrical, electronic, and magnetic**	**Other physical**	**Corrosion and oxidation**	**Processibility**
Civil engineering	X	X		X			X		X	X	X			X	X
Transportation	X	X	X		X		X			X	X			X	X
Power generation	X	X	X							X	X	X		X	X
Aerospace	X	X	X	X	X			X		X	X	X	X	X	X
Defense	X	X	X	X	X	X				X	X	X	X	X	X
Chemical	X	X		X		X				X	X			X	
Oil and gas	X		X							X	X			X	
Electronics and communication		X		X				X				X	X		X
Materials producers	X	X	X	X			X		X	X	X	X	X	X	X
Consumer products	X	X		X	X		X	X		X	X	X		X	X

Information Needs

This section examines more closely the information needs at various points in the design, manufacture, and use cycle. These points are laid out schematically in Fig. 2 with notation as to the types of information needed at each stage. Actual practice is even more complex than shown with numerous reiteration loops that refine the design, materials selection, and process selection and provide feedback of application experience that impacts the next generation of product. These matters are discussed in more detail in other articles in this Volume as well as in the work by Waterman and Ashby (Ref 2).

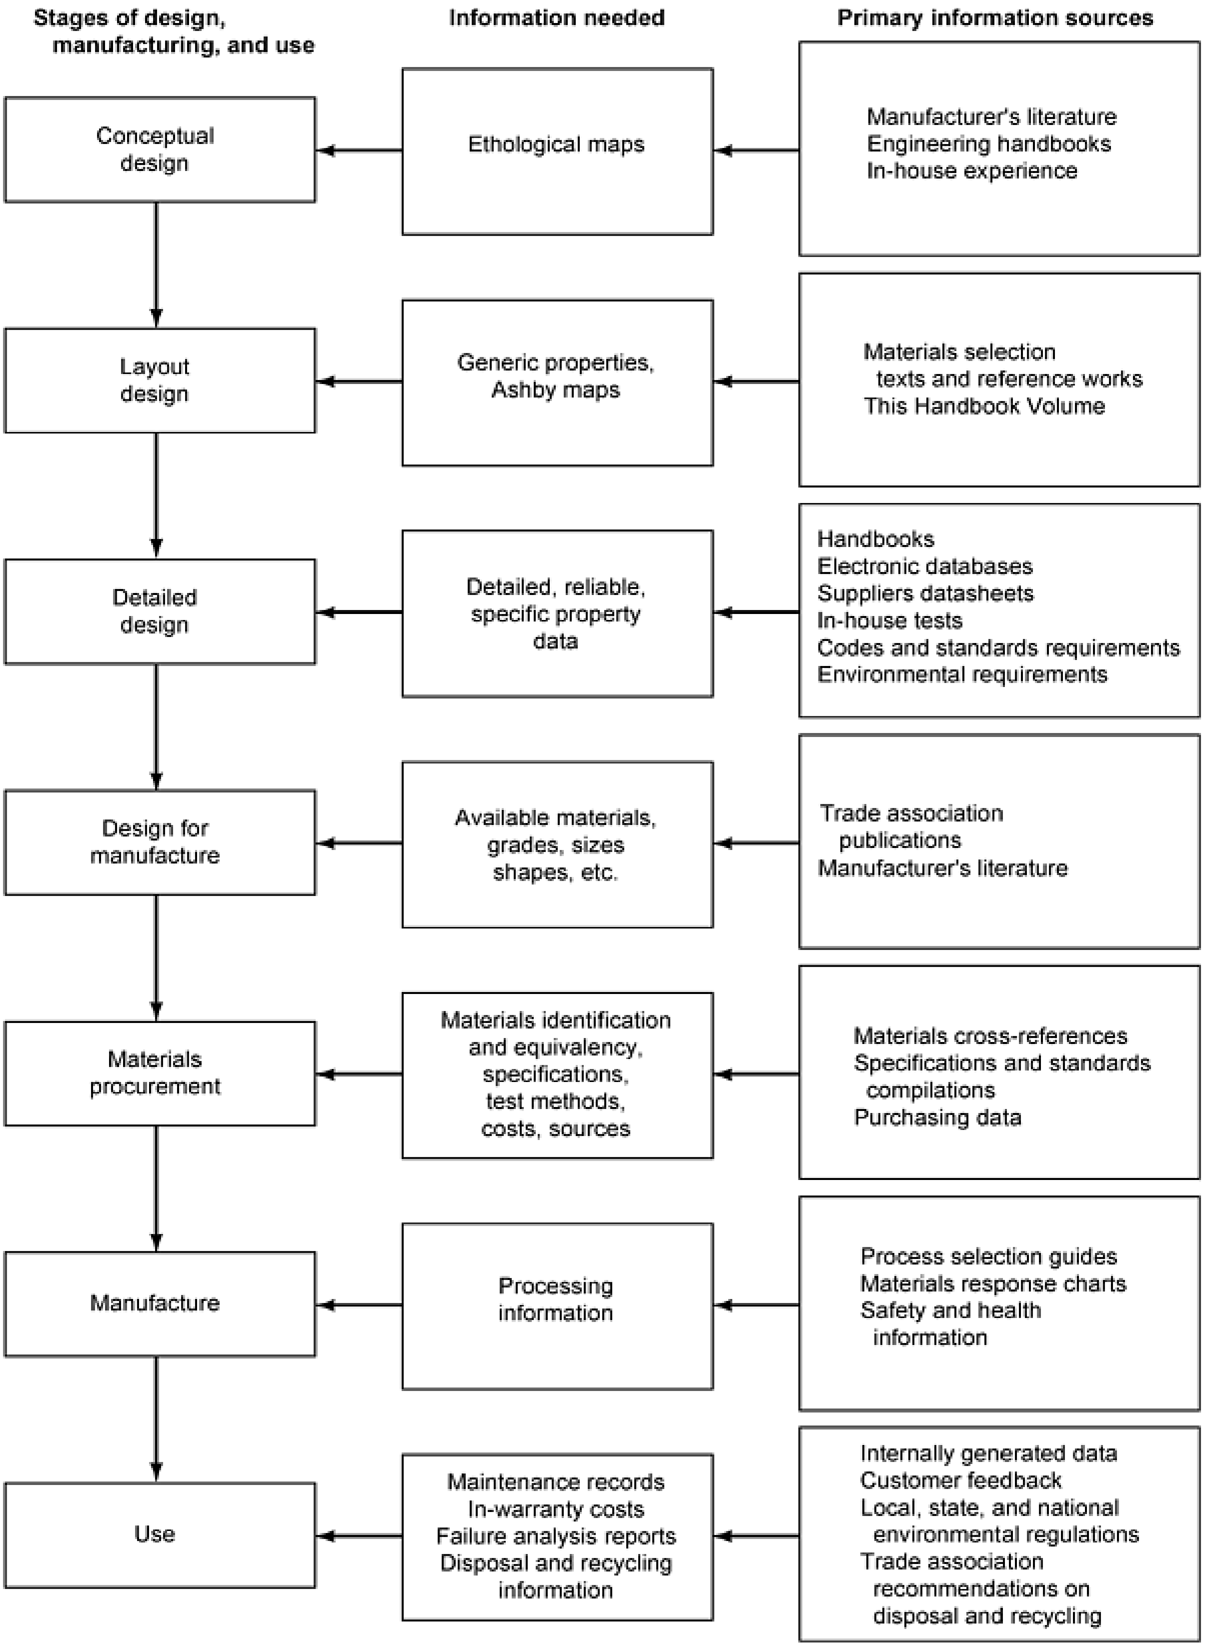

Fig. 2 Information needs and sources at various steps in the design-manufacture-use cycle

A few words follow that more fully characterize the various sources of information and differentiate the quality of that information at different points in the design-manufacture cycle, even when the nominal identification of property needed is the same. Finally, examples are given of specific sources of information needed at each stage. (Detailed source listings are provided in the section "Specific Sources of Data" in this article.)

Requirements definition, the first step in particularizing a conceptual design, is based in part on ethological maps, two- or three-dimensional graphs showing the relationship of important parameters of existing products. Such information is rarely available already compiled, but must be assembled on an ad hoc basis from the generic sources shown. This step focuses attention on which properties are likely to be critical for various components.

Layout design (also called embodiment design) presents a general arrangement of the conceptual design with appropriate dimensions. Ashby maps can be used to facilitate consideration of all possible generic classes of materials at this very early stage in the design process. Ashby maps are available in print form (Ref 2) or electronically via the *Cambridge Materials Selector,* a "Windows"-based PC tool-kit (available from Granta Design, Ltd., Cambridge, United Kingdom); examples of Ashby maps are provided in the article "Material Property Charts" in this Volume. Another approach using formal logic trees has been developed by Allen et al. (Ref 3) at Brigham Young University. At this stage the aim is to view potential materials as widely as possible and with a focus on just a few critical properties. Nominal values of key properties are sufficient, but costs should also be considered.

Detailed design is the stage in which a fully dimensioned preferred layout design is developed. The layout out design includes dimensional tolerances, surface finishes, and determination of the actual specifications of materials to be used. Calculational activities include finite element analysis; failure modes and effects analysis; effects of notches, stress concentrations, and other fracture-mechanics-related factors; effects of mode of loading (fatigue and impact); and effects of environment.

At this point, nominal values of properties no longer suffice. Probabilistic design approaches require still more detailed information. Property values must be as precise as possible with effects of all known variables considered, and their reliability or statistical variability well documented. The contrast between the features of information needs for preliminary materials selection and detailed component design are highlighted in Table 2. A common attribute of materials property information sources, either print or electronic, is that they often are not clearly differentiated and documented as to whether they are intended for preliminary materials selection or for detailed design. It is also often the case that publicly available information does not include effects of the known important variables or the expected statistical spread of the property concerned. In such cases, resort must be made to in-house testing, following accepted standard test methods, and a proprietary handbook built up with the necessary information. Sometimes such programs are sponsored by a consortium of interested parties who cooperatively fund the work, carry out and analyze the tests, and report the data to their membership. Examples of this kind include the work of the Materials Property Council, the U.S. Department of Defense Military Handbook Committees, trade associations (e.g., Aluminum Association, Copper Development Association, American Iron and Steel Institute), and user groups (e.g., the Government-Industry Data Exchange Program). Finally, designers at this stage must also be cognizant of any requirements imposed by codes and standards groups (Ref 4) or by environmental considerations. Representative articles describing the uses of information in materials selection and design are given in Ref 5, 6, 7, and 8, and this topic is discussed in several of the articles in the Sections "The Design Process," "Criteria and Concepts in Design," and "The Materials Selection Process" in this Volume.

Table 2 Contrasting features of databases for materials selection and design

Feature	Selection	Design
Scope	Broad	Narrow
No. of properties	Few	Many
No. of materials	Many	Few
Multifaceted properties, (composition, processing, time, and temperature dependent)	NA	Key requirement
Data quality	Nominal	Precise
Cost of material	Important	NA

Manipulation capability of database	NA	Essential

NA, not applicable

Design for Manufacture. This stage comprises analysis and possibly modification of the detailed design to establish its amenability to low-cost manufacturing and assembly with an acceptably small (or negligible) downgrading of product performance. The first stage in this process requires assessment of commercial availability of the material in the grades, sizes, and shapes determined by prior design work. Such information is usually available in publications of trade associations such as those previously cited.

Materials Procurement. The first step in materials procurement is to learn the most common designation for the material--international, national, trade association, or other--and its equivalence in other designation systems. Various directories and cross-reference guides have been developed to aid in this activity (see Table 3).

Table 3 Directories and cross references to materials standards and specifications

(C) *Alloy Finder CD-ROM*, 2nd ed., ASM International. Incorporates *Woldman's Engineering Alloys*, 8th ed., 1994; *Worldwide Guide to Equivalent Irons and Steels*, 3rd ed., 1993; and *Worldwide Guide to Equivalent Nonferrous Metals and Alloys*, 3rd ed., 1996
(P) *British and Foreign Specifications for Steel Castings*, Steel Casting Research and Trade Association, Sheffield, UK, 1980
(P) *Department of Defense Index of Specifications and Standards*, Part 1, Alphabetical Listing; Part 2, Numerical Listing. U.S. Government Printing Office, Published annually
(C) EQUIST 2.0, Hungarian database with comparisons and equivalencies for 6500 standard steels from 18 countries
(P) European Committee for Iron and Steel Standardization (ECISS), *Index of Standards*, PSP 2, British Steel, plc., Head Office Standards, London, United Kingdom, 1986
(P/C) J.P. Frick, Ed., *Woldman's Engineering Alloys*, 8th ed., ASM International, 1994. Lists compositions, selected properties, and manufacturers for 55,000 alloys. Available in print (1400 pp) and on diskette; data also included in *Alloy Finder CD-ROM* (see separate listing)
(P) *German Standards*, Beuth, Germany. English translation of more than 4750 popular DIN standards plus 1500 DIN-EN, DIN-EC, and DIN-ISO standards
(C) *Global Standards Network*, A directory on the World Wide Web of >100,000 regional, national, and international standards, produced by ANSI and NIST (http://www.nssn.org)
(P)*Handbook of Comparative World Steel Standards*, DS 67, ASTM, 1996, 552 pp
(P) *Handbook of International Alloy Compositions and Designations*, Vol 1R, Titanium, Metals and Ceramics Information Center, Battelle Columbus Laboratories, 1990

(P) *Metals and Alloys in the Unified Numbering System*, 7th ed., DS 56F, ASTM, 1996, 450 pp
(C) *Metals Infodisk*, A CD-ROM database integrating data on tens of thousands of metal grades, over 5000 worldwide standards, a directory of leading suppliers, and limited property information. Also accessible via a Web site. ILI Infodisk, Inc., Paramus, NJ
(P/C) D.L. Potts and J.G. Gensure, *International Metallic Materials Cross-Reference*, 3rd ed., Genium Publishing, 1988. Print (699 pp) and diskette
(P) R.B. Ross, Ed., *Metallic Materials Specifications Handbook*, 4th ed., Chapman and Hall, 1992, 830 pp
(P/C) H. Schmitz, *Stahl-Eisen-Listen/Steel-Iron Lists*, 7th ed., VDEh, Dusseldorf, Germany, 1987. 2500 German and 1000 foreign materials covered; also in a computerized database
(P/C) *Stahlschlüssel (Key to Steel)*, 17th ed., Verlag Stahlschlüssel, 1995. Print (580 pp) and CD-ROM
(C) *Standards Infodisk*, A CD-ROM database covering >300,000 U.S. and foreign standards issued by 42 U.S. and 28 international or European organizations, ILI Infodisk, Inc., Paramus, NJ
(P) *Supplement to Dechema Corrosion Handbook--Concordance of U.S. and German Designations for Metallic Materials*, VCH, Weiheim, Germany, 1992, 254 pp
(P) *Technical Data*, Technical Indexes, Ltd., Bracknall, UK, updated monthly. >100 indexed microfilm or microfiche files covering 10^7 pp of technical information, 1000 pp printed index
(P) F.T. Traceski, *Specifications and Standards for Plastics and Composites*, ASM International, 1990, 224 pp
(C) *UNSearch*, a computerized form of the book *Metals and Alloys in the Unified Numbering System*, ASTM/SAE
(P) M.J. Wahl, *Handbook of Superalloys*, International Alloy Compositions and Designations Series, Springer Verlag, 1982, 258 pp
(P) W.A. Woishnis, Ed., *Engineering Plastics and Composites*, 2nd ed., ASM International, 1993, 590 pp. Identifies tradenames and manufacturer designations for polymeric materials
(D) World Metal Index, Sheffield City Libraries, Sheffield, United Kingdom. A service covering 70,000 standard grades of metallic materials worldwide
(P/C) *Worldwide Guide to Equivalent Irons and Steels*, 3rd ed., ASM International, 1992. Available in print (600 pp) and on diskette; data also included in *Alloy Finder CD-ROM* (see separate listing)
(P/C) *Worldwide Guide to Equivalent Nonferrous Metals and Alloys*, 3rd ed., W. Mack, Ed., ASM International, 1995. Available in print (500 pp) and on diskette; data also included in *Alloy Finder CD-ROM* (see separate listing)

C, computer readable; D, data center; P, print

Next, it must be determined what specifications shall be invoked to ensure that the materials acquired will behave as expected. A specification has been defined as "a document intended primarily for use in procurement that clearly and accurately describes the essential technical requirements for items, materials, or services, including the procedures by which it will be determined that the requirements have been met" (Ref 4). The principal content elements of a materials specification are: title, statement of scope, requirements, quality-assurance provisions, applicable reference documents, preparations for delivery, notes, and definitions.

The most effective specification is that which accomplishes the desired result with the fewest requirements. In writing a new specification, properties and performance should be emphasized rather than how the objectives are to be achieved. Effort should be made by a company to avoid "specials" and to try whenever possible to adopt a standard or specification already established by an organization at a higher hierarchical level, that is, a trade association, or national or international standard. Sources of standards and specifications have been compiled in directories (see Table 3) and are discussed in Ref 9 (see also the article "Designing to Codes and Standards" in this Volume). Whenever necessary to be included in a specification, the test method or quantitative inspection technique cited should be one recognized nationally, for example, an ASTM standard. Finally, for actual procurement of the material it is necessary to have information on sources (vendors) and costs. Again, a variety of directories and periodicals are available.

Manufacture. Information is also needed during manufacture itself for several purposes: selection of the most economic process (may impact back on the component design), to understand the response of the material to processing variables, and to observe best practices with respect to safety and health in the workplace.

Use. When the component made from the material selected is placed in service, it now generates over its lifetime information that may be profitably used, either in redesign of the component or in the next generation of a product to serve the same function. This category includes both internally generated data and that resulting from customer feedback.

Locating Sources of Data

A persistent problem for seekers of materials information, whether printed or electronic, is the lack of adequate guides and directories. The inadequacies of existing directories arise from poor currency, narrowness of focus (by country, by materials class, by properties class, by format, etc.), inadequate descriptions of database or print sources, and poor characterization of the reliability of the information contained. References 1 and 10 are overviews of materials information sources. The first covers guides to technical information sources: encyclopedias; dictionaries, thesauri, and glossaries; numeric, graphical, and pictorial data sources; auxiliary information sources; the primary literature; reviews; and special topics. The second treats data and information sources relevant to materials economics, policy, and management. A comprehensive materials information directory that is most relevant in the present context has been compiled by Wawrousek et al. (Ref 11); it is an indexed catalog of some 1250 different sources of data on the mechanical and physical properties of engineering materials. Each identified source was categorized by type (computer-readable, data center, printed handbook, etc.) and located in one or several of the approximately 1100 cells of a materials-property matrix. The resource is described in more detail in an ASTM publication (Ref 12). Unfortunately, this directory is almost 10 years old at the time of this writing and is not accessible for on-line computer searching.

Other useful guides to materials information sources are the series of critical surveys of data sources in a variety of fields (Ref 13, 14, 15, 16), sponsored by the National Bureau of Standards (now the National Institute of Standards and Technology). For each selected data source covered, the editors defined the publisher or custodian; the scope (the materials/properties covered); the sources of the data; the size of the data bank; the means of data storage and search; the selectivity, timeliness, and availability of the data; the cost of access; and general comments. These surveys are more than 20 years old at the time of this writing and do not extend to all materials and properties of current interest. Other guides and directories are listed in Table 4.

Suppliers of Databases (Hosts). The organizations listed below each supply numerous databases (bibliographic as well as numeric or factual) relevant to materials. A given database may be available from several suppliers:

- DIALOG and DataStar, Knight-Ridder Information, Inc., 2440 W. El Camino Real, Mountain View, CA 94040. Tel: (800) 334-2564
- Questel-Orbit, Inc., France Telecom Group, 8000 Westpark Drive, Suite 130, McLean, VA 22102. Tel: (800) 456-7248
- STN International--The Scientific and Technical Information Network, operated cooperatively by Fachinformationszentrum (FIZ) Karlsruhe, Chemical Abstracts Service (CAS), and The Japan Science and Technology Corporation Information Center for Science and Technology (JICST), c/o Chemical

Abstracts Service, 2540 Olentangy River Road, Columbus, OH 43210. Tel: (614) 447-3600

For more information about database suppliers, see the sources by Allan and Ferrell and by Schmittroth and Maxfield listed in Table 4.

The Internet is rapidly developing as a source of information on a vast array of topics. Unfortunately as of this writing, there is relatively little information available of materials interest. References 17 and 18 are two general guides to science and technology on the Internet. References 19 and 20 are introductions to the Internet for materials scientists and engineers. E-mail, PC software, and mathematical routines are typical examples of available general-interest applications on the Internet. Newsgroups such as "sci.engr.metallurgy" and "sci.materials" can provide free information (from the personal knowledge of individuals) on the existence of databases covering particular materials topics. Because such a vast quantity of information is available on the Internet, considerable time or specialized browsing software is needed to deal with it. Unfortunately, there is no index via browser programs such as Gopher or World Wide Web (WWW) for materials-related archives at the time of this writing. Many materials databases are accessible through the Internet, for example, those on STN International (Ref 21), which has an Internet link. King et al. (Ref 22) have developed an inventory of materials databases to promote knowledge of available (not necessarily via the Internet) materials and chemical property databases. Links to materials-related Web sites are provided in many places on the WWW (for example, at sites sponsored by professional societies, government agencies, and college/university materials science departments).

Sources of Materials Property Data and Information

Jack H. Westbrook, Brookline Technologies

Specific Sources of Data

In addition to the materials information sources already cited directly, many others are listed in Tables 5, 6, 7, 8, and 9 to give the reader some indication of what is available, but without implication that those listed are the most current, most authoritative, or most important. Thus, the listings in these tables are *representative,* not exhaustive. Many more can be found by perusal of Ref 11. In selecting sources for inclusion, emphasis was placed on sources containing substantial amounts of quantitative information on engineering properties of materials, rather that those of a descriptive or tutorial character in their coverage of particular materials classes, properties, phenomena, or application areas. In contrast, sources of data on crystallography, thermodynamics, and analytical information receive scant attention. Three different types of source are coded as C, computer readable; D, data center; and P, print:

- *Computer readable* comprises all electronic formats: floppy disk, tape, CD-ROM, and on-line. (The state-of-the-art with respect to electronic access to materials information as of 1995 is reviewed in Ref 23.)
- *Data centers* are organizations that maintain both print and electronic files of data in one or more fields. Their staffs often are not only information specialists, but also individuals with expertise in the subject field of their collections and who usually have experience in the evaluation of the data in the collection. Both direct and indirect access to the files is usually possible as well as consultative assistance.
- *Print* includes handbooks, review articles, data sheets, and reports. The information provided may be numeric tables, graphs, images, or other pictorial formats.

Table 5 Sources of materials data

General
(D) Advanced Materials and Processes Technical Information and Analysis Center (AMPTIAC), operated by the Illinois Institute of Technology Research Institute (IITRI), 201 Mill St., Rome NY 13440. Tel: (315) 339-7117. Incorporates the Metals and Ceramics Information Center (MCIC), the High-Temperature Materials Information Analysis Center (HTMIAC), the Ceramics Information Analysis Center (CIAC), and the Metal-Matrix Information Analysis Center (MMIAC). These encompass the following subjects: ceramics and ceramic composites; organic structural materials and matrix composites; monolithic metals, alloys and metal-matrix composites; electronic, optical and photonic materials; and environmental protection and special function materials
(C) AEA Metals Databases (*Ni-DATA, Ti-DATA, Al-DATA, and Fe-DATA*), AEA Technology, Engineering Software Inc., Bethel Park, PA. Databases designed to work with thermochemical modeling software *MTDATA* or *Thermo-calc* for predicting phase behavior and properties
(P) *Aerospace Structural Metals Handbook,* 5 vol with quarterly updates, Mechanical Properties Data Center, Battelle Columbus Laboratories, over 4000 pp. Referenced alloy data of special interest to the aerospace designer. The data, currently covering 200 alloys, are carefully characterized as to source, product form, size, and pertinent details of thermal-mechanical processing and testing history
(P/C) *Alloy Digest,* (1952-present) ASM International. Approximately 3500 data sheets on commercially available metals and alloys; eight new data sheets appear each month. Now also available on CD-ROM
(D) American Bureau of Metal Statistics (ABMS), 400 Plaza Drive, Harmon Meadow, P.O. Box 1405, Secaucus, NJ 07094-0405. Tel: (201) 863-6900
(P/C) *Annual Book of ASTM Standards,* ASTM, West Conshohocken, PA. Approximately 60 vol per year. A comprehensive compilation of standards, tests, and specifications. Each volume published separately throughout the year, covering a specific topic. Available in electronic formats
(D) ASM International, Materials Park, OH 44073. Tel: (440) 338-5151
(P) M. Bauccio, Ed., *ASM Engineered Materials Reference Book,* 2nd ed., 1994, 580 pp. A compilation of data for ceramics, polymers, and composites
(P) M. Bauccio, Ed., *ASM Metals Reference Book,* 3rd ed., ASM International, 1993, 614 pp. A compilation of tabular properties and processing data for ferrous and nonferrous metals
(P) C.F. Beaton and G.F. Hewitt, *Physical Property Data for the Design Engineer,* Hemisphere, 1988
(P) M.B. Bever, Ed., *Encyclopedia of Materials Science and Engineering,* MIT Press, 1986, 8 volumes
(C) *Binary Alloy Phase Diagrams CD-ROM,* ASM International. Collection of 4700 binary metallic phase diagrams derived from the classic 3-vol handbook edited by T. Massalski
(P) A. Blake, Ed., *Handbook of Mechanics, Materials, and Structures,* Wiley, 1985, 736 pp
(P) D. Bloor et al., Ed., *Encyclopedia of Advanced Materials,* Pergamon, 1994, 4 vol
(P) G.S. Brady, H.R. Clauser, and J.A. Vaccari, Ed., *Materials Handbook,* 14th ed., McGraw-Hill, 1996, 1072 pp. Has 800 A-to-Z entries providing descriptions and data for more than 13,000 materials and tradenames

(C) *Cambridge Materials Selector, V2.0 for Windows*, Granta Design Limited, Cambridge, UK. Implements the Ashby materials selection scheme for personal computers

(C) *CenBASE/Materials on CD-ROM*, CenTOR Software Corp., Garden Grove, CA. Detailed information on over 30,000 grades of thermoplastics, thermosets, elastomers, rubbers, adhesives, composites, fibers, ceramics, and metals. Also available via the World Wide Web

(D) Center for Information and Numerical Data Analysis and Synthesis (CINDAS), Purdue University, 2595 Yeager Rd., West Lafayette, IN 47906. Tel: (765) 494-9393. Thermal, electrical, mechanical, physical, and chemical properties of more than 3000 materials, including ferrous and nonferrous metals, organic and inorganic materials, glasses, ceramics, polymers, and composites

(C) *CETIM-Materiaux* (common properties of engineering materials used in materials selection), Centre Technique des Industries Mechaniques (CETIM). CETIM, 74 route de la Jonoliere, B.P. 957, 44076 Nantes Cedex, France

(P) N.P. Cheremisinoff, *Materials Selection Deskbook*, Noyes, 1997, 207 pp

(C) *DASMAT* (Data Sheet system of Materials), Ishikawajima Haruna Heavy Industries Co. Ltd., 3-1-15 Toyosu, Koto-ku, Tokyo 135, Japan

(P) *Engineered Materials Handbook Desk Edition*, ASM International, 1995, 1300 pp. Considers polymers, composites, ceramics, and glasses

(D) Engineering Sciences Data Unit (ESDU), 27 Corsham St., London N1 5UA, United Kingdom. Tel: 44 171 490-5151. Critically evaluated engineering design data on physical properties, heat transfer, stress and strength, fluid mechanics, fatigue, structures, and aerodynamics; also publishes for Ministry of Defense a handbook of data on aerospace materials

(P) D.J. Fisher, *Rules of Thumb for the Physical Scientist*, Trans Tech, Soloturn, Switzerland, 1988, 320 pp. Collects many simple, empirical correlations observed between diverse properties; helpful in estimating unknown properties and in forecasting likely properties of unknown systems

(P) *Handbook of Industrial Materials*, 2nd ed., Elsevier, 1992, 803 pp. Covers ferrous metals, nonferrous metals and alloys, nonmetallic materials, thermoplastics, thermoset plastics (processed), plastis, materials for electrical applications, joining materials

(D) Information Center on Advanced Materials. Institute of Materials Science (ICAM-RIMSE) Tsinghua University (TH Univ), Main Building of Tsinghua University, Beijing, China 10084. Tel: 2824541, ext. 2758

(D) Information System on Measurement of Mechanical Quantities, Bundesanstalt für Materialforschung und Prüfung (BAM), Berlin, Unter den Eichen 87, D-12200 Berlin 45, 3615, Germany. Tel: 49 30 8104 3615

(P) *Key Engineering Materials*, Mechanical Properties Research, Trans Tech, 1990

(P) C.T. Lynch, Ed., *Practical Handbook of Materials Science*, CRC Press, 1989, 636 pp. Selected reference data for the physical properties of solid-state and structural materials in tabular form

(C) *MAPP*, ESM Software, Hamilton, OH. Materials databases from ASM International Mat.DB collection, in personal computer format, of properties and processing for metals and some polymers

(C) *MATADOR* (nonferrous and ferrous metals, numerical data for physical and mechanical properties) . Motoren und Turbinen Union München GmbH, Postfach 50 06 40. Tel: 49 89 1489 3323

(D) Materials Research Society (MRS), 506 Keystone Dr., Warrendale, PA 15086. Tel: (412) 779-3003

(D) The Materials Properties Council, Inc. (MPC), 345 East 47th St., New York, NY 10017. Tel: (212) 705-7693

(P) *Materials Selector*, Penton Publishing Co., a special issue of *Machine Design* magazine giving tabular data for a broad range of metals, ceramics, plastics, and composites

(P) *Metals Handbook Desk Edition*, American Society for Metals, 1985, 1376 pp. Considers all metallic alloys and processing methods

(C) *Metals Infodisk*, A CD-ROM database integrating data on tens of thousands of metal grades, over 5000 worldwide standards, a directory of leading suppliers, and limited property information. Also accessible via a Web site. ILI Infodisk, Inc., Paramus, NJ

(D) The Minerals, Metals & Materials Society (TMS), 420 Commonwealth Dr., Warrendale, PA 15086. Tel: (412) 776-9000

(C) *MSC/MVISION*, MacNeal-Schwendler Corp., Los Angeles. A materials database that is integrated with the Pro/ENGINEER analysis system

(P) C.E. Nunez, R.A. Nunez, and A.C. Mann, *CenBASE Materials in Print, 1990*, 4 vol, J. Wiley, 1990, 4492 pp

(C) *PERITUS*, Matsel Systems Ltd., Liverpool. A database for metals, polymers, and ceramics aimed at materials and process selection

(P) D.D. Pollock, *Physical Properties of Materials for Engineers*, Vol 1, 1981, 224 pp; Vol 2, 1982, 312 pp; CRC Press

(D) Research into Artifacts, Center for Engineering, University of Tokyo. 2-11-16 Yayoi, Bunkyo-ku, Tokyo 113, Japan. Tel: 81-3-3812-2111. Generic data on all engineering materials, nuclear fuel data, fusion reactor materials data, industrial standards for metals and alloys, high-temperature superconducting materials

(P) C. Robb, *Metals Databook*, Institute of Metals, London, 1990. Chemical, physical, and mechanical properties of commercially available metallic materials

(P) R.B. Ross, Ed., *Handbook of Metal Treatments and Testing*, 2nd ed., Wiley, 1988,

(C) *Rover Electronic DataBooks*, William Andrew Inc., Norwich, NY. Materials databases including ASM International Mat.DB data collection, in personal computer format, of properties and processing for metals and polymers

(P) J.F. Shackleford, W. Alexander, and J.S. Park, Ed., *CRC Materials Science and Engineering Handbook*, 2nd ed., CRC Press, 1994, 1532 pp

(P) C.J. Smithells, Ed., *Smithells Metals Reference Book*, 7th ed., Butterworth, 1991

(C) STN International, Chemical Abstracts Services, Columbus, OH. On-line service for metals, ceramics, and polymers databases developed by the Materials Property Data (MPD) Network

(P) *Structural Alloys Handbook*, 3 vol with annual updates, CINDAS/Purdue University. Vol 1, *Wrought Iron and Cast Iron;* Vol 2, *Wrought Stainless Steel, Cast Steel, and Cast Stainless Steel;* Vol 3, *Structural Steel, Wrought and Cast Aluminum, Copper, Brass, Bronze, Magnesium, and Titanium*

(C) Supplier's Data on a Full Spectrum of Materials: Plastics, Metals, Ceramics and Other Non-metallics (MATUS). Engineering Information Company, Ltd., 30 Hampton House, 15/17 Ingate Place, London SW8 3NS, United Kingdom. Tel: 44 71-662-8155

(D) TNO Metal Institute. Netherlands Organization for Applied Scientific Research, Laan Van Westenenk 501, Postbus 541, 7300 AM Apeldorn, Netherlands. Tel: (055) 73344

(P/C) P. Villars, A. Prince, and H. Okamoto, Ed., *Handbook of Ternary Alloy Phase Diagrams*, ASM International. >15,000 diagrams from 7380 systems. 10-vol set in print, or full set CD-ROM, or 7 subsets in CD-ROM (industrial/heat resistant alloys; solders, brazes, and copper alloys; light metal structural alloys; electronic materials/semiconductors; precious metals; rare earth/actinides; carbides/nitrides)

(P) N.A. Waterman and M.F. Ashby, Ed., *The Materials Selector*, 2nd ed., Chapman and Hall, 1997. A three-volume compilation of data on all materials, with selection and design guide

(D) World Bureau of Metal Statistics, 27a High St., Ware, Herts SG12 9BA, United Kingdom. Tel: 44 0920 461 274

(D) World Metal Index, Sheffield Library and Information Service, Central Library, Surrey St., Sheffield, S. Yorkshire S1 1XZ, United Kingdom. Tel: 44 114 273 4744 and 44 114 273 4714. A service with coverage of over 70,000 grades of ferrous and nonferrous materials, including all British Standards and most United States, European, and National Standards. Also features a large collection of metallurgical and engineering journals and literature

Ferrous metals

(D) American Iron and Steel Institute (AISI), 1101 17th St., N.W., Suite 1300, Washington, DC 20036-4700. Tel: (202) 452-7100

(P) H.T. Angus, *Cast Iron: Physical and Engineering Properties,* 2nd ed., Butterworths, 1976, 542 pp

(D) British Cast Iron Research Association (BCIRA), Alvechurch, Birmingham, Warwickshire B48 7QB, United Kingdom. Tel: 44 527 66414. Databases on ductile and malleable iron and on gray cast iron

(P) J.R. Davis, Ed., *ASM Specialty Handbook: Carbon and Alloy Steels,* ASM International, 1996, 731 pp

(P) J.R. Davis, Ed., *ASM Specialty Handbook: Cast Irons,* ASM International, 1996, 450 pp

(P) J.R. Davis, Ed., *ASM Specialty Handbook: Stainless Steels,* ASM International, 1994, 577 pp

(P) J.R. Davis, Ed., *ASM Specialty Handbook: Tool Materials,* ASM International, 1995, 501 pp

(P) P. Harvey, Ed., *Engineering Properties of Steel,* American Society for Metals, 1982, 527 pp

(D) International Iron & Steel Institute, Rue Colonel Bourg 120, B-1140 Brussels, Belgium. Tel: 32-2-735-90-75

(D) Iron & Steel Society (ISS), 410 Commonwealth Dr., Warrendale, PA 15086. Tel: (412) 776-1535

(C) Material Strength Database for Engineering Steels and Alloys (ENSTAL), National Research Institute for Metals--Japan Information Center for Science and Technology, Tsukuba, Japan

(P/C) *The Metals Black Book,* Vol 1, *Ferrous Metals,* 2nd ed., J.E. Bringas, Casti Publishing, Edmonton, Alberta, Canada, 1996, 740 pp

(C) Minitech Computerized Alloy Steel Information System (CASIS). Hardenability and related properties including as-rolled, quenched and tempered, and carburized properties. Minitech Ltd., Box 5185, Station E, Hamilton, Ontario, Canada L8S 4L3.Tel: (416) 523-7721

(P) F.B. Pickering, Ed.,*Constitution and Properties of Steels,* Vol 7, *Materials Science and Technology--A Comprehensive Treatment,* R.W. Cahn, P. Haasen, and E.J. Kramer, Ed., VCH Publishers, 1991, 824 pp

(P) *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Vol 1, *ASM Handbook* (formerly *Metals Handbook,* 10th ed.), ASM International, 1990, 1063 pp

(C) Properties of Iron Castings, Institüt für Leichtbau, Dresden, Germany. Database containing physicochemical properties, data on processing and reprocessing of materials, information on the form and production technology of 200 types of iron casting materials selected by application with reference to their properties, testing conditions, and treatment

(C) Properties of Steel, Institüt für Leichtbau, Dresden, Germany. Database containing physicochemical properties, information on processing and reprocessing, on the form and production technology of 300 types of German steels together with their specific application areas and test conditions

(P) R. Serjantson, *Ferro-Alloy Directory and Databook,* 3rd ed., Metal Bulletin, 1992

(P) Y.S. Touloukian and C.Y. Ho, Ed., *Properties of Selected Ferrous Alloying Elements,* Hemisphere, 1989, 269 pp

(P) C.W. Wegst, Ed., *Stahlschlüssel (Key to Steel),* 17th ed., Verlag Stahlschlüssel GmbH, Germany, 1995

(C) Werkstoffdatenbank (WDB), Kraftwerk Union AG-Erlangen (KWU), Werkstoffabteilung, Postfach 32 20, Hammerbacherstr. 12 + 14, 8520, Erlangen, Germany. Tel: 49 9131 18 5785. Data on the technical and mechanical properties of steels and iron alloys

Nonferrous metals

(D) Aluminum Association, Inc., 900 19th St., NW, Suite 300, Washington DC 20006. Tel: (202) 862-5100

(P) *Aluminum: Properties and Physical Metallurgy,* J.E. Hatch, Ed., American Society for Metals, 1984, 424 pp

(P) J.R. Davis, Ed., *ASM Specialty Handbook: Aluminum and Aluminum Alloys,* ASM International, 1993, 784 pp

(P) B.T. Barry and C.G. Thwaites, *Tin and Its Alloys and Compounds,* John Wiley & Sons, 1983, 268 pp

(P) W. Betteridge, *Nickel and Its Alloys,* John Wiley & Sons, 1984, 211 pp

(P) R. Boyer, E.W. Collings, and G. Welsch, Ed., *Materials Properties Handbook: Titanium Alloys,* ASM International, 1994, 1169 pp

(P) J.E. Bringas, Ed., Vol 2, *The Metals Red Book, Non-ferrous Metals,* Casti Publishing, Edmonton, Alberta, Canada, 1993, 600 pp

(D/C) Copper Development Association Inc., 260 Madison Ave., New York, NY 10016. Tel: (212) 251-7200. Technical data and information on the selection, fabrication, and use of copper and its alloys. Operates the Copper Data Center (an on-line bibliographic database of the world literature on copper and copper technology) in cooperation with the International Copper Association

(P) W. Hofmann, *Lead and Lead Alloys--Properties and Technology,* Springer-Verlag, 1970, 551 pp

(D) International Copper Association Ltd., 260 Madison Ave., New York, NY 10016. Tel: (212) 251-7240

(D) International Lead Zinc Research Organization (ILZRO), 2525 Meridian Parkway, P.O. Box 12036, Research Triangle Park, NC 27709. Tel: (919) 361-4647

(D) International Magnesium Association (IMA), 1303 Vincent Place, Suite 1, McLean, VA 22101. Tel: (703) 442-8888

(D) International Precious Metals Institute (IPMI), 4905 Tilgman St., Suite 160, Allentown, PA 18104. Tel: (610) 395-9700

(D) International Titanium Association (ITA), 1871 Folsom St., Suite 100, Boulder, CO 30302. Tel: (303) 443-7515. Formerly the Titanium Development Association (TDA)

(D) Lead Development Association, 42 Weymouth St., London W1N 3LQ, United Kingdom. Tel: 071 499-8422

(D) Lead Industries Association, Inc., 295 Madison Ave., New York, NY 10017. Tel: (212) 578-4750

(P) K.H. Matucha, *Structure and Properties of Non-Ferrous Alloys,* Vol 8, *Materials Science and Technology--A Comprehensive Treatment,* R.W. Cahn, P. Haasen, and E. Kramer, Ed., VCH Publishers, 1995

(D) Nickel Development Institute (NiDI), 214 King St. W., No. 510, Toronto, Ontario M5H 3S6, Canada. Tel: (416) 591-7999

(P) F. Porter, *Zinc Handbook--Properties, Processing and Use in Design,* Marcel Dekker, 1991, 648 pp

(P) *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials,* Vol 2, *ASM Handbook* (formerly *Metals Handbook,* 10th ed.), ASM International, 1991, 1328 pp

(P) *The Properties of Aluminium and its Alloys,* 8th (revised) ed., Aluminium Federation, ALFED, Birmingham, United Kingdom, 1983, 88 pp

(D) Refractory Metals Association, 105 College Rd., East, Princeton, NJ 08540. Tel: (609) 452-7700

(P) E.M. Savitskii, Ed. (A. Prince, Ed., English ed.), *Handbook of Precious Metals,* Taylor and Francis, 1990, 600 pp

(P) E.A. Starke, Jr. and T.H. Sanders, Jr., Ed., *Aluminum Alloys: Their Physical and Mechanical Properties,* Engineering Materials Advisory Services Ltd., West Midlands, United Kingdom, 1986, 1700 pp

(P) *Engineering Plastics,* Vol 2, *Engineered Materials Handbook,* ASM International, 1988, 883 pp

(C) *ENGINPLAST* (guide to the selection of engineering plastics). ENGINPLAST, 148 rue d'Aulnay, 92290 Chatenay Malabry, France. Tel: (33) 46 60 17 55

(P) C.A. Harper, Ed., *Handbook of Plastics, Elastomers, and Composites,* 3rd ed., McGraw-Hill, 1996, 848 pp

(P/C) *International Plastics Selector, Plastics,* 9th ed., International Plastics Selector, San Diego, CA, 1987. Also two computer databases: *PLASTICS* (thermoplastics and thermosets) and *SELECTOR* (adhesives, sealants, composites, and laminates)

(C) *IPS Plastics and Adhesives,* International Plastics Selector, 15 Iverness Way East, Englewood, CO 80112. Tel: (303) 397-2472. Plastics properties for >15,500 thermoplastics and thermosets from >230 manufacturers. Adhesives properties for >7800 adhesives, sealants, and primers from >230 manufacturers

(P) J.I. Kroschwitz, Ed., *Concise Encyclopedia of Polymer Science and Engineering,* Wiley, 1990, 1341 pp

(P/C) J.E. Kroschwitz, Ed., *Encyclopedia of Polymer Science and Engineering,* 2nd ed., Wiley, 1985-1990, 23 vol. Coverage includes natural and synthetic polymers, plastics, fibers, elastomers, computer topics, and processing. Also available on CD-ROM and on-line

(P) S. Levy and J.H. Dubois, *Plastic Product Design Engineering Handbook,* 2nd ed., Chapman and Hall, 1985, 376 pp

(P) J.M. Margolis, Ed., *Conductive Polymers and Plastics Handbook,* Chapman and Hall, 1989, 208 pp

(P) E. Miller, Ed., *Plastic Product Design Handbook,* part B, Marcel Dekker, 1983, 392 pp

(P) P. Mitchell, Ed., *Plastic Part Manufacturing,* Vol 8, *Tool and Manufacturing Engineers Handbook,* Society of Manufacturing Engineers, 1996

(P) *Modern Plastics Encyclopedia,* McGraw-Hill, Annual. A special issue each year of the magazine *Modern Plastics.* Both an encyclopedia and a directory of information about plastics. Covers resins and compounds, chemicals and additives, reinforced plastics and compounds, primary processing, auxiliary equipment and components, and fabricating and finishing. Also included are sections on engineering data, a buyer's guide, and a directory of tradenames

(C) *Plaspec,* Mechanical, physical, optical, and electrical properties of more than 4200 plastics and polymers. Plaspec, 633 Third Ave., 32nd Floor, New York, NY 10017

(D/C) Plastics and Rubber Advisory Service, 6 Bath Place, Rivington St., London EC2A 3JE, United Kingdom. Tel: 44 171 457 5000. Backed by computer- and text-based databases

(C) *POLYMAT,* DKI Kunstsoff Datenbank (Suppliers data on commercially available plastics), Deutsches Kunststoff-Institut (DKI) Abteilung Dokumentation, Schlossartenstr. 6R, 6100 Darmstadt, Germany. Tel: 49 (06151) 16-2106

(P) *Polymer Engineering Principles: Properties, Process, and Tests for Design,* Hanser Gardner Publications, 1993

(C) *PROCOP-M* (physical, thermodynamic and rheological data on thermoplastics for injection molding). Available through Cisigraph, 76 rue des Gemeaux SILIC 413, 94573 Rungis Cedex, France. Tel: (33) 14 687 22 16

(P) I.I. Rubin, Ed., *Handbook of Plastic Materials and Technology,* Wiley, 1990, 1792 pp. Comprises 119 chapters on plastic materials, properties, processes, and industry practices

(P) H.J. Saechtling, Ed., *International Plastics Handbook,* Macmillan, London, 1983 (English ed.)

(C) *SciPolymer,* SciVision Inc., Lexington MA. A program for de novo design of polymers or estimation of polymer properties. Includes a database of 650 polymers, 200 common monomers, and 150 common substituent groups

(P) R.B. Seymour, *Polymers for Engineering Applications,* ASM International, 1987, 198 pp

(C) *SPAO* (computer-assisted selection of polymers). Provides information on 4000 to 5000 commercial grades of polymers on the European market: manufacturer, applicable standards and test methods, forming characteristics, engineering properties, and applications. Laboratoire National d'Essais, 1 rue Gaston Boissier, 75015 Paris, France. Tel: (33) 145 32 29 89

Evaluation and Interpretation of Data

Having located one or more pieces of data relevant to his or her problem, the scientist or engineer must usually answer additional questions before the information can be used. If the data found are for conditions not precisely those pertinent to the problem situation, how would the requisite interpolation or extrapolation be performed? If two or more sets of data are not in agreement with each other, which should be chosen; or should some sort of averaging technique be applied? Is the functional dependence of the data on measured variables such as temperature or composition in such accord with theoretical expectations as to give credence to their validity? What does the internal scatter of the data or the disparity between these data and those from another source imply about their reliability? Can a self-consistent data set of stated reliability be synthesized from limited, fragmentary, and conflicting experimental data? Such questions have been dealt with in a general way by Ho and Touloukian (Ref 24), Lide and Paul (Ref 25), and Barrett (Ref 26, 27, 28), among others.

Development of answers to the questions just posed involves a sequence of processes in the analysis of the available data. Briefly, these comprise:

- *Reduction of data:* A process by which physical measurements of observations are subjected to a series of adjustments (including such steps as the correction of the measured results for known errors of the instruments, the conversion to standard units and, perhaps, the transformation to standard conditions appropriate to the type of experiment or observation), so as to permit the results of observations made at different times or places to be compared and combined more readily.
- *Homogenization:* The process by which comparable data sets arising from dissimilar sources, possibly with differing nomenclatures and associated units are converted to a harmonized terminology and unit system applicable to a local standard.
- *Evaluation:* The process of establishing the accuracy and integrity of property data. Evaluation involves examination and appraisal of the data presented, assessment of experimental technique and associated errors, consistency checks for allowed values and units, comparison with other experimental or theoretical values, reanalysis and recalculation of derived quantities as required, selection of best values, and assignment of probable error or reliability.

A typical result of such an analysis is shown in Fig. 3. It must be emphasized that these are not clerical activities, but ones that require substantial expertise by individuals experienced in the subject area of the data but also in the techniques of data analysis. These persons usually are relatively senior and require extensive bibliographic and computer support; hence the data analysis process can be quite expensive.

In selecting data for use or for incorporation in an authoritative reference work or electronic database, there are two overriding considerations to be applied, even before the analytical processes just reviewed are undertaken. First, can an explicit trail be documented to the original source of the raw data; and second, are the metadata associated with the number or numbers to be used adequately complete? Metadata are the descriptive data about the material reported on, about the test methods used to determine the properties cited, and about the reporting of the test data. They have been more fully detailed by Kaufman (Ref 29) as listed in Table 10.

Table 10 Types of metadata associated with materials properties data

Completeness of description of material
Producer Heat/lot identification Status of material (commercial or experimental) Name/UNS No. Specification(s) Condition/temper/grade/class Product form Chemical analysis Any special melting practice or source material, for example, vacuum cast, powder metallurgy product, etc. Process/thermal history Microstructure Background properties (e.g., tensile properties)
Completeness of description of test method
Test standard Specimen type, size, shape, finish Specimen location and orientation Specimen relation to end-use situation Loading rate Temperature and method of measurement Environment and method of monitoring Statements of precision and accuracy
Completeness of reporting of test data
Report format Coverage of logical variables Tests run to completion according to test plan Replications Documentation of units and conversions Consistency of results Failure type and description

Source: Ref 29

Data may also be considered for use that do not derive from physical tests, but result from some theoretical prediction or are estimated from values for similar materials. Here, too, metadata are required that describe the theoretical techniques, the basis for the estimate, the estimation procedures and reference cases, and so forth. Other references (Ref 30, 31, 32, 33) also examine the importance of metadata and the multiple roles metadata can play.

The various data evaluation methods and procedures to be used have been reviewed in some detail for the general case by Barrett (Ref 28) and need not be recapitulated here. However, some additional comments are important. First, while the procedures Barrett describes can be generally applied, more specific techniques have been examined for important individual mechanical property classes such as creep, fatigue, and stress rupture (Ref 34, 35, 36, 37, 38). Assessment of large data sets can be eased in cases where some constitutive law, theoretical or empirical, is applicable. A familiar example is the so-called Larson-Miller analysis of stress-rupture data as shown in Fig. 4. Such an approach is useful for identification of a discordant data set or for interpolation within the range of the actual test parameters; it should not be

used for extrapolation. A long-range goal is to have the capability for prediction of material behavior in more realistic situations where two or more processes are combined, for example, creep and fatigue, or where the stress and/or temperature history is complex, even within a single deformation regime. For recent progress in this area see the chapters by Jenkins, Evans, and McLean in Ref 38.

Sources of Materials Property Data and Information

Jack H. Westbrook, Brookline Technologies

Obtaining and Reporting Test Data

Of all test data on materials, those most readily available and most used in materials selection and design activities are mechanical properties data. The subsequent discussion relates specifically to that class of properties, but the principles outlined can be extended to other families of properties.

The utility of test data is not simply enhanced when standard tests are used, but, as previously discussed, may only be *permitted* when:

- Standard tests are used
- The test equipment has been calibrated using well-defined, certified reference materials
- Standards for reporting of test data have been fully met
- Terms used, descriptive of the material and the test, are recorded and defined

The accelerating use of computers to store and analyze test data has forced increasing rigor, especially with respect to the last two points. Without the meeting of these conditions, it would be difficult to search a database or to properly merge or compare independent data sets. For these reasons ASTM E-49 (Committee on Computerization of Material and Chemical

Property Data) has been active in recent years developing standards for describing materials and recording test results and properties. Notwithstanding the desirability of using standardized test methods whenever possible, prototype service testing can often yield crucial information to aid a design decision.

The materials property database standards issued by ASTM E-49 as of 1996 (Table 11) include guides for identification of a material under discussion (Ref 40) and for data recording (Ref 41). Specific recommendations are made for bearing tests, plane strain fracture toughness, tension, compression, and notch-bar impact test data for metals and plastics as well as for arc-welded properties and corrosion data. Related work includes standards for codes, terminology, quality indicators, chemical structure information, and laboratory management information systems as summarized in Table 11. Other work by ASTM E-49 concerns standards developed in collaboration with other professional organizations but maintained by them as summarized in Table 12. Still more work of this kind is also going forward for other types of tests and other classes of materials, but has not yet resulted in a formal standard.

Table 11 ASTM E-49 materials database standards

ASTM No.	Topic
Materials designations	
E 1308	Polymers
E 1338	Metals and alloys
E 1339	Aluminum alloys
Data recording formats	
E 1313	Material properties data
E 1723	Test data for plastics
E 1761	Fatigue and fracture data for metals
Codes for use in databases	
E 1722	Materials and chemical property data codes
Terminology	
E 1314	Structuring terminological records
E 1443	Terminology for materials and chemical databases
E 1013	Terminology for computerized systems

Data and database quality	
E 1407	Materials database management
E 1484	Quality indicators for data and databases
E 1485	Material and chemical property database descriptors
Chemical structural information	
E 1586	Computerization of chemical structural information
Laboratory information management systems	
E 1578	Guide for laboratory information management systems
E 622	Guide for development of computerized systems
E 625	Guide for training users
E 1340	Guide for rapid prototyping
E 1283	Guide for procurement of computer integrated manufacturing systems
E 1034	Guide for classifying industrial robots
E 627	Guide for documenting computerized systems
E 919	Specification for software documentation of computerized systems
E 731	Guide for selection and acquisition of commercially available computer systems
E 1206	Guide for computerization of existing equipment

Table 12 Standards developed by ASTM E-49 in cooperation with, but maintained by, other committees or organizations

No.	Topic	Jurisdictional body
D 5592	Guide for materials properties needed in engineering design using plastics	ASTM D-20
E 1309	Identification of composite materials	ASTM D-30

E 1434	Recording mechanical property test data for high-modulus fiber-reinforced composites	ASTM D-30
E 1471	Identification of fibers, fillers, and core materials	ASTM D-30
G 107	Recording corrosion data for metals	ASTM G-1
E 1454	Recording computerized ultrasonic test data	ASTM E-7
E 1475	Recording computerized radiological test data	ASTM E-7
A9.1	Recording data descriptive of arc welds	AWS
A9.2	Recording arc weld property and inspection data	AWS

The work of ASTM was preceded by a general reconnaissance of standards and metadata requirements for computerization of selected mechanical properties of metallic materials (Ref 31). The specific properties covered were tensile behavior, hardness numbers, notch-bar impact test parameters, and fatigue properties. While test methods for the properties examined were considered to be generally adequate, improved standards for data recording were recommended as well as the availability of standard reference materials certified as to their mechanical properties.

The standardization of industrial data by and for ISO is reviewed in Ref 42, which describes three ISO-developed standards: STEP (standard for exchange of product model data), P-LIB (parts libraries), and MANDATE (manufacturing data exchange).

Other useful references on data development, recording, and use may also be cited. The *ASM Handbook* includes volumes that cover mechanical testing (Ref 43), corrosion (Ref 44), nondestructive testing (Ref 45), tribological behavior (Ref 46), and fatigue and fracture (Ref 47). Other ASM reference works are devoted specifically to tensile testing (Ref 48) and hardness testing (Ref 49). Two British works considered high-temperature mechanical properties, specifically, Loveday et al. (Ref 50) and Curbishley (Ref 51). The latter work is directed at the nonspecialist who needs to know what types of tests are available and how to select the most appropriate test for a particular purpose, and who needs to have an appreciation of the methods for data determination and analysis and a knowledge of applicable standards. The emphasis is on metals, but the principles are pertinent to ceramics, polymers, and composites as well. The particular properties addressed include: tensile, creep, fatigue crack growth, low-cycle fatigue, high-cycle fatigue, and fracture toughness. Unfortunately, this work fails to show, even by reference, data compilations, print or computerized, in any of the subject fields examined.

For ceramics, a two-part handbook for the engineer and designer has been prepared (Ref 52, 53). The first part presents an overview of the properties of technical and engineering ceramics (not just mechanical properties, but thermal, electrical, optical, and chemical as well), and the second part is intended to cover data sheets for specific classes of commercially available ceramic materials (oxides, silicates, silicon carbide, silicon nitride, nonoxide ceramics, halides, glasses, etc.). To date, only the volume on high-alumina ceramics has appeared (Ref 53).

Conclusions

Great progress has been made in the materials information field in the second half of the 20th century. Enormous problems still remain, however. Adequate directories of information sources are needed; much of the accessible data is of indeterminate reliability; gaps exist in the coverage of the materials-properties matrix; most existing data sources are mutually incompatible and cannot easily be used together; only a fraction of all needed data is in electronic form; and there has been a general failure to appreciate how expensive, yet rewarding, are data compilation and evaluation activities. This situation has been analyzed in some detail by Westbrook and Kaufman (Ref 54).

Properties Needed for the Design of Static Structures

Mahmoud M. Farag, The American University in Cairo

Introduction

ENGINEERING DESIGN can be defined as the creation of a product that satisfies a certain need. A good design should result in a product that performs its function efficiently and economically within the prevailing legal, social, safety, and reliability requirements. In order to satisfy such requirements, the design engineer has to take into consideration a large number of diverse factors:

- *Function and consumer requirements,* such as capacity, size, weight, safety, design codes, expected service life, reliability, maintenance, ease of operation, ease of repair, frequency of failure, initial cost, operating cost, styling, human factors, noise level, pollution, intended service environment, and possibility of use after retirement
- *Material-related factors,* such as strength, ductility, toughness, stiffness, density, corrosion resistance, wear resistance, friction coefficient, melting point, thermal and electrical conductivity, processibility, possibility of recycling, cost, available stock size, and delivery time
- *Manufacturing-related factors,* such as available fabrication processes, accuracy, surface finish, shape, size, required quantity, delivery time, cost, and required quality

Figure 1 illustrates the relationship among the above three groups. The figure also shows that there are other secondary relationships between material properties and manufacturing processes, between function and manufacturing processes, and between function and material properties.

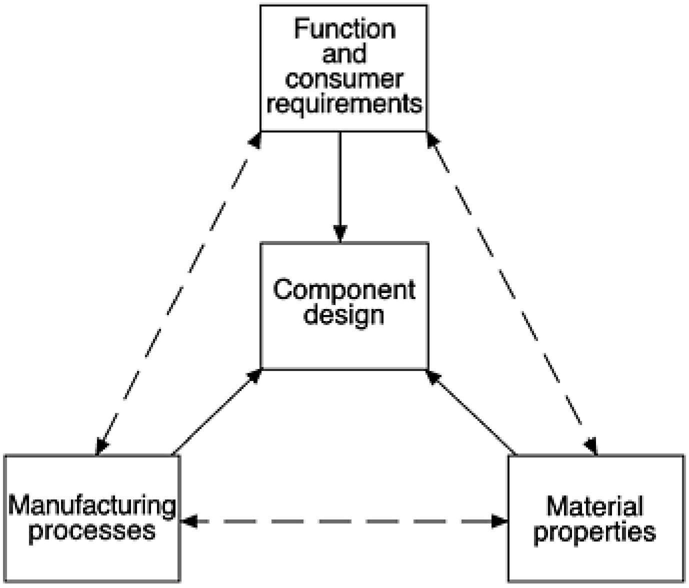

Fig. 1 Factors that should be considered in component design. Source: Ref 1

The relationship between design and material properties is complex because the behavior of the material in the finished product can be quite different from that of the stock material used in making it. This point is illustrated in Fig. 2, which

shows that in addition to stock material properties, production method and component geometry have direct influence on the behavior of materials in the finished component. The figure also shows that secondary relationships exist between geometry and production method, between stock material and production method, and stock material and component geometry. The effect of component geometry on the behavior of materials is discussed in the following section.

Effect of Component Geometry

In almost all cases, engineering components and machine elements have to incorporate design features that introduce changes in their cross section. For example, shafts must have shoulders to take thrust loads at the bearings and must have keyways or splines to transmit torques to or from pulleys and gears mounted on them. Under load, such changes cause localized stresses that are higher than those based on the nominal cross section of the part. The severity of the stress concentration depends on the geometry of the discontinuity and the nature of the material. A geometric, or theoretical, stress concentration factor, K_t, is usually used to relate the maximum stress, S_{max}, at the discontinuity to the nominal stress, S_{av}, according to the relationship:

$$K_t = S_{max}/S_{av} \quad \textbf{(Eq 1)}$$

The value of K_t depends on the geometry of the part and can be determined from stress concentration charts, such as those given in Ref 2 and 3. Other methods of estimating K_t for a certain geometry include photoelasticity, brittle coatings, and finite element techniques. Table 1 gives some typical values of K_t.

Table 1 Values of the stress concentration factor K_t

Component shape		Value of critical parameter, K_t	
Round shaft with transverse hole			
Bending		d/D = 0.025	2.65
		= 0.05	2.50
		= 0.10	2.25
		= 0.20	2.00

		$r/d = 0.10$	2.0
		$r/d = 0.20$	1.6
Bending		$d/D = 1.1$, $r/d = 0.05$	2.35
		$r/d = 0.10$	1.9
		$r/d = 0.20$	1.5
Torsion		$d/D = 1.1$, $r/d = 0.05$	1.65
		$r/d = 0.10$	1.4

		$r/d = 0.20$	1.25

Source: Ref 1

Experience shows that, under static loading, K_t gives an upper limit to the stress concentration value and applies it to high-strength low-ductility materials. With more ductile materials, local yielding in the very small area of maximum stress causes some relief in the stress concentration. Generally, the following design guidelines should be observed if the deleterious effects of stress concentration are to be kept to a minimum:

- Abrupt changes in cross section should be avoided. If they are necessary, generous fillet radii or stress-relieving grooves should be provided (Fig. 3a).
- Slots and grooves should be provided with generous run-out radii and with fillet radii in all corners (Fig. 3b).
- Stress-relieving grooves or undercuts should be provided at the end of threads and splines (Fig. 3c).
- Sharp internal corners and external edges should be avoided.
- Oil holes and similar features should be chamfered and the bore should be smooth.
- Weakening features like bolt and oil holes, identification marks, and part numbers should not be located in highly stressed areas.
- Weakening features should be staggered to avoid the addition of their stress concentration effects (Fig. 3d).

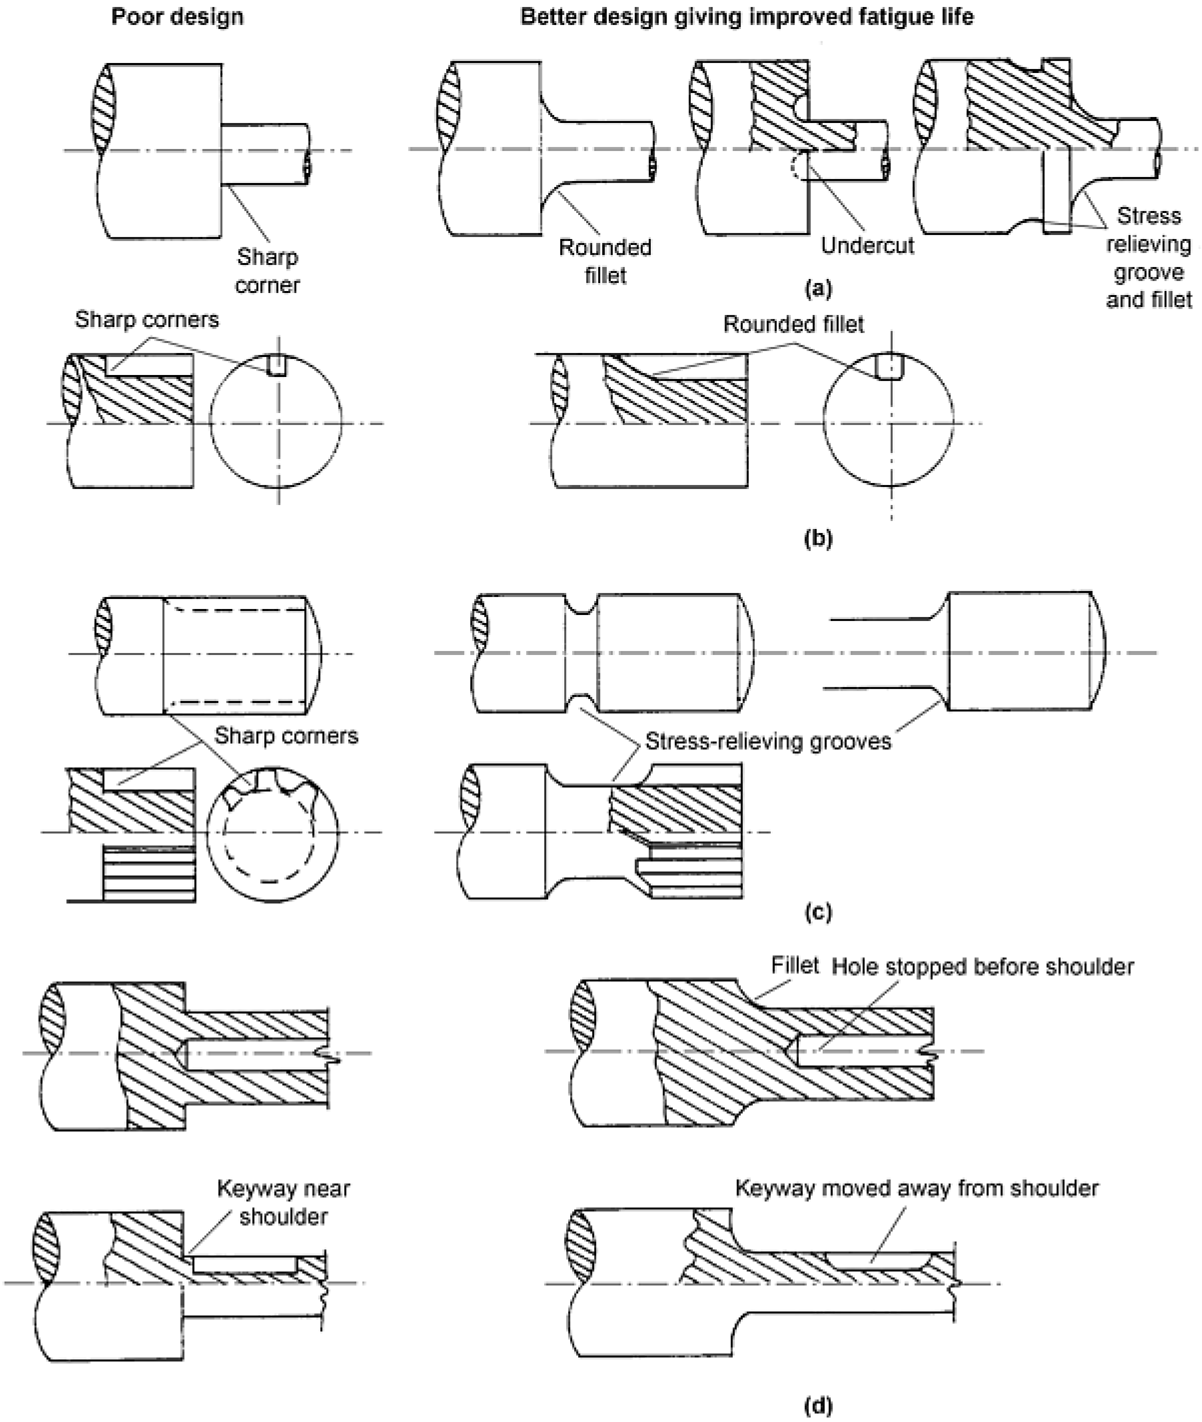

Fig. 3 Design guidelines for reducing the deleterious effects of stress concentration. See text for discussion. Source: Ref 1

Factor of Safety

The term factor of safety is applied to the factor used in designing a component to ensure that it will satisfactorily perform its intended function. The main parameters that affect the value of the factor of safety, which is always greater than unity, can be grouped into:

- Uncertainties associated with material properties due to variations in composition, heat treatment, and processing conditions as well as environmental variables such as temperature, time, humidity, and ambient chemicals. Manufacturing processes also contribute to these uncertainties as a result of variations in surface roughness, internal stresses, sharp corners, and other stress raisers.
- Uncertainties in loading and service conditions

Generally, ductile materials that are produced in large quantities show fewer property variations than less ductile and advanced materials that are produced by small batch processes. Parts manufactured by casting, forging, and cold forming are known to have variations in properties from point to point.

To account for uncertainties in material properties, the factor of safety is used to divide into the nominal strength (S) of the material to obtain the allowable stress (S_a) as follows:

$$S_a = S/n_s \qquad \textbf{(Eq 2)}$$

where n_s is the material factor of safety.

In simple components, S_a in the above equation can be viewed as the minimum allowable strength of the material. However there is some danger involved in this use, especially in the cases where the load-carrying capacity of a component is not directly related to the strength of the material used in making it. Examples include long compression members, which could fail as a result of buckling, and components of complex shapes, which could fail as a result of stress concentration. Under such conditions it is better to consider S_a as the load-carrying capacity that is a function of both material properties and geometry of the component.

In assessing the uncertainties in loading, two types of service conditions have to be considered:

- *Normal working conditions,* which the component has to endure during its intended service life
- *Limited working conditions,* such as overloading, which the component is only intended to endure on exceptional occasions, and which if repeated frequently could cause premature failure of the component

In a mechanically loaded component, the stress levels corresponding to both normal and limited working conditions can be determined from a duty cycle. The normal duty cycle for an airframe, for example, includes towing and ground handling, engine run, take-off, climb, normal gust loadings at different altitudes, kinetic and solar heating, descent, and normal landing. Limited conditions can be encountered in abnormally high gust loadings or emergency landings. Analyses of the different loading conditions in the duty cycle lead to determination of the maximum load that will act on the component. This maximum load can be used to determine the maximum stress, or damaging stress, which if exceeded would render the component unfit for service before the end of its normal expected life. The load factor of safety (n_l) in this case can be taken as:

$$n_l = P/P_a \qquad \textbf{(Eq 3)}$$

where P is the maximum load and P_a is normal load.

The total or overall factor of safety (n) that combines the uncertainties in material properties and external loading conditions can be calculated as:

$$n = n_s \cdot n_l \qquad \textbf{(Eq 4)}$$

Factors of safety ranging from 1.1 to 20 are known, but common values range from 1.5 to 10.

In some applications a designer is required to follow established codes when designing certain components, for example, pressure vessels, piping systems, and so forth. Under these conditions, the factors of safety used by the writers of the codes may not be specifically stated, but an allowable working stress is given instead.

Mahmoud M. Farag, The American University in Cairo

Probability of Failure

As discussed earlier, the actual strength of the material in a component could vary from one point to another and from one component to another. In addition, it is usually difficult to precisely predict the external loads acting on the component under actual service conditions. To account for these variations and uncertainties, both the load-carrying capacity S and the externally applied load P can be expressed in statistical terms. As both S and P depend on many independent factors, it would be reasonable to assume that they can be described by normal distribution curves. Consider that the load-carrying capacity of the population of components has an average of $\overline{S}$ and a standard deviation σ_S while the externally applied load has an average of $\overline{P}$ and a standard deviation σ_P. The relationship between the two distribution curves is important in determining the factor of safety and reliability of a given design. Figure 4 shows that failure takes place in all the components that fall in the area of overlap of the two curves, that is, when the load-carrying capacity is less than the external load. This is described by the negative part of the (S - P) curve of Fig. 4. Transforming the distribution ($\overline{S} - \overline{P}$) to the standard normal deviate z, the following equation is obtained:

$$z = [(S - P) - (\overline{S} - \overline{P})]/[(\sigma_S)^2 + (\sigma_P)^2]^{1/2} \qquad \textbf{(Eq 5)}$$

From Fig. 4, the value of z at which failure occurs is:

$$z = -(S - P)/[(\sigma_S)^2 + (\sigma_P)^2]^{1/2} \qquad \textbf{(Eq 6)}$$

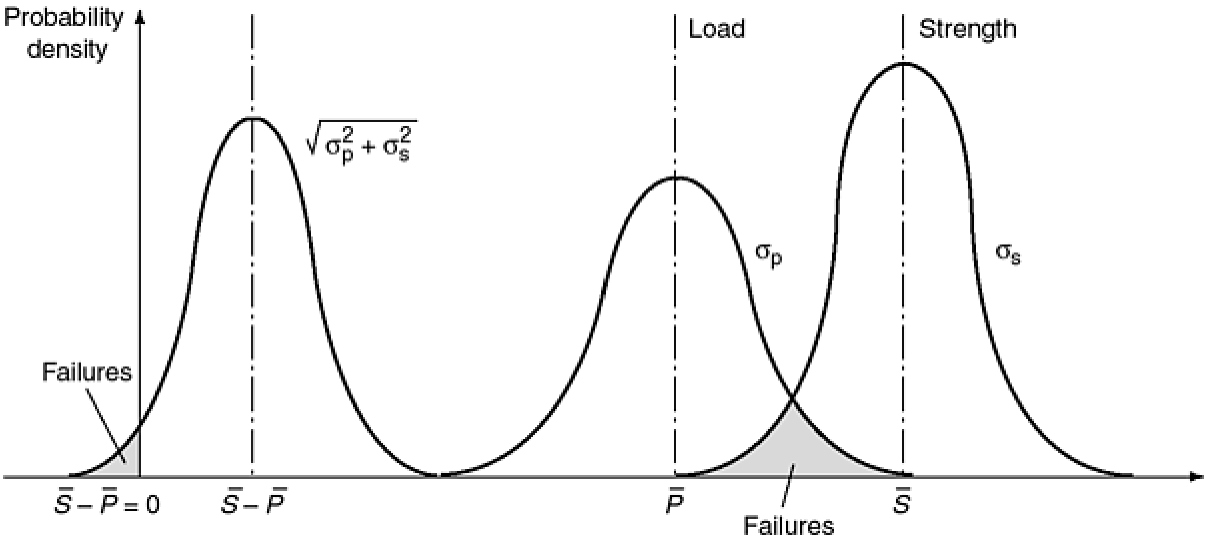

Fig. 4 Effect of variations in load and strength on the failure of components. Source: Ref 1

For a given reliability, or allowable probability of failure, the value of *z* can be determined from cumulative distribution function for the standard normal distribution. Table 2 gives some selected values of *z* that will result in different values of probabilities of failure.

Table 2 Values of *z* and corresponding levels of reliability and probability of failure

z	Reliability	Probability of failure
-1.00	0.8413	0.1587
-1.28	0.9000	0.1000
-2.33	0.9900	0.0100
-3.09	0.9990	0.0010
-3.72	0.9999	0.0001
-4.26	0.99999	0.00001
-4.75	0.999999	0.000001

Knowing σ_S, σ_P, and the expected $\bar{P}$, the value of $\bar{S}$ can be determined for a given reliability level. As defined earlier, the factor of safety in the present case is simply *S*/*P*. The following example illustrates the use of the above concepts in design; additional discussion of statistical methods is provided in the article "Statistical Aspects of Design" in this Volume.

Example 1: Estimating Probability of Failure.

A structural element is made of a material with an average tensile strength of 2100 MPa. The element is subjected to a static tensile stress of an average value of 1600 MPa. If the variations in material quality and load cause the strength and stress to vary according to normal distributions with standard deviations of $\sigma_S = 400$ and $\sigma_P = 300$, respectively, what is the probability of failure of the structural element? The solution can be derived as follows: From Fig. 4, $(\bar{S} - \bar{P}) = 2100 - 1600 = 500$ MPa, standard deviation of the curve $(\bar{S} - \bar{P}) = [(400)^2 + (300)^2]^{1/2} = 500$; from Eq 6, $z = -500/500 = -1$. Thus, from Table 2, the probability of failure of the structural element is 0.1587 (15.87%), which is too high for many practical applications.

One solution to reduce the probability of failure is to impose better quality measures on the production of the material and thus reduce the standard deviation of the strength. Another solution is to increase the cross-sectional area of the element in order to reduce the stress. For example, if the standard deviation of the strength is reduced to $\sigma_S = 200$, the standard deviation of the curve $(\bar{S} - \bar{P})$ will be $[(200)^2 + (300)^2]^{1/2} = 360$, $z = -500/360 = -1.4$, which, according to Table 2, gives a more acceptable probability of failure value of 0.08 (8%).

Alternatively, if the average stress is reduced to 1400 MPa, $(\bar{S} - \bar{P}) = 700$ MPa, $z = -700/500 = -1.4$, with a similar probability of failure as the first solution.

Experimental Methods. As the above discussion shows, statistical analysis allows the generation of data on the probability of failure and reliability, which is not possible when a deterministic safety factor is used. One of the difficulties with this statistical approach, however, is that material properties are not usually available as statistical quantities. In such cases, the following approximate method can be used.

In the case where the experimental data are obtained from a reasonably large number of samples, more than 100, it is possible to estimate statistical data from nonstatistical sources that only give ranges or tolerance limits. In this case, the standard deviation σ_S is approximately given by:

$$\sigma_S = (\text{maximum value of property} - \text{minimum value})/6 \qquad \textbf{(Eq 7)}$$

This procedure is based on the assumption that the given limits are bounded between plus and minus three standard deviations.

If the results are obtained from a sample of about 25 tests, it may be better to divide by 4 in Eq 7 instead of 6. With a sample of about 5, it is better to divide by 2.

In the cases where only the average value of strength is given, the following values of coefficient of variation, which is defined as $\nu' = \sigma_S/S$ can be taken as typical for metallic materials: $\nu' = 0.05$ for ultimate tensile strength, and $\nu' = 0.07$ for yield strength.

Properties Needed for the Design of Static Structures

Mahmoud M. Farag, The American University in Cairo

Designing for Static Strength

The design and materials selection of a component or structure under static loading can be based on static strength and/or stiffness depending on the service conditions and the intended function.

In the case of ductile materials, designs based on the static strength usually aim at avoiding yielding of the component. The manner in which the yield strength of the material affects the design depends on the loading conditions and type of component, as illustrated in the following cases.

Designing for Axial Loading. When the component is subjected to uniaxial stress, yielding takes place when the local stress reaches the yield strength of the material. The critical cross-sectional area, *A*, of such a component can be estimated as:

$$A = K_t\, n\, P/YS \qquad \textbf{(Eq 8)}$$

where K_t is the stress concentration factor (described in the section "Effect of Component Geometry" in this article), *P* is the applied load, *n* is the factor of safety, (described in the section "Factor of Safety" in this article), and *YS* is the yield strength of the material.

Designing for Torsional Loading. The critical cross-sectional area of a circular shaft subjected to torsional loading can be determined from the relationship:

$$2\, I_p/d = K_t\, n\, T/\tau_{max} \qquad \textbf{(Eq 9)}$$

where *d* is the shaft diameter at the critical cross section, τ_{max} is the shear strength of the material, *T* is the transmitted torque, and I_p is the polar moment of inertia of the cross section. ($I_p = \pi d^4/32$ for a solid circular shaft; $I_p = \pi(d_o^4 - d_i^4)/32$ for a hollow circular shaft of inner diameter d_i and outer diameter d_o.)

While Eq 9 gives a single value for the diameter of a solid shaft, a large combination of inner and outer diameters can satisfy the relationship in the case of a hollow shaft. Under such conditions, either one of the diameters or the required thickness has to be specified in order to calculate the other dimension.

The ASTM code of recommended practice for transmission shafting gives an allowable value of shear stress of 0.3 of the yield or 0.18 of the ultimate tensile strength, whichever is smaller. With shafts containing keyways, ASTM recommends a reduction of 25% of the allowable shear strength to compensate for stress concentration and reduction in cross-sectional area.

Designing for Bending. When a relatively long beam is subjected to bending, the bending moment, the maximum allowable stress, and dimensions of the cross section are related by:

$$Z = (n\, M)/YS \qquad \textbf{(Eq 10)}$$

where *M* is the bending moment and *Z* is the section modulus (*Z* = *I*/*c*, where *I* is the moment of inertia of the cross section with respect to the neutral axis normal to the direction of the load, and *c* is the distance from center of gravity of the cross section to the outermost fiber). Bending moment can be determined by consulting a standard reference on the strength of materials, such as Ref 4.

Mahmoud M. Farag, The American University in Cairo

Designing for Stiffness

In addition to being strong enough to resist the expected service loads, there may also be the added requirement of stiffness to ensure that deflections do not exceed certain limits. Stiffness is important in applications such as machine elements to avoid misalignment and to maintain dimensional accuracy of machine parts.

Design of Beams. The deflection of a beam under load can be taken as a measure of its stiffness, and this depends on the position of the load, the type of beam, and the type of supports. For example, a beam that is simply supported at both ends suffers maximum deflection (y) in its middle when subjected to a concentrated central load (P). In this case the maximum deflection, y, is a function of both E and I, as follows:

$$y = (P \cdot L^3) / (48 \cdot E \cdot I) \qquad \textbf{(Eq 11)}$$

where L is the length of the beam, E is Young's modulus of the beam material, and I is the second moment of area of the beam cross section with respect to the neutral axis.

Design of Columns. Columns and struts, which are long slender parts, are subject to failure by elastic instability, or buckling, if the applied axial compressive load exceeds a certain critical value, P_{cr}. The Euler column formula is usually used to calculate the value of P_{cr}, which is a function of the material, geometry of the column, and restraint at the ends. For the fundamental case of a pin-ended column, that is, ends are free to rotate around frictionless pins, P_{cr} is given as:

$$P_{cr} = \pi^2 E I/L^2 \qquad \textbf{(Eq 12)}$$

where I is the least moment of inertia of the cross-sectional area of the column, and L is the length of the column.

The above equation can be modified to allow for end conditions other than the pinned ends. The value of P_{cr} for a column with both ends fixed--built-in as part of the structure--is four times the value given by Eq 12. On the other hand, the critical load for a free-standing column--one end is fixed and the other free as in a cantilever--P_{cr} is only one-quarter of the value given by Eq 12.

The Euler column formula given above shows that the critical load for a given column is only a function of E and I and is independent of the compressive strength of the material. This means that resistance to buckling of a column of a given material and a given cross-sectional area can be increased by distributing the material as far as possible from the principal axes of the cross section to increase I. Hence, tubular sections are preferable to solid sections. Reducing the wall thickness of such sections and increasing the transverse dimensions increases the stability of the column. However, there is a lower limit for the wall thickness below which the wall itself becomes unstable and causes local buckling.

Experience shows that the values of P_{cr} calculated according to Eq 12 are higher than the buckling loads observed in practice. The discrepancy is usually attributed to manufacturing imperfections, such as lack of straightness of the column and lack of alignment between the direction of the compressive load and the axis of the column. This discrepancy can be accounted for by using an appropriate imperfection parameter or a factor of safety. For normal structural work, a factor of safety of 2.5 is usually used. As the extent of the above imperfections is expected to increase with increasing slenderness of the column, it is suggested that the factor of safety be increased accordingly. A factor of safety of 3.5 is recommended for columns with $[L(A/I)^{1/2}] > 100$, where A is cross-sectional area.

Equation 12 shows that the value of P_{cr} increases rapidly as the length of the column, L, decreases. For a short enough column, P_{cr} becomes equal to the load required for yielding or crushing of the material in simple compression. Such a case represents the limit of applicability of the Euler formula as failure takes place by yielding or fracture rather than elastic instability. Such short columns are designed according to the procedure described for simple axial loading.

Design of Shafts. The torsional rigidity of a component is usually measured by the angle of twist, θ, per unit length. For a circular shaft, θ is given in radians by:

$$\theta = T/G\, I_p \qquad \textbf{(Eq 13)}$$

where G is the modulus of elasticity in shear, and:

$$G = E/[2(1 + \nu)] \qquad \textbf{(Eq 14)}$$

where ν is Poisson's ratio.

The usual practice is to limit the angular deflection in shafts to about 1° (π/180 radians) in a length of 20 times the diameter.

Properties Needed for the Design of Static Structures

Mahmoud M. Farag, The American University in Cairo

Selection of Materials for Static Strength

Static Strength and Isotropy. The resistance to static loading is usually measured in terms of yield strength, ultimate tensile strength, and compressive strength. When the material does not exhibit a well-defined yield point, the stress required to cause 0.1 or 0.2% plastic strain, the proof stress, is used instead. (This is usually called the 0.2% offset yield strength.) For most ductile wrought metallic materials, the tensile and compressive strengths are very close, and in most cases only the tensile strength is given. However, brittle materials like gray cast iron and ceramics are generally stronger in compression than in tension. In such cases, both properties are usually given. For polymeric materials, which usually do not have a linear stress-strain curve, and whose static properties are very temperature dependent, other design methods must be used; additional information is provided in the article "Design with Plastics" in this Volume.

Although many engineering materials are almost isotropic, there are important cases where significant anisotropy exists. In the latter case, the strength depends on the direction in which it is measured. The degree of anisotropy depends on the nature of the material and its manufacturing history. Anisotropy in wrought metallic materials is more pronounced when they contain elongated inclusions and when processing consists of repeated deformation in the same direction. Composites reinforced with unidirectional fibers also exhibit pronounced anisotropy. Anisotropy can be useful if the principal external stress acts along the direction of highest strength.

The level of strength in engineering materials may be viewed either in absolute terms or relative to similar materials. For example, it is generally understood that high-strength steels have tensile strength values in excess of 1400 MPa (200 ksi), which is also high strength in absolute terms. Relative to light alloys, however, an aluminum alloy with a strength of 500 MPa (72 ksi) would also be designated a high-strength alloy even though this level of strength is low for steels.

From the design point of view, it is more convenient to consider the strength of materials in absolute terms. From the materials and manufacturing point of view, however, it is important to consider the strength as an indication of the degree of development of the material concerned, that is, relative to similar materials. This is because highly developed materials are often complex, more difficult to process, and relatively more expensive. Figure 5 gives the strength of some materials both in absolute terms and relative to similar materials. In a given group of materials, the medium-strength members are usually more widely used because they generally combine optimal strength, ease of manufacture, and economy. The most-developed members in a given group of materials are usually highly specialized, and as a result they are produced in much lower quantities. The low-strength members of a given group are usually used to meet requirements other than strength. For example, electrical and thermal conductivities, formability, or corrosion resistance may be more important than strength in some applications.

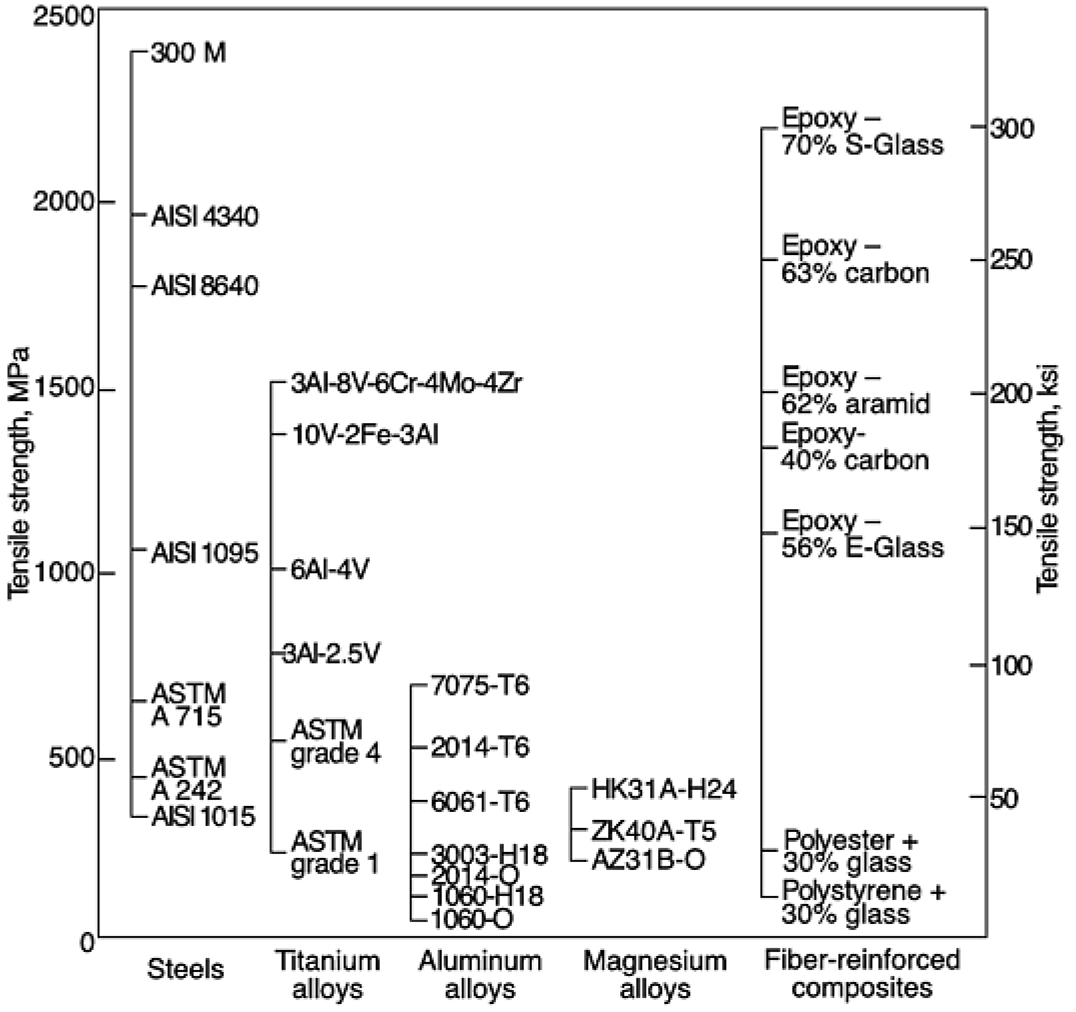

Fig. 5 Comparison of various engineering materials on the basis of tensile strength. Source: Ref 1

Frequently, higher-strength members of a given group of materials are more expensive. However, using a stronger but more expensive material could result in a reduction of the total cost of the finished component. This is because less material would be used, and consequently processing cost could also be less.

Weight and Space Limitations. The load-carrying capacity of a given component is a function of both the strength of the material used in making it and its geometry and dimensions. This means that a lower-strength material can be used in making a component to bear a certain load, provided that its cross-sectional area is increased proportionally. However, the designer is not usually completely free in choosing the strength level of the material selected for a given part. Other factors such as space and weight limitations could limit the choice.

Weight limitations are encountered with many applications including aerospace, transport, construction, and portable appliances. In such cases, the strength/density, or specific strength, becomes an important basis for comparing the different materials. Figure 6 compares the materials of Fig. 5 on the basis of specific strength, which is the tensile strength of a material divided by its density. The figure shows a clear advantage of the fiber-reinforced composites over other materials.

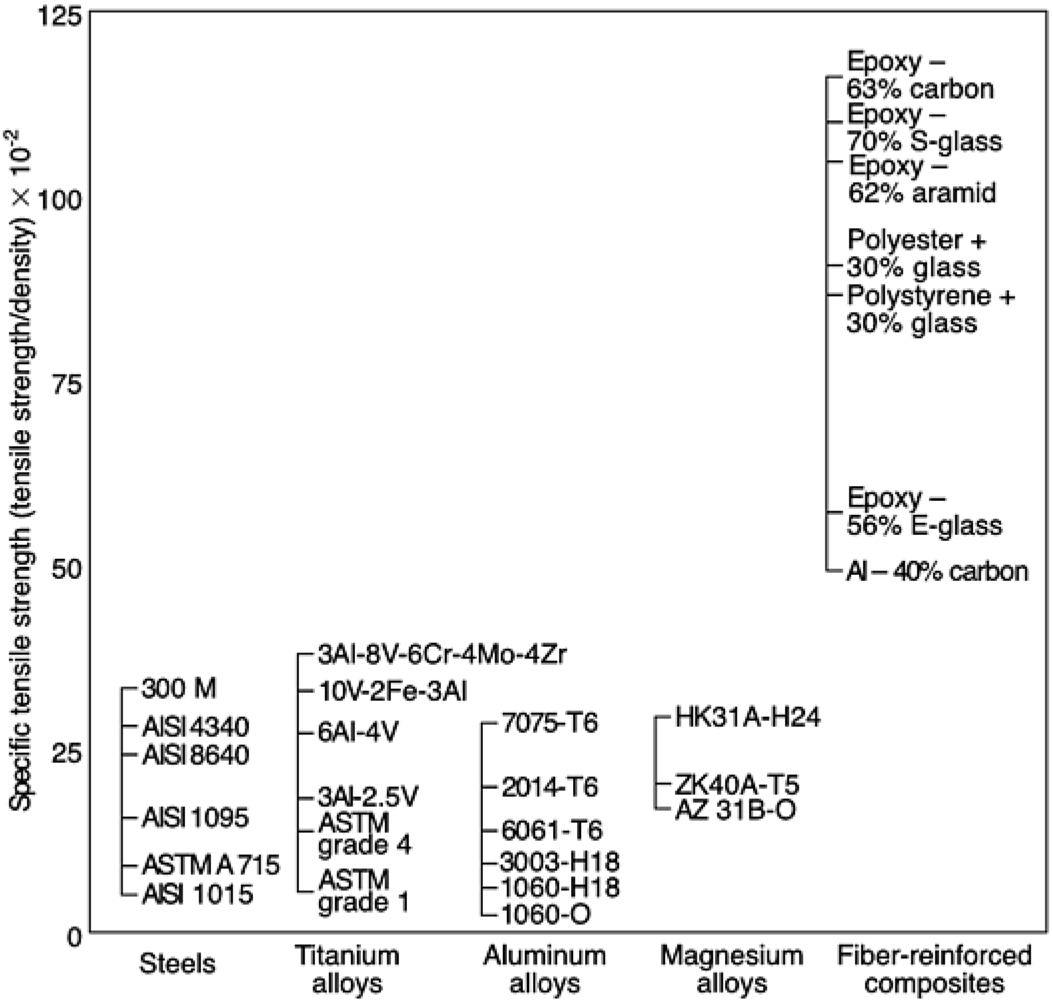

Fig. 6 Comparison of various engineering materials on the basis of specific tensile strength. Source: Ref 1

Using stronger material will allow smaller cross-sectional area and smaller total volume of the component. It should be noted, however, that reducing the cross-sectional area below a certain limit could cause failure by buckling due to increased slenderness of the part.

Example 2: Materials Selection for a Cylindrical Compression Element.

A load of 50 kN is to be supported on a cylindrical compression element of 200 mm length. As the compression element has to fit with other parts of the structure, its diameter should not exceed 20 mm. Weight limitations are such that the mass of the element should not exceed 0.25 kg. Table 3 shows the calculated diameter of the compression element when made of different materials. The diameter is calculated on the basis of strength and on the basis of buckling. The larger value for a given material is used to calculate the mass of the element. The results in Table 3 show that only epoxy-62% Kevlar satisfies both the diameter and weight limits for the compression element.

Table 3 Comparison of materials considered for a cylindrical compression element

Properties Needed for the Design of Static Structures

Mahmoud M. Farag, The American University in Cairo

Selection of Materials for Stiffness

Deflection under Load. As discussed in the section "Design of Beams" in this article, the stiffness of a component may be increased by increasing its second moment of area, which is computed from the cross-sectional dimensions, and/or by selecting a high-modulus material for its manufacture.

An important characteristic of metallic materials is that their elastic moduli are very difficult to change by changing the composition or heat treatment. Using high-strength materials in attempts to reduce weight usually comes at the expense of reduced cross-sectional area and reduced second moment of area. This could adversely affect stiffness of the component if the elastic constant of the new strong material does not compensate for the reduced second moment of area.

Selecting materials with higher elastic constant and efficient disposition of material in the cross section are essential in designing beams for stiffness. Placing material as far as possible from the neutral axis of bending is generally an effective means of increasing I for a given area of cross section. See the discussion of shape factor in the article "Performance Indices" in this Volume.

When designing with plastics, whose elastic modulus is 10 to 100 times less than that of metals, stiffness must be given special consideration. This drawback can usually be overcome by making some design adjustments. These usually include increasing the second moment of area of the critical cross section, as shown in the following example.

Example 3: Design Changes Required for Materials Substitution.

This example considers the design changes required when substituting high-density polyethylene (HDPE) for stainless steel in making a fork for a picnic set while maintaining similar stiffness. The narrowest cross section of the original stainless steel fork is rectangular with an area of 0.6 by 5 mm.

Analysis:

- E for stainless steel = 210 GPa.
- E for HDPE = 1.1 GPa.
- I for the stainless steel section = $5 \times (0.6)^3/12 = 0.09$ mm^4.
- From Eq 11, EI should be kept constant for equal deflection under load.
- EI for stainless steel = $210 \times 0.09 = 18.9$.
- EI for HDPE design = $1.1 \times I$.
- I for HDPE design = 17.2 mm^4. Taking a channel section of thickness 0.5 mm, web height 4 mm, and width 8 mm, $I = [8 \times (4)^3 - 7 \times (3.5)^3]/12 = 17.7$ mm^4, which meets the required value.
- Area of the stainless steel section = 3 mm^2.
- Area of the HDPE section = 7.5 mm^2.
- The specific gravity of stainless steel is 7.8 and that of HDPE is 0.96.
- Relative weight of HDPE/stainless steel = $(7.5 \times 0.96)/(3 \times 7.8) = 0.3$.

Weight Limitations. In applications where both the stiffness and weight of a structure are important, it becomes necessary to consider the stiffness/weight (specific stiffness), of the structure. In the simple case of a structural member under tensile or compressive load, the specific stiffness is given by E/ρ, where ρ is the density of the material. In such cases, the weight of a member of a given stiffness can be easily shown to be proportional to ρ/E and can be reduced by selecting a material with lower density or higher elastic modulus. When the component is subjected to bending, the dependence of the weight on ρ and E is not as simple. From Eq 11 it can be shown that the weight w of a simply supported beam of square cross-sectional area is given by:

$$w = L \cdot b^2 \cdot \rho = \frac{L^{5/2}}{2} \cdot \left(\frac{P}{y}\right)^{1/2} \cdot \frac{\rho}{E^{1/2}} \qquad \textbf{(Eq 15)}$$

Related information is provided in the article "Performance Indices" in this Volume.

Equation 15 shows that for a given deflection *y* under load *P*, the weight of the beam is proportional to ($\rho/E^{1/2}$). As *E* in this case is present as the square root, it is not as effective as ρ in controlling the weight of the beam. It can be similarly shown that the weight of the beam in the case of a rectangular cross section is proportional to ($\rho/E^{1/3}$), which is even less sensitive to variations in *E*. This change in the effectiveness of *E* in affecting the specific stiffness of structures as the mode of loading and shape change, is shown in Table 4.

Table 4 Comparison of the stiffness of selected engineering materials

Material	Modulus of elasticity (*E*), GPa	Density (ρ), mg/m^3	E/ρ $\times 10^{-5}$	$E^{1/2}/\rho$ $\times 10^{-2}$	$E^{1/3}/\rho$
Steel (carbon and low alloy)	207	7.825	26.5	5.8	35.1
Aluminum alloys (average)	71	2.7	26.3	9.9	71.2
Magnesium alloys (average)	40	1.8	22.2	11.1	88.2
Titanium alloys (average)	120	4.5	26.7	7.7	50.9
Epoxy-73% E-glass fibers	55.9	2.17	25.8	10.9	81.8
Epoxy-70% S-glass fibers	62.3	2.11	29.5	11.8	87.2
Epoxy-63% carbon fibers	158.7	1.61	98.6	24.7	156.1
Epoxy-62% aramid fibers	82.8	1.38	60	20.6	146.6

Source: Ref 1

Buckling Strength. Another selection criterion that is also related to the elastic modulus of the material and cross-sectional dimensions is buckling under compressive loading. The compressive load, P_b, that can cause buckling of a strut is given by Euler formula (Eq 12).

Equation 12 shows that increasing *E* and *I* will increase the load-carrying capacity of the strut. For an axially symmetric cross section, the weight of a strut, *w*, is given by:

$$w = L \cdot \frac{\pi \cdot D^2}{4} \cdot \rho = \frac{2 \cdot L^2 \cdot P_b^{1/2}}{\pi^{1/2}} \left(\frac{\rho}{E^{1/2}} \right) \qquad \textbf{(Eq 16)}$$

Equation 16 shows that the weight of an axisymmetric strut can be reduced by reducing ρ or by increasing *E* of the material, or both. However, reducing ρ is more effective, as *E* is present as the square root. In the case of a panel subjected to buckling, it can be shown that the weight is proportional to ($\rho/E^{1/3}$).

Types of Mechanical Failure under Static Loading at Normal Temperatures

Generally, a component can be considered to have failed when it does not perform its intended function with the required efficiency. The general types of mechanical failure encountered in practice are:

- *Yielding of the component material under static loading.* Yielding causes permanent deformation that could result in misalignment or hindrance to mechanical movement.
- *Buckling.* This type of failure takes place in slender columns when they are subjected to compressive loading, or in thin-walled tubes when subjected to torsional loading.
- *Failure by fracture due to static overload.* This type of failure can be considered an advanced stage of failure by yielding. Fracture can be either ductile or brittle.
- *Failure due to the combined effect of stresses and corrosion.* This usually takes place by fracture due to cracks at stress concentration points, for example, caustic cracking around rivet holes in boilers.

Of the above types of mechanical failure, the first two do not usually involve actual fracture, and the component is considered to have failed when its performance is below acceptable levels. On the other hand, the latter two types involve actual fracture of the component, and this could lead to unplanned load transfer to other components and perhaps other failures.

Mahmoud M. Farag, The American University in Cairo

Causes of Failure of Engineering Components

As discussed earlier, the behavior of a material in service is governed not only by its inherent properties, but also by the stress system acting on it and the environment in which it is operating. Causes of failure of engineering components can be classified into the following main categories:

- *Design deficiencies.* Failure to evaluate working conditions correctly due to the lack of reliable information on loads and service conditions is a major cause of inadequate design. Incorrect stress analysis, especially near notches, and complex changes in shape could also be a contributing factor.
- *Poor selection of materials.* Failure to identify clearly the functional requirements of a component could lead to the selection of a material that only partially satisfies these requirements. As an example, a material can have adequate strength to support the mechanical loads, but its corrosion resistance is insufficient for the application.
- *Manufacturing defects.* Incorrect manufacturing could lead to the degradation of an otherwise satisfactory material. Examples are decarburization and internal stresses in a heat-treated component. Poor surface finish, burrs, identification marks, and deep scratches due to mishandling could lead to

failure under fatigue loading.

- *Exceeding design limits and overloading.* If the load, temperature, speed, and so forth, are increased beyond the limits allowed by the factor of safety in design, the component is likely to fail. Subjecting the equipment to environmental conditions for which it was not designed also falls under this category. An example here is using a freshwater pump for pumping seawater.
- *Inadequate maintenance and repair.* When maintenance schedules are ignored and repairs are poorly carried out, service life is expected to be shorter than anticipated in the design.

As this article has described, various material properties influence the design of components. The type of property and the sensitivity of the design to variations in this property depend on the component geometry and type of load. Underestimation of the load and/or overestimation of the material property and service conditions could lead to failure in service.

Design for Fatigue Resistance

Erhard Krempl, Rensselaer Polytechnic Institute

Introduction

FATIGUE is a gradual process caused by repeated application of loads, such that each application of stress causes some degradation or damage of the material or component. An appropriate measure of deterioration or damage has not been found, and this fact makes fatigue design difficult.

The design of components against fatigue failure may involve several considerations of irregular loading, variable temperature, and environment. In this article, the effect of environment is excluded. The effects of environment on material performance are considered elsewhere in this Volume.

The main objective here is the discussion of design considerations against fatigue related to material performance under mechanical loading at constant temperature (isothermal fatigue, or simply fatigue). In this article, periodic loading of specimens is considered, and the material properties related to fatigue derived from these tests are discussed.

Design methods considering the irregular nature of actual load applications, which requires the statistical treatment of the load histories and their translation into load spectra, cycle counting methods, and damage accumulation will not be discussed. These topics are addressed in more detail in *Fatigue and Fracture,* Volume 19 of *ASM Handbook* (Ref 1).

This article reviews "traditional" methods of fatigue design. In recent years, the fracture mechanics approach to crack propagation has gained acceptance in the prediction of fatigue life. In this approach, crack initiation is neglected and crack propagation to final failure is considered. This method can give a conservative estimate of fatigue life. There has been considerable success with this method. However, the treatment of short cracks, the propagation of cracks for negative *R*-ratios, and for irregular loading, crack closure effects and multiaxial loadings provide significant challenges. Reference 2 gives an introduction to the current research in this area.

In addition, the design methods reviewed in this article focus principally on smooth and notched components. Mechanically fastened joints and welded joints require special attention. In particular, such joints tend to negate alloy and composition effects. More detailed information on fatigue of welds and mechanical joints is contained in Ref 1, 3, and 4.

Design for Fatigue Resistance

Erhard Krempl, Rensselaer Polytechnic Institute

The Fatigue Process

The fatigue process consists of a crack initiation and a crack propagation phase. The demarcation between these two phases is, however, not clearly defined. There is no general agreement when (or at what crack size) the crack initiation process ends, and the crack growth process begins. Nonetheless, the separation of the fatigue process in initiation and propagation phases has been developing during the last forty years. The tendency is now to investigate crack growth of preexisting flaws and to neglect the crack initiation process. This method has been driven by the development of the fracture mechanics approach. Previously, the cycles-to-failure needed to completely separate the test specimens were reported, and no separation in crack initiation and crack growth life had been made.

For metals and alloys, two regimes of the fatigue phenomenon are generally considered--high-cycle fatigue and low-cycle fatigue.

High-cycle fatigue involves nominally linear elastic behavior and causes failure after more than approximately 100,000 cycles. As the loading amplitude is decreased, the cycles-to-failure increase. For many alloys, a fatigue (endurance) limit exists beyond 10^6 cycles. The endurance or fatigue limit represents a stress level below which fatigue life *appears* to be infinite upon extrapolation. However, fatigue limits from controlled laboratory tests (often limited from 10^6 to 10^8 cycles)

are not necessarily valid in application environments. For example, a fatigue limit can be eradicated by one large overload or the onset of additional crack-initiation mechanisms such as corrosion at the surface. Moreover, even though testing ceases at 10^6 or 10^8 cycles for practical reasons, it is known that fatigue limits cannot be extrapolated to infinity. In some cases, there may be a change in failure mechanisms at lives above 10^6 or 10^8 cycles.

Due to the nominally elastic behavior, dissipation is small and high-frequency testing at small amplitudes can be performed without causing self-heating of the specimen. In mechanical testing machines, frequencies up to 300 Hz are possible. Usual testing speeds, however, are below 100 Hz. At this frequency, approximately 8.6×10^6 cycles are accumulated per day. To impose 8.6×10^8 cycles, more than a hundred days of testing time at 100 Hz are required. It is therefore no surprise that fatigue data extending to more than 10^8 cycles are hard to find.

Stresses involving inelastic deformation so that a significant stress-strain hysteresis loop develops during cyclic loading lead to low-cycle fatigue failure, usually in less than 100,000 cycles. Cyclic inelastic deformation causes dissipation of energy, which can lead to significant self-heating of a specimen if a high frequency is used for testing. This is one reason why low-cycle fatigue testing is usually performed at frequencies below 1 Hz. Low-cycle fatigue investigations started in the 1950s in response to failures that were found in power-generation equipment. The problems were caused by frequent start/stop operations and thermal stresses induced by temperature changes.

The simultaneous advent of servocontrolled testing machines, using feedback control, clip-on extensometers, and computer control made testing relevant to the engineering problem at hand and established low-cycle fatigue testing as a separate discipline. Complex waveforms can be imposed in both displacement (strain) or load (stress) control; no backlash exists upon zero-load crossing with modern machines. Reliable stress-strain data are generated. Computer control and computer analysis of data permit a detailed correlation between deformation behavior and fatigue life.

Because of the nominally elastic behavior during high-cycle fatigue loading, cracks will initiate from defects such as inclusions, second-phase particles, and other stress concentrators, and inelastic deformation is restricted to these sites. Persistent slip bands, which cover a large area of the specimen gage section volume, are not to be expected because the nominal behavior is elastic in high-cycle fatigue loading. Therefore, initiation from persistent slip bands, which is the predominant mechanism for low-cycle fatigue crack initiation, can only occur in very few, highly stressed grains. These sites will become less frequent as the load amplitude is decreased. Defects are normally randomly distributed in a material and vary in their size and distribution from specimen to specimen. Therefore, crack initiation and propagation are not going to be identical in different specimens. A comparatively large scatter of high-cycle fatigue data is to be expected. The nominally inelastic deformation in low-cycle fatigue loading causes many persistent slip bands to develop. Crack initiation and propagation can be more uniformly distributed than in high-cycle fatigue loading. Therefore, the low-cycle-fatigue data scatter is expected to be less than that of the high-cycle-fatigue data.

Nomenclature. This article uses, unless stated otherwise, engineering stress σ and strain ε and cycles to failure *N*, where failure denotes separation of the test specimens. Results from constant amplitude, periodic loadings are the basis of most of the discussions.

A periodic loading of stress (sinusoidal, triangular, or other) is imposed, and test results are reported in terms of stress. In reference to Fig. 1, the maximum and minimum stress is designated by σ_{max} and σ_{min}, respectively. The mean stress σ_{mean} and the stress range $\Delta\sigma$ are given by (a tensile stress is introduced as a positive quantity and a compressive stress is defined as a negative quantity):

$$\sigma_{mean} = (\sigma_{max} + \sigma_{min})/2 \text{ and } \Delta\sigma = (\sigma_{max} - \sigma_{min}) \qquad \textbf{(Eq 1)}$$

respectively. The stress amplitude or alternating stress is $\sigma_a = \Delta\sigma/2$. The stress range and the stress amplitude are always positive; the mean stress can change sign. A completely reversed loading has zero mean stress.

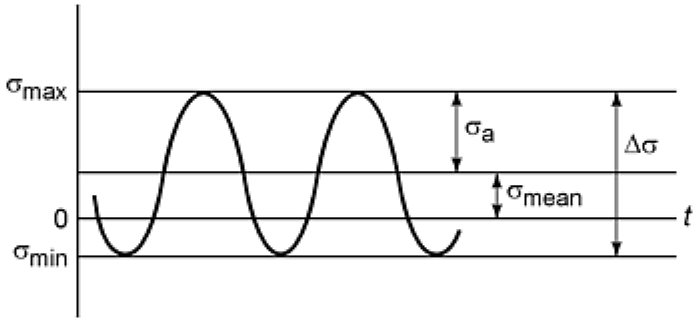

Fig. 1 Schematic showing the imposed periodic stress and the definition of terms

In addition to these quantities the *R*-ratio:

$$R = \sigma_{min}/\sigma_{max} \quad \textbf{(Eq 2)}$$

and the *A*-ratio:

$$A = \sigma_a/\sigma_{mean} = (\sigma_{max} - \sigma_{min})\ (\sigma_{max} + \sigma_{min}) \quad \textbf{(Eq 3)}$$

are used. A simple calculation shows that:

$$A = (1 - R)/(1 + R) \quad \textbf{(Eq 4)}$$

and that:

$$R = (1 - A)/(1 + A) \quad \textbf{(Eq 5)}$$

Either one of the three expressions σ_{mean}, *A*, or *R* can be used to describe the loading. For completely reversed loading $\sigma_{mean} = 0$, $R = -1$, and $A = \infty$; for tension/tension loading $\sigma_{mean} > 0$, $0 < R < 1$, and $A > 0$. Similar values hold for other types of loading that are less frequently employed.

Design for Fatigue Resistance

Erhard Krempl, Rensselaer Polytechnic Institute

High-Cycle Fatigue

To establish a fatigue curve several identical specimens are needed. The first specimen is subjected to a given loading intended to result in a number of cycles to failure. For the next specimen, the loading is either increased or decreased, and the number of cycles is observed again. In such a way the fatigue or endurance curves, also referred to as *S*-*N* curves, shown in Fig. 2, are established. The data are for steels and other metallic alloys subjected to completely reversed loading. The decrease of the maximum strength with cycles is evident for every alloy. For steels, the endurance limit, or fatigue limit--the stress below which no fatigue failure is expected no matter how many cycles are applied--is well pronounced.

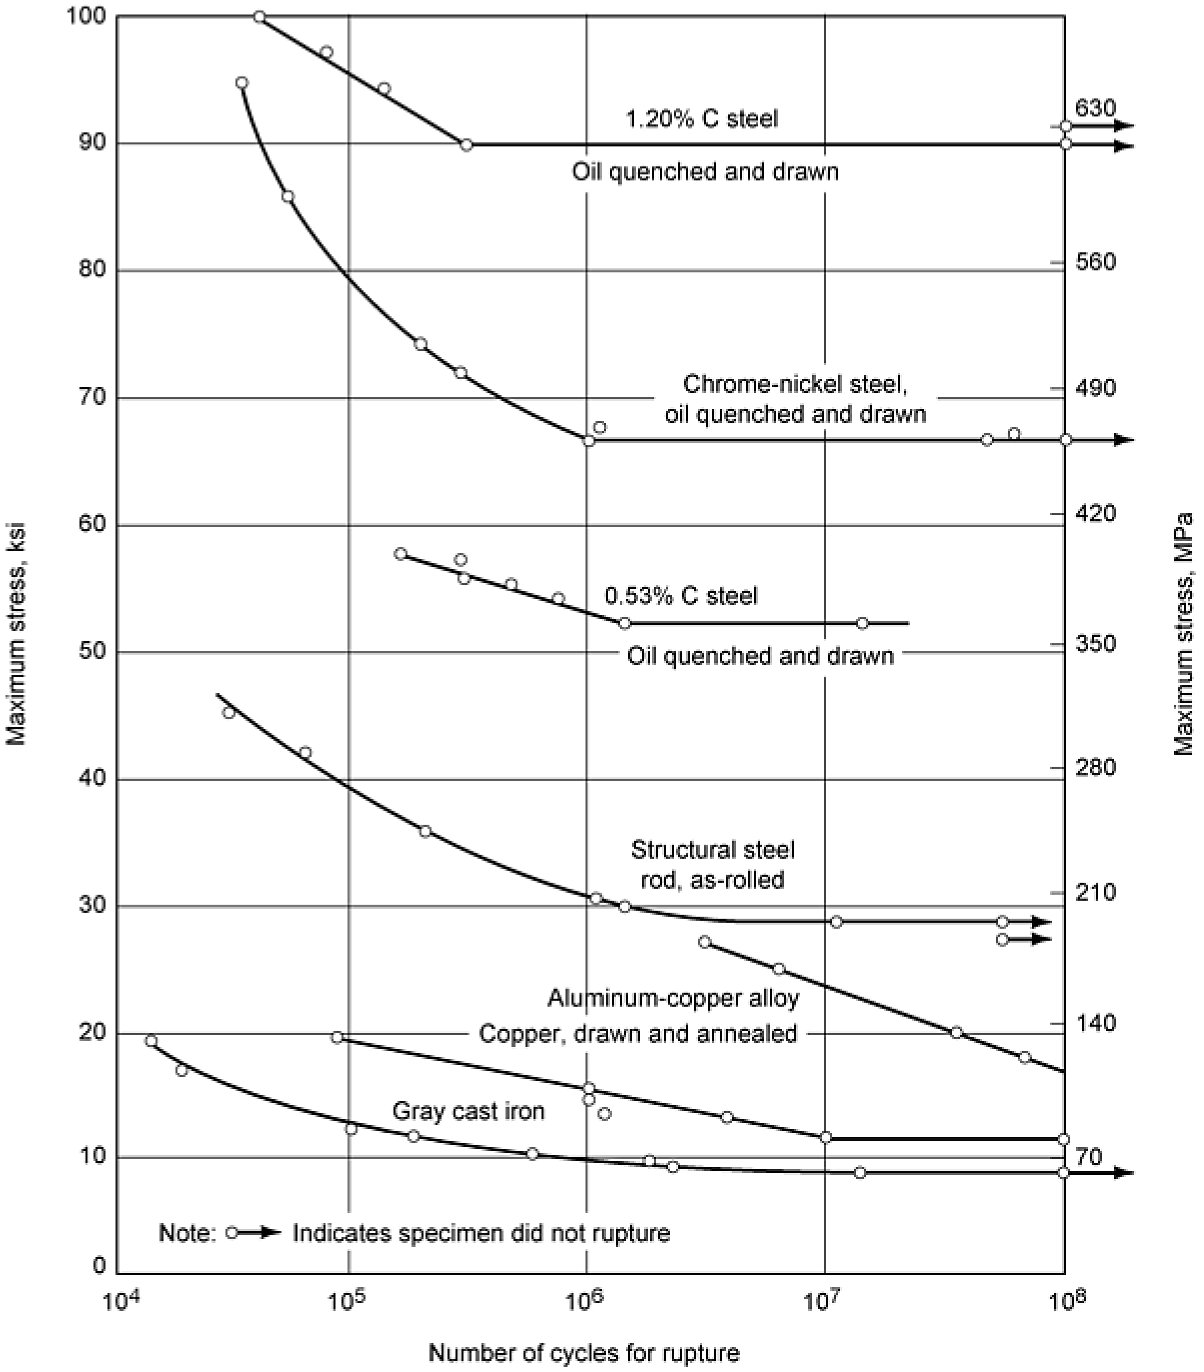

Fig. 2 *S-N* diagram for various alloys subjected to completely reversed loading at ambient temperature. The decrease in fatigue strength with cycles and the endurance limit of some steels is shown. Source: Ref 6

Under certain conditions, an endurance limit may be observed in steels at ambient temperature, but it may not be present at elevated temperatures, or may be eradicated with an overload or the onset of corrosion. In other alloys, such as age-hardening aluminum alloys for example, endurance limits at 10^8 cycles, are not observed. Thus, the endurance limit is not an inherent property of metallic alloys.

Fatigue Strength and Tensile Strength. Figure 2 clearly demonstrates that the fatigue performance increases with an increase in tensile strength. The increase of the fatigue strength with tensile strength (Fig. 3) is true for specimens with good surface finish and without stress concentrators and only up to a certain hardness where flaws do not govern behavior. In the presence of notches or of corrosive environment, the fatigue strength does not improve substantially with an increase of tensile strength. Notches and stress raisers are likely going to be present in actual components, and it may

not be possible to achieve the desired fatigue strength by selecting an alloy with increased tensile strength without changing the geometry.

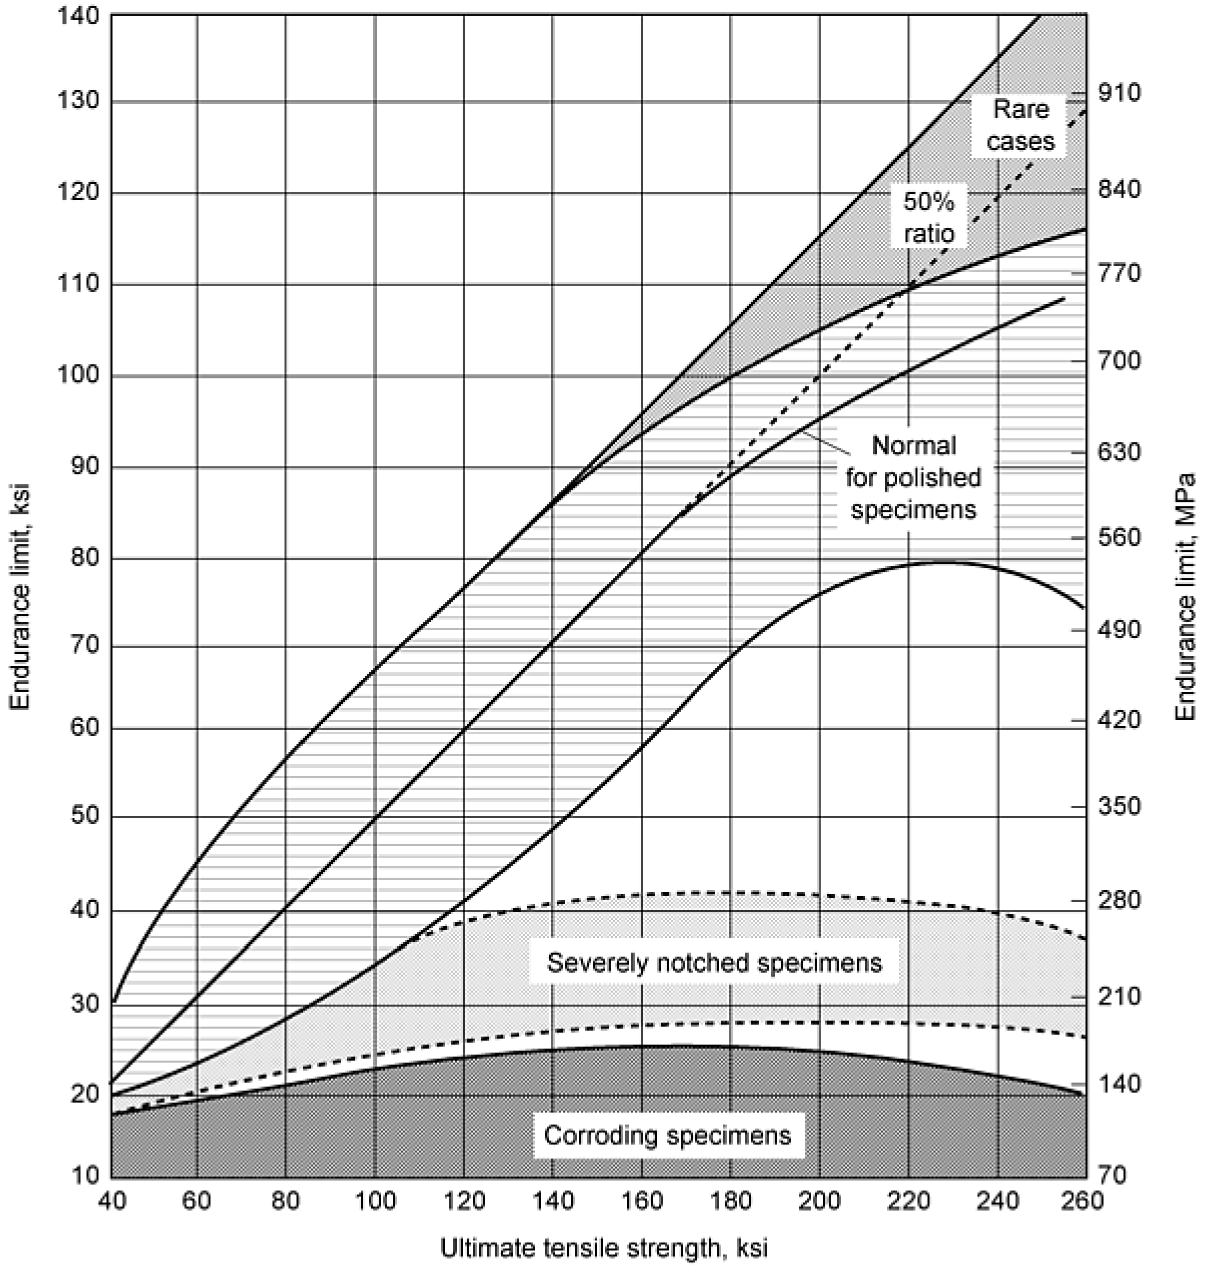

Fig. 3 The relation between fatigue strength and tensile strength of polished, notched specimens and of specimens subjected to a corrosive environment. Source: Ref 7

Figure 4(a) shows the relation between tensile strength and the fatigue strength for wrought steels, and it is seen that the endurance ratio (fatigue strength at the endurance limit or at a given number of cycles/tensile strength) is between 0.6 and 0.35. A comparable relation holds for aluminum alloys (see Fig. 4b) with the endurance ratio between 0.35 and 0.5.

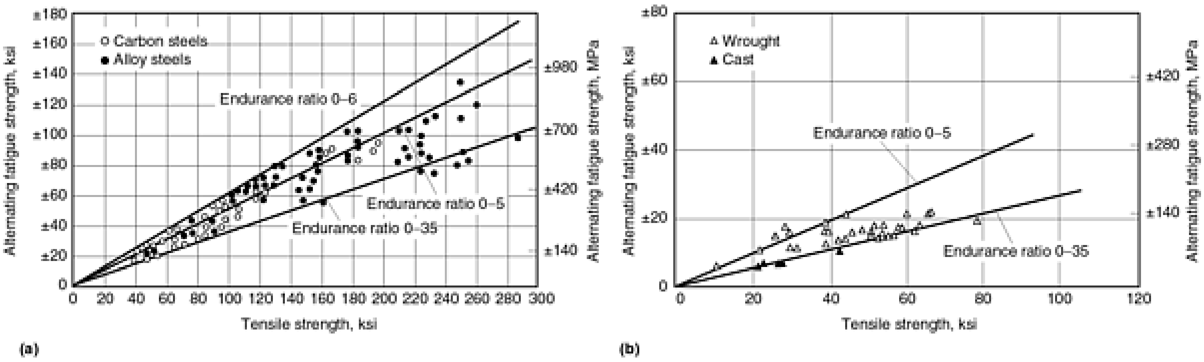

Fig. 4 Alternating fatigue strength in rotating bending (stress amplitude) and tensile strength. Wrought steels, fatigue strength between 10^7 to 10^8 cycles. Source: Ref 8

For steels, the fatigue strength at high number of cycles is approximately 50% of the tensile strength.

Data Scatter. For most of the fatigue curves in Fig. 2, only one test per stress level was performed and the fatigue (S-N) curve was drawn through these data points, giving the impression that there is a unique relationship between cycles to failure and fatigue strength. If more than one specimen is tested at the same stress level, so that the loading and testing conditions are duplicated within experimental accuracy, different cycles to failure will in general be found. It is then possible to plot a histogram of number of failed specimens in a certain cycle interval, as shown in Fig. 5. Normalization of the histogram is accomplished by dividing the ordinate by the total number of specimens, 57 in this case. Then the ordinate gives the percentage of specimens that fail at a given number of cycles to failure. This method of testing and plotting reveals that fatigue is associated with scatter. The scatter has been found in carefully performed tests and has been established as a basic property of the fatigue strength. (Note also the difference in the histogram when plotted on a linear and a log scale.)

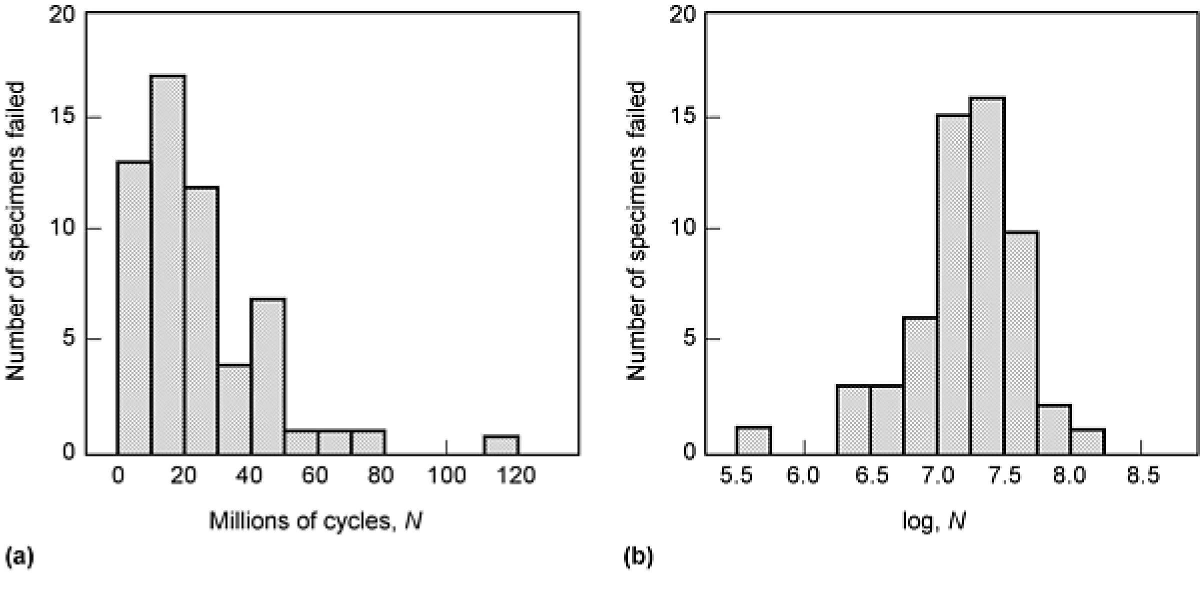

Fig. 5 Histograms showing fatigue-life distribution for 57 specimens of a 75S-T6 aluminum alloy tested at 30 ksi. Note the influence of a linear (a) or logarithmic (b) plot of cycles to failure *N* on the shape of the histogram. Source: Ref 10

To appreciate the effects of scatter it is advantageous to keep the relation shown in the schematic of Fig. 6 in mind. In this figure, a normalized histogram as shown in Fig. 5 is superposed on the fatigue curve at three different stress levels. The ordinates of the bell-shaped curves give the percentage of specimens expected to fail at a given number of cycles. The

peaks of the distributions can be connected by a fatigue curve. This curve would indicate the number of cycles to failure at which the largest percentage of specimens are expected to fail. If only a few tests are run, the results are expected to be close to this curve. The width of the band in Fig. 6 indicates that all specimens are expected to fail in this interval. The distributions become broader as the stress levels decrease, indicating an increase in scatter. The reason for this observation has been discussed in the section "The Fatigue Process" in this article.

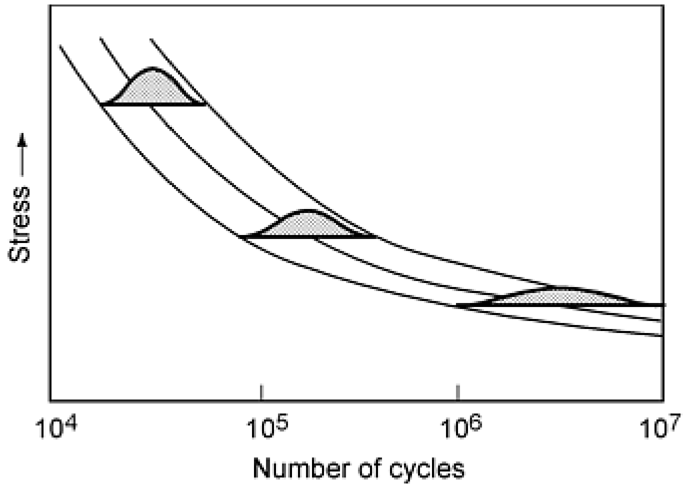

Fig. 6 Schematic showing the fatigue curve with the distribution of lives at three different stress levels. Note that the distribution widens as the stress level decreases. Source: Ref 11

It is possible to treat fatigue as a probabilistic process and to use methods of probability theory for design. However, a probabilistic design of components is prevalent if a large number of components are involved and is then part of a reliability analysis. In the majority of cases, a probabilistic fatigue design is not performed because of the expense and time involved in getting the data. However, it is always important to keep the nondeterministic nature of fatigue strength in mind. A discussion of probabilistic design methods for fatigue can be found in Ref 12, 13, and 14. Statistical analysis of fatigue data is described in Ref 15 and 16.

Mean Stress Effects. Fatigue life is affected by the presence of a mean stress as shown schematically in Fig. 7. A tensile mean stress reduces the life at a given amplitude and a compressive mean stress increases it.

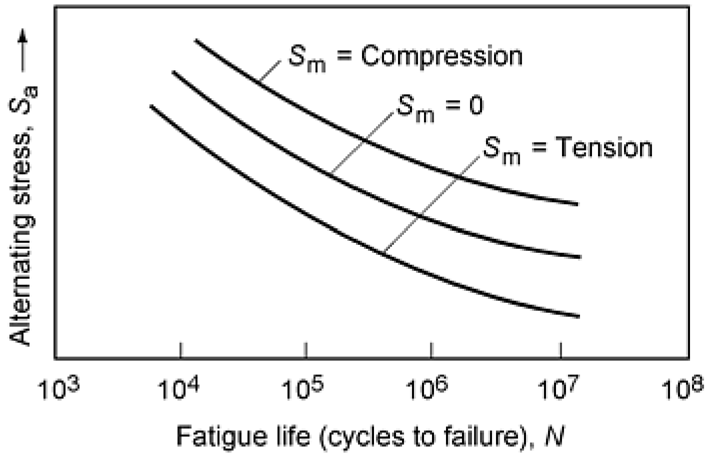

Fig. 7 Schematic showing the influence of mean stress on fatigue life. S_m, mean stress. Source: Ref 9

Test data, which most likely pertain to endurance or to a life around the endurance limit, for example, 10^8 cycles, are shown for steels and aluminum alloys in Fig. 8. The beneficial effects of a compressive mean stress and the deleterious

effect of a tensile mean stress are evident. It is interesting to observe that in this normalized plot very little difference exists between steels and aluminum alloys.

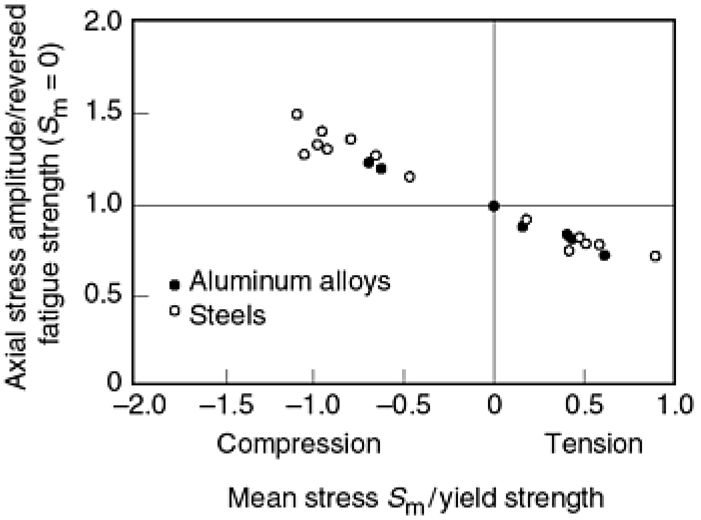

Fig. 8 The influence of compressive and tensile mean stresses on the fatigue strength amplitude of steels and aluminum and alloys. Source: Ref 17

Figure 9 shows constant fatigue-life diagrams from 10^4 to 10^7 cycles for smooth specimens (solid lines) and for notched specimens (dashed lines) for an age-hardened aluminum alloy. Both maximum/minimum stress coordinates and alternating/mean stress coordinates are used for plotting. In addition, lines of constant *A* and *R* ratios are also entered. The lines for the smooth specimens end at mean stress of 82 ksi, which corresponds to the ultimate strength of the aluminum alloy. In plotting the data, the authors have used the relationships given in Eq 1, 2, 3, 4, and 5. Although the diagram is very busy, it shows, in addition to the fatigue information, how the same data can be plotted differently.

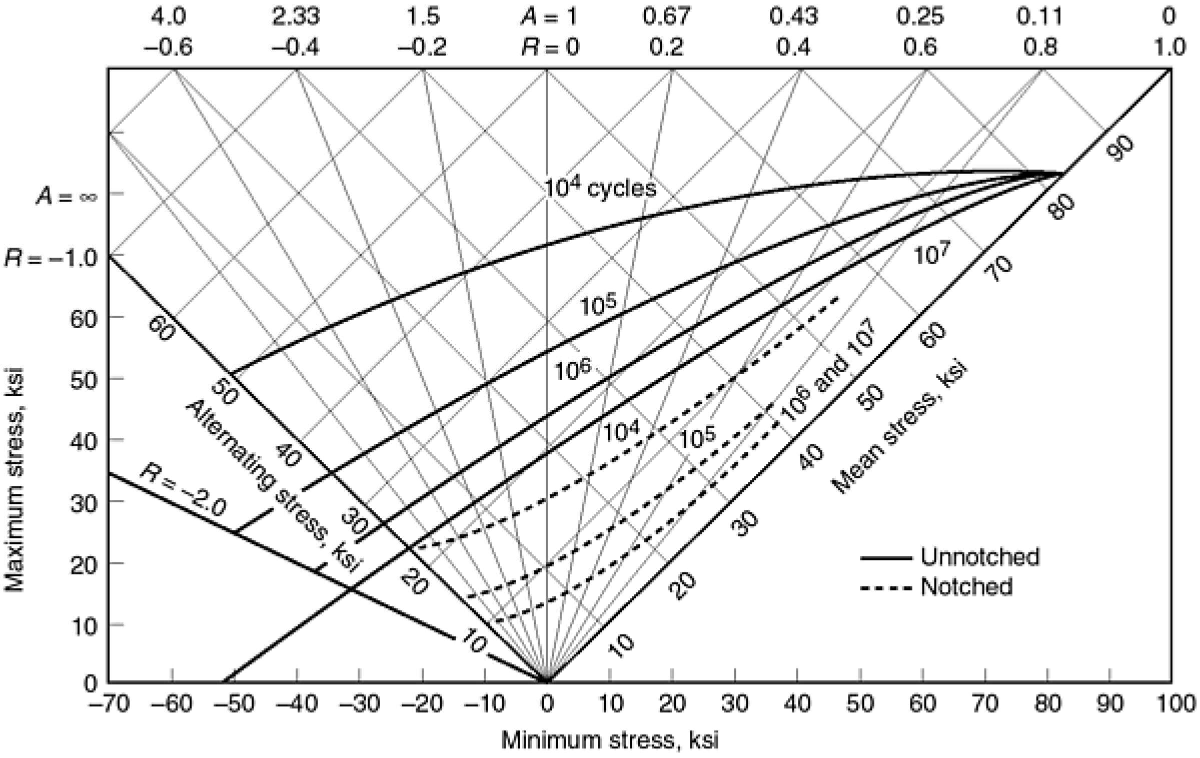

Fig. 9 Constant-life fatigue diagrams for unnotched (solid lines) and notched (dashed lines) 7075-T6 specimens

with an ultimate tensile strength of 82 ksi. The stress concentration factor for the notched specimens is K_t = 3.4. Data were obtained at 2000 cycles/min. 1 ksi = 6.895 MPa. Source: Ref 17

Figure 9 demonstrates again that for a given fatigue life the allowable amplitude decreases as the mean stress increases.

The influence of mean stress in high-cycle fatigue at the endurance limit is often predicted using only the engineering ultimate tensile or yield strength as shown schematically in Fig. 10. The fatigue strength amplitude for R = -1 is plotted on the ordinate and the ultimate stress and the yield strength are marked on the abscissa. Straight lines are then drawn to the endurance at zero mean stress. These lines are known as Soderberg and modified Goodman lines as seen in Fig. 10. The modified Goodman line is sometimes too conservative, and therefore the Gerber parabola is drawn as shown. Forrest (Ref 18) shows that the data fall largely between the Gerber parabola and the modified Goodman line. This empirical construction gives a good prediction of the mean stress effect for positive mean stresses.

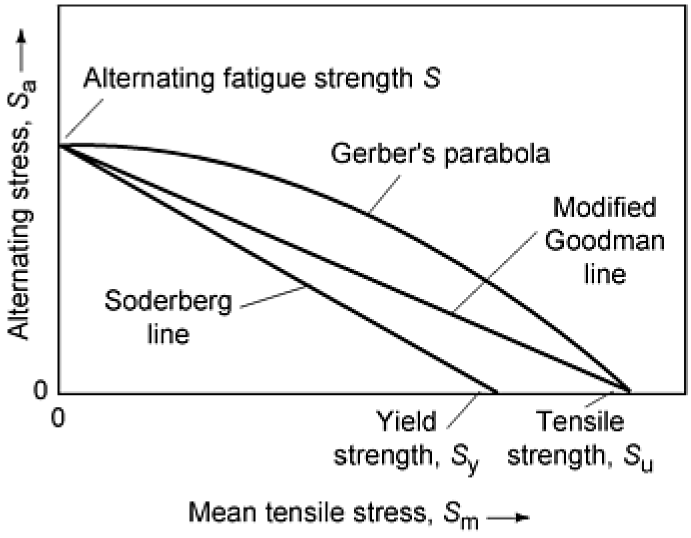

Fig. 10 Schematic showing the construction of Soderberg and modified Goodman lines and of the Gerber parabola. Note that this construction is a prediction of the mean stress influence on fatigue. Source: Ref 18

Stress Concentration. The equilibrium conditions of mechanics result in a constant stress for a bar of uniform cross section and loaded in the direction of the axis of the bar. In bending or torsion, a linear distribution of stress across the section is computed under the assumption of linear elastic behavior. For a real specimen, the actual distribution of stresses varies from grain to grain and at the grain boundaries and cannot be determined accurately, if at all, without knowing the exact location, the individual properties, and the orientations of the grains.

The average of the actual distribution must be equal to the stress derived from continuum analysis, and this average stress is used in calculations.

If changes in cross section occur in a component, the stress distribution calculated by elastic stress analysis is no longer uniform and no longer one-dimensional. An example of an actually calculated linear elastic stress distribution for a deeply notched bar under axial load P is given in Fig. 11. The graph is normalized and is valid for any material that exhibits linear elastic behavior.

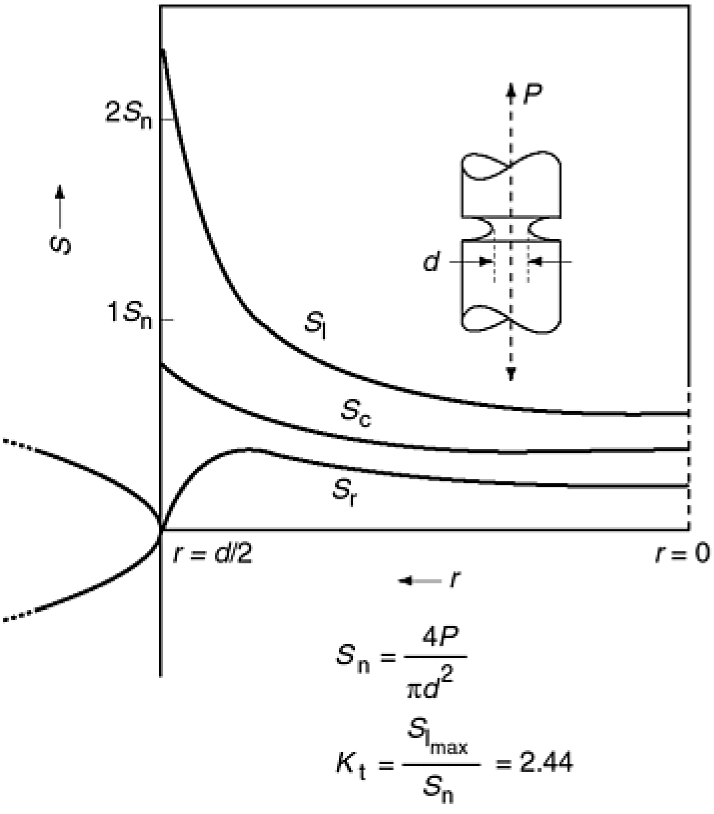

Fig. 11 Stress distribution in a deeply notched bar. S_l, S_c, and S_r are the longitudinal, the circumferential, and the radial stress, respectively. The nominal stress is given by $S_n = (4P)/(\pi d^2)$. Source: Ref 19

The principal normal stresses plotted are the longitudinal stress S_l, the circumferential stress S_c, and the radial stress S_r. The variation of these stresses are shown as a function of the radius. The distribution is symmetric to the center line at $r = 0$, and no shear stresses are present due to symmetry. The radial stress S_r is 0 at the notch root, and the state of stress is two-dimensional there but changes to a three-dimensional one in the interior. The longitudinal stress reaches its highest value in the notch root, which is 2.44 times the nominal stress S_n based on the minimum cross section. This geometry is said to have a stress concentration factor of 2.44. (The solution used in Fig. 11 is for a deep notch; the outer diameter is very large and need not be specified.)

The stress concentration factor K_t is defined as the ratio of the highest longitudinal stress over the net section nominal stress (sometimes the nominal stress is based on the unnotched section). It simply measures how many times the notch-root longitudinal stress is greater than the nominal stress. Effects of multiaxiality are not included.

For many geometries and simple loading cases the stress concentration factor has been determined, for example, in Ref 20 and 21. If in addition to the stress concentration factor the stress distribution is desired, it can be determined by experiments or by analysis, or, of course, by finite-element calculations.

The stress concentration factor does not give any information on the fatigue strength of a notched member. To find out how weakening the notch is going to be in cyclic loading, a fatigue test must be performed. As in the case of smooth specimens a fatigue curve is obtained. Using the smooth and the notched specimen data obtained under the same loading conditions a fatigue strength reduction factor K_f can be calculated by:

$$K_f = \left(\frac{\text{Smooth specimen strength}}{\text{Notched specimen strength}}\right)_{\text{at a given life}} \quad \textbf{(Eq 6)}$$

where the notched specimen strength is based on the nominal stress usually referred to the minimum cross section. Most of the tests are done for completely reversed conditions, but results with mean stress can also be analyzed as long as the

conditions for the smooth and the notched specimens are the same. In contrast to the stress concentration factor K_t, the fatigue reduction factor K_f is material specific.

The results shown in Fig. 9 permit the calculation of the fatigue strength reduction factor K_f based on stress amplitude (alternating stress) for several values of the mean stress at different cycles to failure. It can be seen that:

$$K_f \leq K_t \quad \textbf{(Eq 7)}$$

always. This has been found true in many other studies and a "fatigue notch sensitivity index" q is in use:

$$q = (K_f - 1)/(K_t - 1) \quad \textbf{(Eq 8)}$$

The index varies from 0 for a material with no notch sensitivity to full sensitivity if $q = 1$.

A conservative estimate for the fatigue strength reduction factor K_f is the assumption that it is equal to the stress concentration factor K_t or that $q = 1$.

This estimate is too conservative in some cases and does not consider the multiaxial state of stress in the notch root. Other, more complicated methods of predicting fatigue strength of notched members have been proposed: see Ref 3, 22, 23, and 24.

Multiaxial Fatigue. Components can be subjected to complex loadings in the presence of multiaxial states of stress and design methods must be developed for these conditions. Multiaxial fatigue tests are performed to elucidate the basic fatigue properties from which life-prediction methods can be derived. A thin-walled tube subjected to axial and torsional loading and bars subjected to bending and torsion are examples of possible specimens and loading conditions. As a first step, it is desirable to have a measure of stress that can correlate the data obtained under different conditions.

A thin-walled tube subjected to axial and torsional loading is considered to elucidate the approach. For the tube, the torque generates shear stresses τ, and the axial forces induces a normal stress σ in planes perpendicular to the axis. For a sinusoidal loading:

$$\begin{aligned} \sigma &= \sigma_0 \sin \omega t \\ \tau &= \tau_0 \sin (\omega t + \varphi) \end{aligned} \quad \textbf{(Eq 9)}$$

where the subscript 0 indicates amplitude and where ω and φ denote the frequency and the phase shift, respectively.

If the phase shift φ is 0, proportional loading is imposed. Fatigue curves can be obtained for axial and torsional loading and combined loading. Figure 12(a) shows a schematic plotting multiaxial fatigue results for constant amplitude, completely reversed loading. The usual *S-N* curves are obtained for axial and torsion loading. Iso cycles-to-failure curves are obtained for $N = 10^4$ and $N = 10^8$ cycles. They represent the combination of axial and shear stress that lead to failure in the stated number of cycles. These curves are replotted in Fig. 12(b).

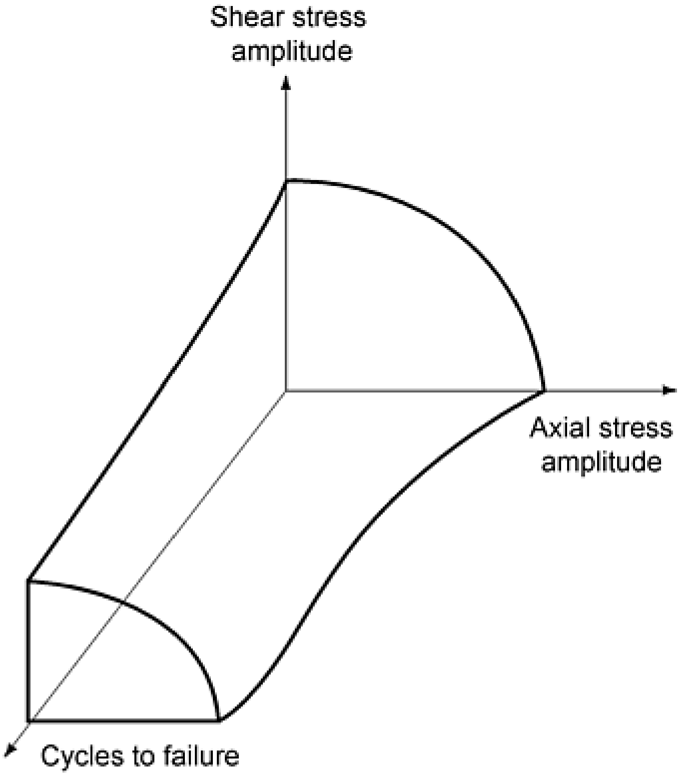

Fig. 12(a) Schematic showing *S-N* curves for multiaxial loading and surface and equal cycles to failure

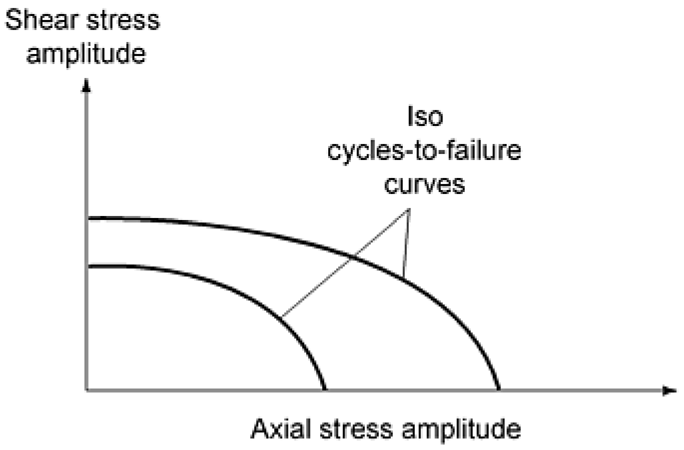

Fig. 12(b) The results of Fig. 12(a) replotted as iso-cycles-to-failure curves

A multiaxial stress criterion should be able to reproduce the iso cycles-to-failure curves shown in Fig. 12(b).

The von Mises or effective stress criterion is in indicial notation:

$$\bar{\sigma}^2\{N\} = \frac{3}{2}(\sigma_{ij} - \frac{1}{3}\sigma_{kk}\delta_{ij})(\sigma_{ij} - \frac{1}{3}\sigma_{kk}\delta_{ij}) \quad \text{(Eq 10)}$$

where σ_{ij} is the stress matrix, δ_{ij} is the Kronecker delta, and $\bar{\sigma}$ is the effective stress, which is a function of cycles to failure *N*.

If Eq 10 is specialized for the axial-torsion case, the equation of iso cycles to failure curves is given by:

$$\overline{\sigma}^2 [N] = \sigma_0^2 + 3\tau_0^2 \qquad \textbf{(Eq 11)}$$

It is seen that the von Mises criterion requires that the iso cycles to failure curves are ellipses that vary as a function of *N*. Other criteria, the Tresca criterion for example, result in different iso-cycle curves.

The von Mises criterion has been used as a model of a yield surface in plasticity. Plastic deformation is known to be insensitive to superposed pressure up to large pressures. As a consequence, Eq 10 would predict a 0 right-hand side for pure hydrostatic loading. Fatigue on the other hand has been shown to be sensitive to superposed hydrostatic pressure; see Ref 25 for a summary. Therefore, the von Mises criterion and other yield criteria are not suitable for correlating fatigue data on principal grounds. It is therefore not surprising that the use of yield criteria for correlating fatigue data has not always shown good results (see Ref 25). Despite these fundamental problems, the yield criteria continue to be used in design codes.

Loading with constant normal and shear stress amplitudes is assumed. Proportional loading is obtained for zero phase shift, $\varphi = 0$. It can be shown easily that in this case the planes of maximum shear stress amplitude are stationary. If, on the other hand, a phase shift between axial and shear loading exists, $\varphi \neq 0$, nonproportional loading takes place and the planes of maximum shear stress amplitude change during a cycle.

Because of the rotation of the planes of maximum shear stress in out-of-phase loading, $\varphi \neq 0$, there are more potential initiation sites in nonproportional than in proportional loading. Different fatigue lives are to be expected, even if axial and shear stress amplitudes are the same. This is indeed the case.

These and other observations and considerations have led to "critical plane approaches" (see Ref 26).

Additional overviews of multiaxial fatigue are given in Ref 27, 28, and 29. A review paper on multiaxial fatigue and notches is given in Ref 30.

Design for Fatigue Resistance

Erhard Krempl, Rensselaer Polytechnic Institute

Low-Cycle Fatigue

Low-cycle fatigue loading usually involves bulk inelastic deformation behavior, and a mechanical hysteresis loop develops between stress and strain. Low-cycle fatigue testing is performed at low frequencies, usually below 1 Hz. The demands of the application and the development of clip-on axial and diametral extensometers and of servocontrolled testing machines have established strain control as the standard practice in low-cycle fatigue.

Low-cycle fatigue investigation was in part prompted by component failures in the power-generation industry. These failures at stress risers (notches, fillets) were caused by few, repeated thermal stresses due to startup and shutdown operations. The elastically stressed neighborhood limited the strains of the inelastic deformation region associated with stress riser. The plastic zone is considered to be under strain control by the surrounding elastic material.

In testing, strain control eliminates potentially large strains caused by small errors in controlling the load and by the small tangent modulus in the plastic range. Strain-controlled testing limits the strains automatically.

Figure 13 explains the terminology used in low-cycle fatigue testing. The terms are essentially the same as shown in Fig. 1, except that strain is replaced by stress. As in the case of high-cycle fatigue, completely reversed testing is done in the majority of cases. In contrast to high-cycle fatigue where the deformation behavior is nominally linearly elastic, nonlinear, inelastic behavior is encountered in low-cycle fatigue testing. A hysteresis loop develops, and terms related to the stable hysteresis loop are explained in Fig. 14.

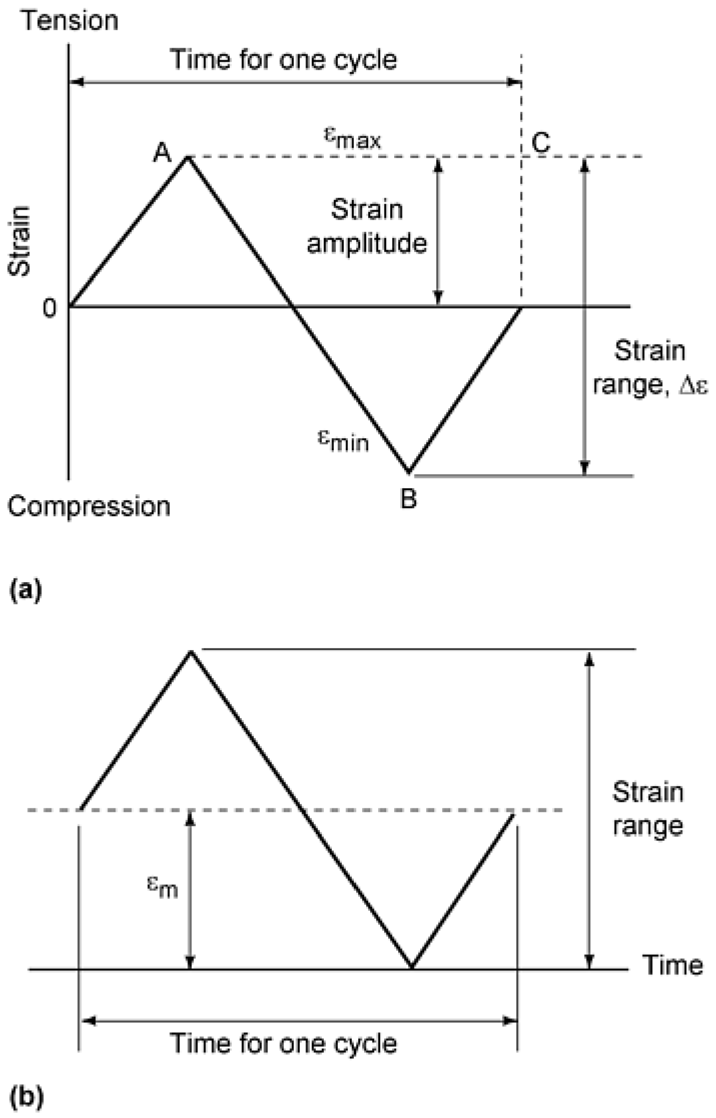

Fig. 13 Definition of terms in low-cycle fatigue testing. Source: Ref 31

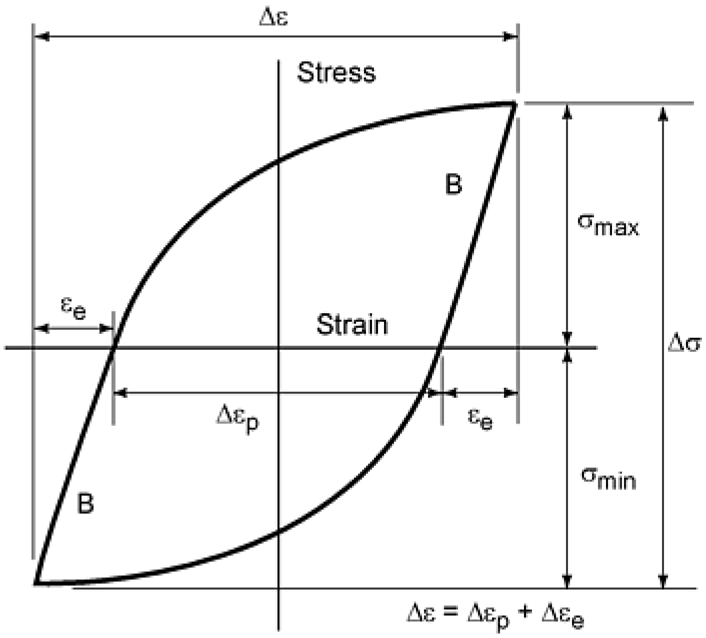

Fig. 14 Definition of terms related to the stable hysteresis loop. Source: Ref 32

Deformation Behavior

Figure 15 shows hysteresis loops for copper at three different levels of cold work. The curves on the left pertain to a fully annealed material (no prior cold work), and the stress range increases considerably. The increase of stress range diminishes from cycle to cycle, and finally the hysteresis loop is traced over and over again (not shown). A stable state, shakedown, a cyclic steady state, or cyclic neutral behavior has been reached.

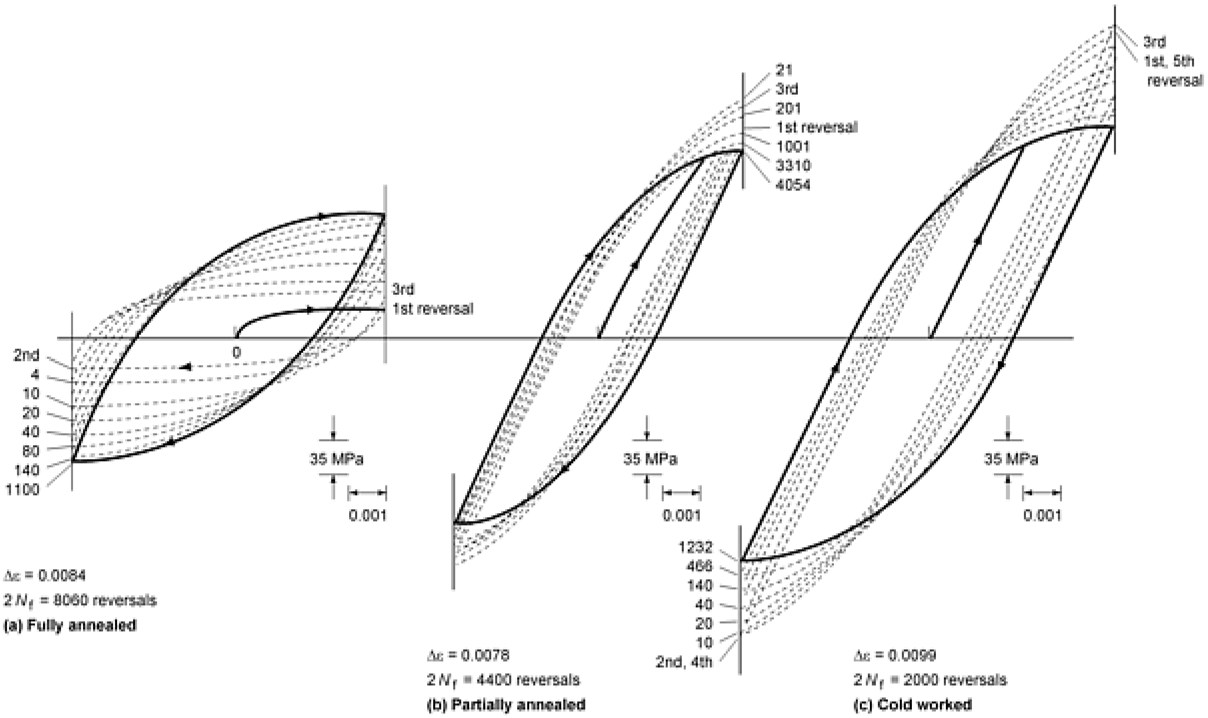

Fig. 15 Hysteresis loops for copper with varying degree of prior cold work. Source: Ref 33

The hysteresis loops of the partially annealed material reach a higher stress amplitude than the ones for the fully annealed material. Hardening continues and is followed by softening, a decrease in stress range (see the cycle numbers written on top right; the stress level at first reversal is higher than that at the 4054th). There may have been a quasi-steady-state between the 2000th and 4000th cycle, where the maximum stress changed very little when measured on a per cycle basis.

The fully cold-worked specimen, hysteresis loops on the right, cyclically softens, and the stress range decreases. The tests depicted in Fig. 15 were done in strain control. The strain amplitude was kept constant. All other quantities, the stresses, especially the stress range, and the plastic strain range (the width of the hysteresis loop at zero stress) can change with cycles. Figure 15 shows that these changes can be significant.

All dependent variables (all those that are not enforced, or controlled) can change in response to the internal microstructural rearrangements and are macroscopic indicators of such changes. If the hysteresis loop changes from cycle to cycle, a new material forms at each cycle, in principle. While the changes and therefore the differences in the material from cycle to cycle are small, they can be significant between the initial condition and steady-state condition.

Figure 15 illustrates a general trend found in cyclic inelastic deformation. Annealed materials tend to harden cyclically. In contrast, cyclic softening is observed in cold-worked materials. The trend is not always uniform; sometimes cyclic hardening (softening) is followed by softening (hardening). An example is given in Fig. 15 for the partially annealed specimen and in Fig. 16 for type 304 stainless steel. At the high strain ranges, cyclic hardening is observed followed by significant softening. At the low strain ranges the initial behavior is cyclic neutral and is followed by softening. It should

be noted that the initial behavior is for a small number of cycles only and that the drops in stress range appear exaggerated due to the vertical scale starting at 400 MPa.

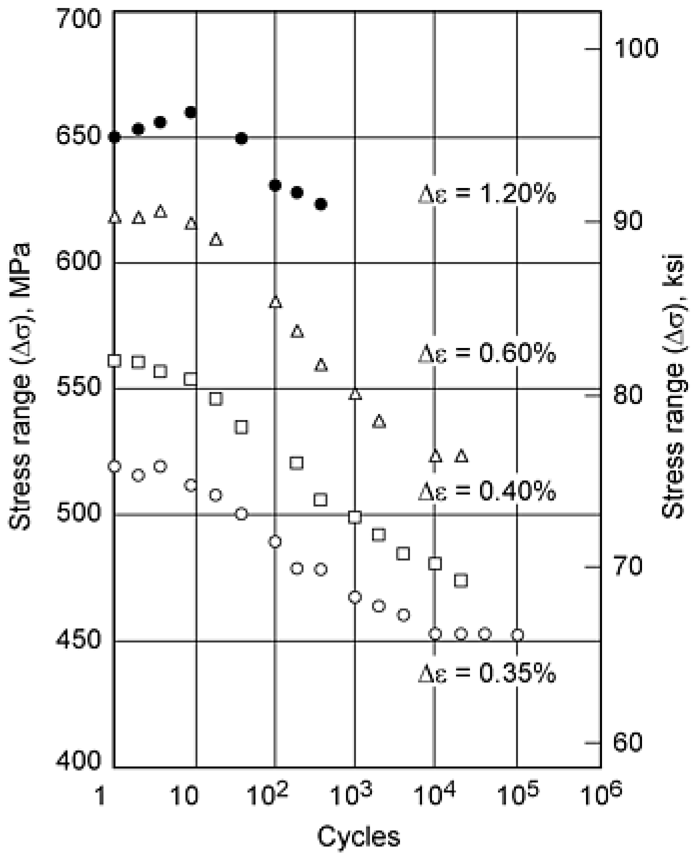

Fig. 16 Stress range versus cycles for type 304 stainless steel showing initial hardening or neutral behavior followed by softening. Source: Ref 34

Designers allow for the difference of a cyclically loaded material and the material when cycling started by constructing the so-called cyclic stress-strain diagrams. Here the stress amplitude at cyclic steady state, or, if such a steady state does not exist, the stress amplitude at half the number of cycles to failure is determined. The corresponding strain amplitude and stress amplitude are then entered into a stress versus strain diagram. Only a few points (around 5 points usually) are obtained this way, but they suffice in most cases to draw a cyclic stress-strain diagram. No significant microstructural changes take place for elastic cycling, and therefore the monotonic and the cyclic stress-strain diagram have the same elastic slope. Differences appear at strain amplitudes beyond the elastic range as shown in Fig. 17, where the monotonic and the cyclic stress-strain diagrams for six different engineering alloys are presented. When the cyclic curve is above (below) the monotonic curve, cyclic hardening (softening) is achieved. For many of the alloys, the cyclic curve is equal or above the monotonic curve.

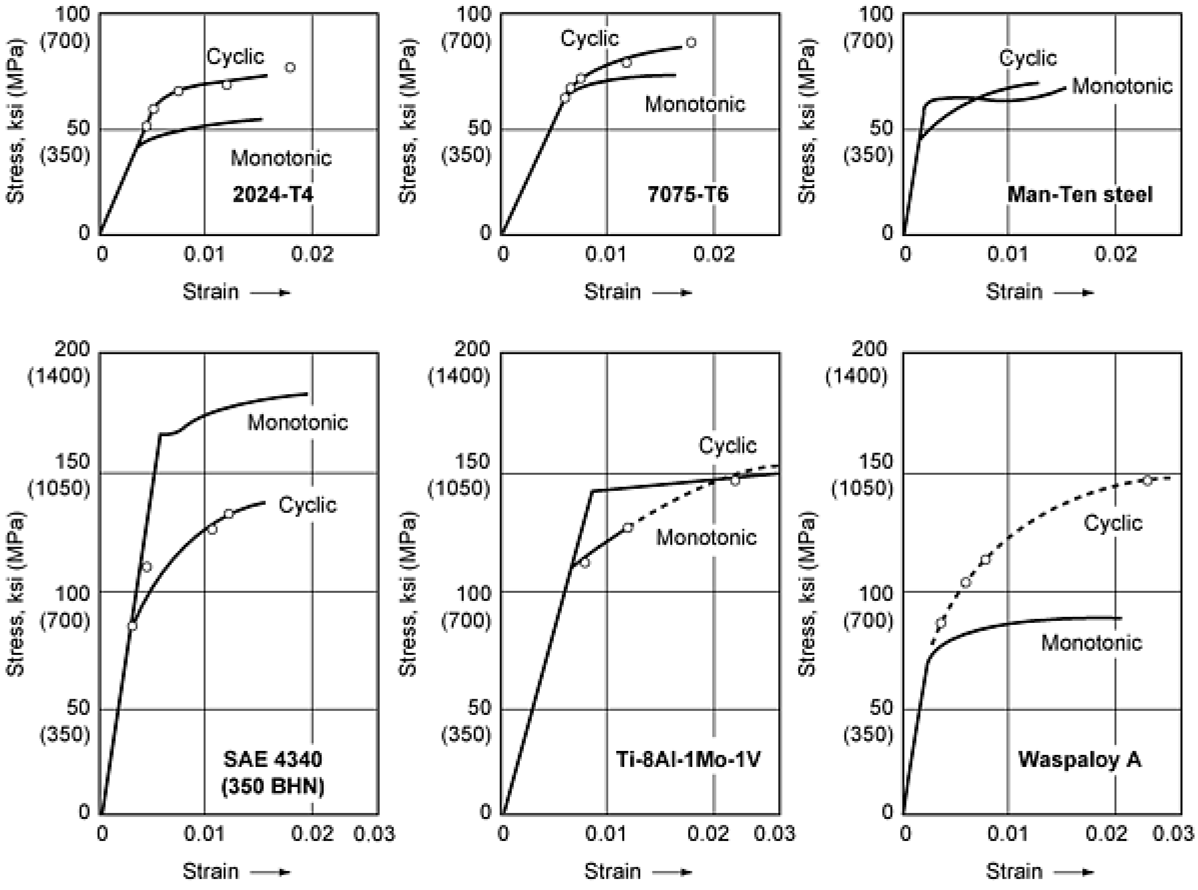

Fig. 17 Monotonic and cyclic stress-strain diagrams for six different engineering alloys. ○, companion specimens; solid line, incremental step. Source: Ref 35

For an analytical representation, the Ramberg-Osgood formula is used for both the cyclic and the monotonic stress strain diagram. For the monotonic case:

$$\varepsilon = \frac{\sigma}{E} + \left(\frac{\sigma}{K}\right)^{1/n} \quad \textbf{(Eq 12)}$$

and for the cyclic condition:

$$\frac{\Delta\varepsilon}{2} = \frac{\Delta\sigma}{2E} + \left(\frac{\Delta\sigma}{2K'}\right)^{1/n'} \quad \textbf{(Eq 13)}$$

where E and K are the elastic modulus and strength constant with dimensions of stress, respectively, and n is the dimensionless strain-hardening exponent. Primed quantities refer to the cyclic stress-strain diagram, and $\Delta\varepsilon$ and $\Delta\sigma$ denote the strain and stress range, respectively. Table 1, from Ref 38, gives typical data for some steels and some aluminum alloys.

Source: Ref 36, 37

Equations 12 and 13 are the simplest representation of stress-strain diagrams. They are only valid for monotonic loading. If the hysteresis loop and its evolution have to be described and modeled, incremental plasticity or unified state variable theories are needed (see Ref 39).

Fatigue Life

For design purposes, the strain amplitude or the strain range are plotted versus cycles to failure as shown in Fig. 18. Log-log coordinates are used, and the elastic and plastic contributions are shown. In addition, hysteresis loops are also drawn to show the nature of the deformation.

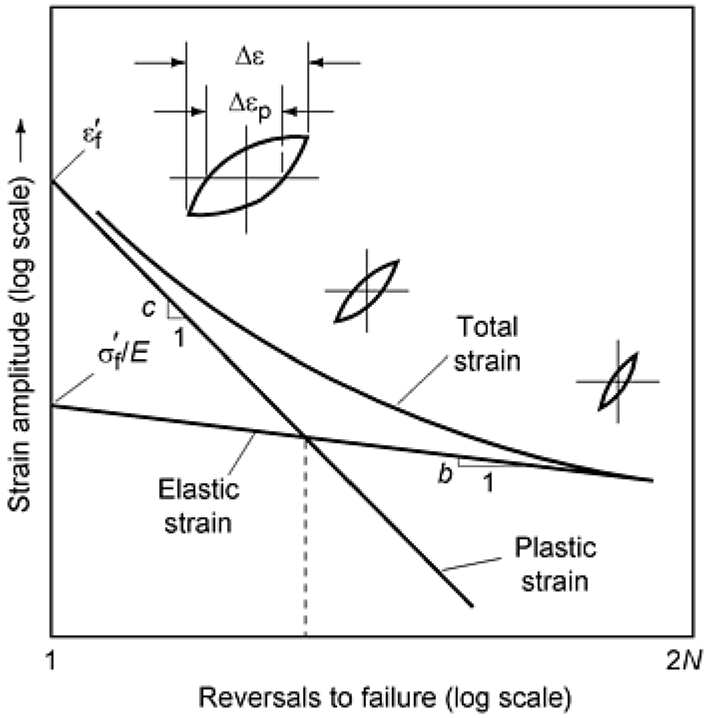

Fig. 18 Strain amplitude versus cycles to failure showing elastic and plastic contributions. Source: Ref 40

In high-cycle fatigue, cycles-to-failure referred to complete separation of a specimen. In low-cycle fatigue, it is customary to plot reversals to failure (2*N*) on the abscissa. In addition, cycles to failure does not designate separation of the specimen. In low-cycle fatigue, strain control is used. As the crack develops (it is assumed to occur within the extensometer gage length), the specimen becomes more and more compliant, and less and less load is required to reach the strain limits. With a large crack, the specimen could be cycled for a long time at very low stresses before complete separation, if any, is experienced.

Because of this uncertainty, cycles to failure are generally determined with regard to the stress response. When the maximum stress or sometimes the stress range is reduced by a certain percentage, usually 5 or 10%, the test is terminated and the specimen is declared to have failed.

The life-time curve is based on strain. It is described by postulating that the total strain range is the sum of the elastic and the plastic strain ranges:

$$\Delta\varepsilon = \Delta\varepsilon^{el} + \Delta\varepsilon^{pl} \quad \textbf{(Eq 14)}$$

and that each "component" is linearly related to the reversals-to failure on log-log coordinates as shown in Fig. 18. When these relations are substituted:

$$\frac{\Delta\varepsilon}{2} = \frac{\Delta\varepsilon^{el}}{2} + \frac{\Delta\varepsilon^{pl}}{2} = \frac{\sigma_f'}{E}(2N)^b + \varepsilon_f'(2N)^c \quad \textbf{(Eq 15)}$$

The quantities σ'_f and ε'_f are called fatigue strength coefficient and fatigue ductility coefficient, respectively, and are usually determined from tests, as are the dimensionless powers *b* and *c*.

Equation 15 was derived from the Coffin-Manson relationship, and the constants can be estimated from tensile tests, a test with one reversal (Ref 41). Table 1 gives the constants for selected steels and aluminum alloys. Extensive tabulations of these coefficients and exponents are given in Ref 43.

Figure 19 shows the details of the construction for a 4340 steel. The number of cycles to failure at the intersection of the elastic and plastic line is called the transition fatigue life.

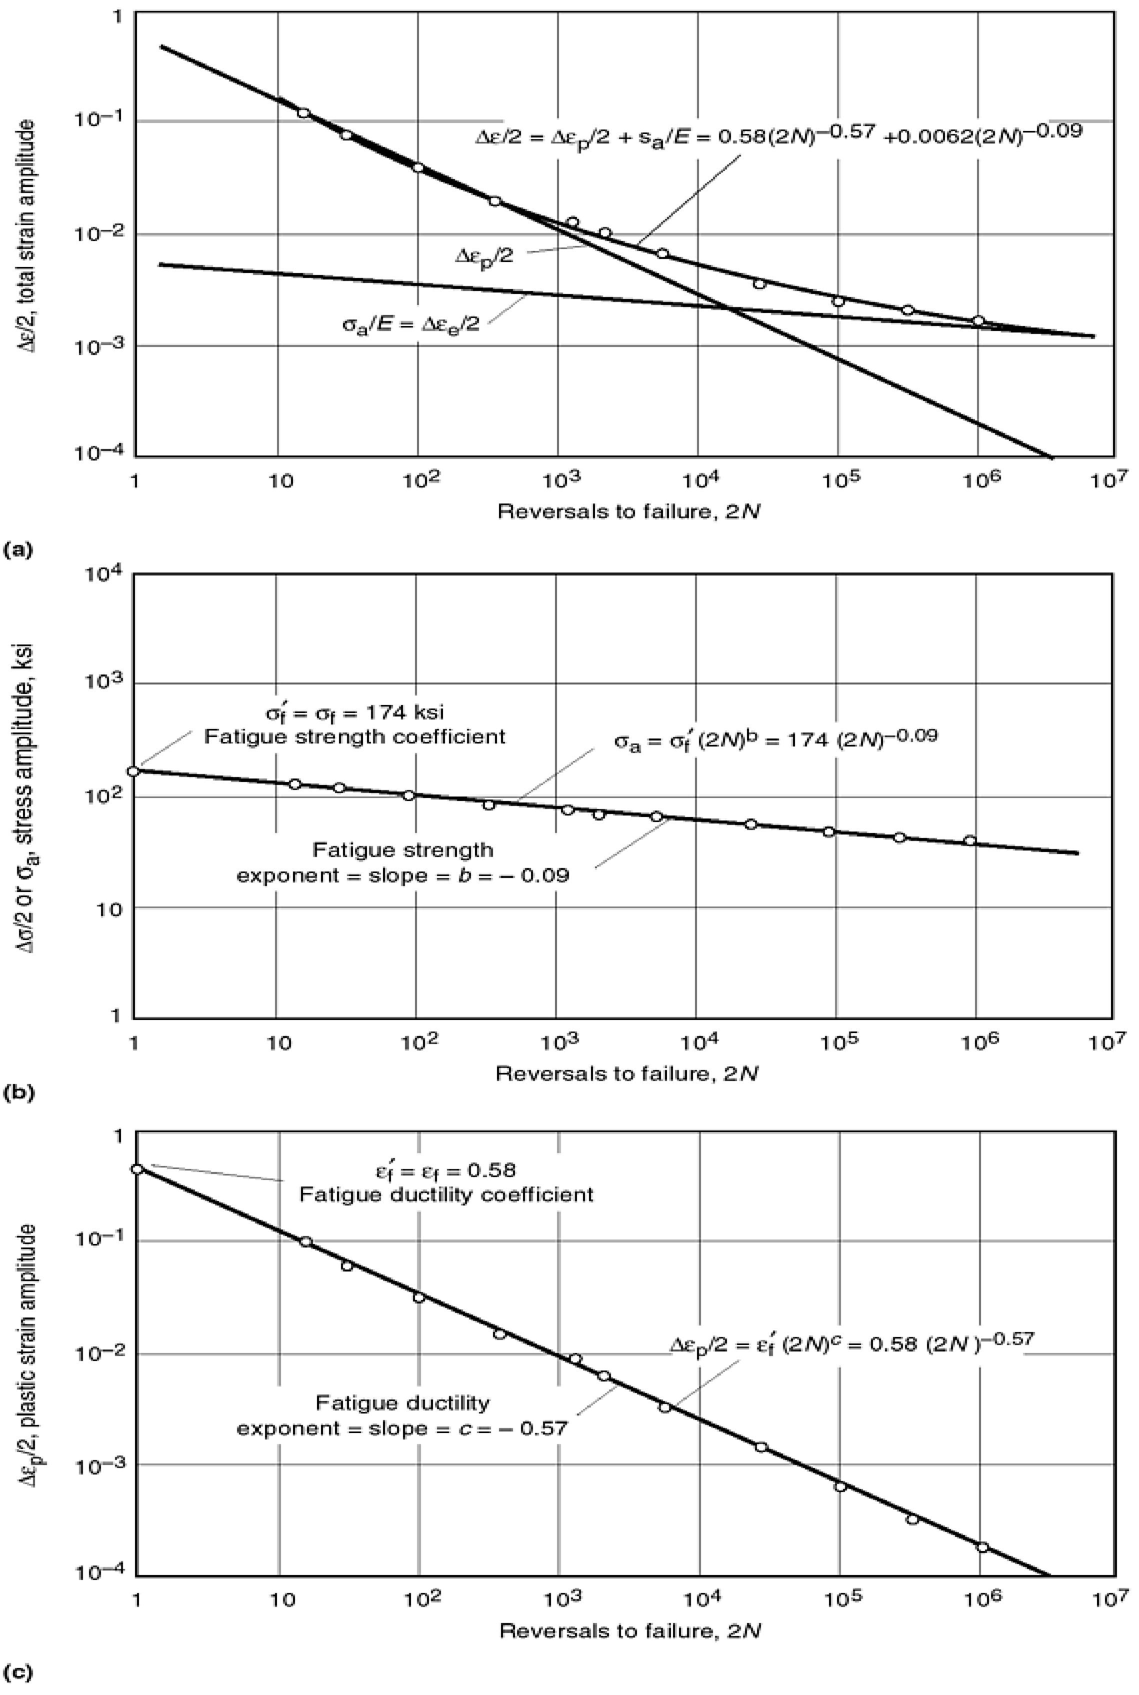

Fig. 19 Determination of the constants for the fatigue life curve for annealed 4340 steel. Source: Ref 42

A rule of thumb for ductile alloys at room temperature is that a fatigue life of 1000 cycles is reached at a strain range of 1%.

The transition from low-cycle to high-cycle fatigue is illustrated in Fig. 20 for specimens made from a carbon steel plate (Ref 44). Note that the data points at high number of cycles to failure are filled. This indicates that these tests were run in load control. They blend smoothly with the strain-controlled tests, and a fatigue curve ranging from 10^2 cycles to the endurance limit is obtained. (Clip-on extensometers for high strain ranges do not have the resolution to accurately measure and control small strain ranges. They also limit the frequency at which cycling can be done. After an initial adjustment period that determines the load range, the extensometer is taken off and the test is continued in load control.)

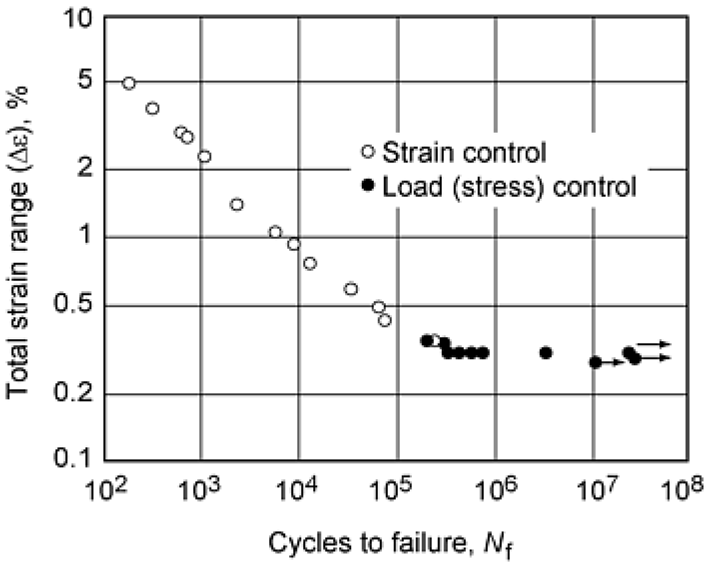

Fig. 20 Transition from low-cycle fatigue to high-cycle fatigue for carbon steel plate. Source: Ref 44

Notched Members

A first hypothesis for the calculation of the life to crack initiation in notched members is to assume that the maximum strain range in the root of the notch governs fatigue life. This hypothesis is called the strain approach to life prediction. It is widely accepted and used (see, for example, Ref 45).

Plastic deformation is involved, and the elastically calculated stress (strain) distributions are no longer valid. For the notch root, the axial strain (the strain in the direction of loading) increases whereas the axial stress decreases when inelastic deformation sets in. This is demonstrated in Fig. 21, where the plastic stress and strain distributions (labeled actual) for a given applied load are plotted. Note that the integral of the axial stresses over the cross section must equal the applied load to satisfy equilibrium. The actual stresses in the interior are higher than the elastic ones to compensate for the drop at the notch root (see Fig. 21). In contrast to elasticity where a single normalized stress distribution exists, the stress distribution varies with load in plasticity.

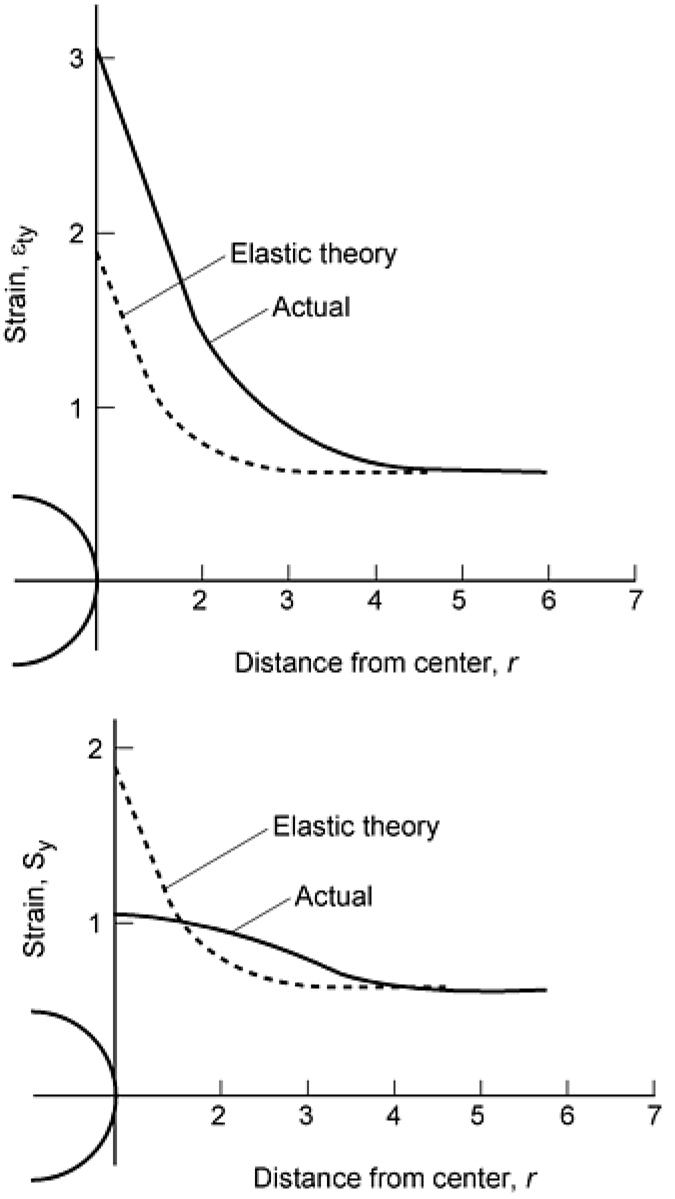

Fig. 21 Changes in the axial strain and stress distribution for elastic and plastic behavior. ε_{ty}, total yield strain; S_y, yield stress. Source: Ref 46

In elasticity, there is only one concentration factor and it is the same for every load in the elastic range. For plasticity, there is a strain and a stress concentration factor and they change with the applied load. Formally:

$$K_\sigma = \frac{\sigma_{max}}{\sigma_N} \qquad \textbf{(Eq 16)}$$

and:

$$K_\varepsilon = \frac{\varepsilon_{max}}{\varepsilon_N} \qquad \textbf{(Eq 17)}$$

where the subscripts max and N denote the value of the maximum axial component in the notch root and the nominal value (usually based on the minimum cross section), respectively.

Because of the redistribution of stress and strain, the strain concentration factor K_ε increases with nominal stress, whereas the stress concentration factor K_σ decreases (Fig. 22). The bifurcation at a nominal stress of about 15 ksi (103 MPa) is very well marked. A relationship similar to Fig. 22, but for an elastic stress concentration factor of 6 is given in Fig. 8.6 of Ref 28.

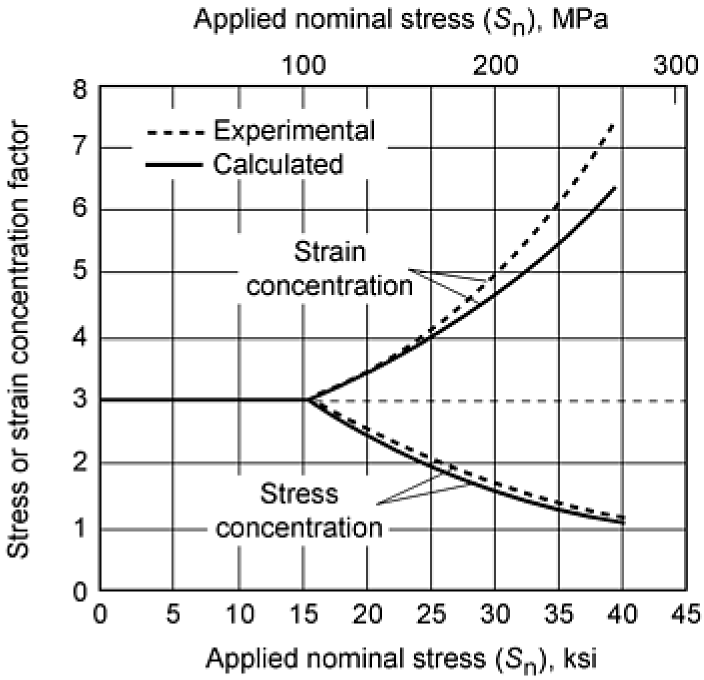

Fig. 22 The variation of the stress (strain) concentration factors with applied nominal stress S_n. Note that initially the stress and strain concentration factors are equal. They diverge as the nominal stress increases. Source: Ref 47

Two simplified procedures to determine the maximum strain in the notch root are given in Fig. 23. In each case, the cyclic stress-strain diagram and the smooth bar low-cycle fatigue curve are needed. Depending on the approach, the stress or the strain concentration factor must also be determined. The strain approach is mostly pursued in the published papers (for a review see Ref 3, 28, and 49).

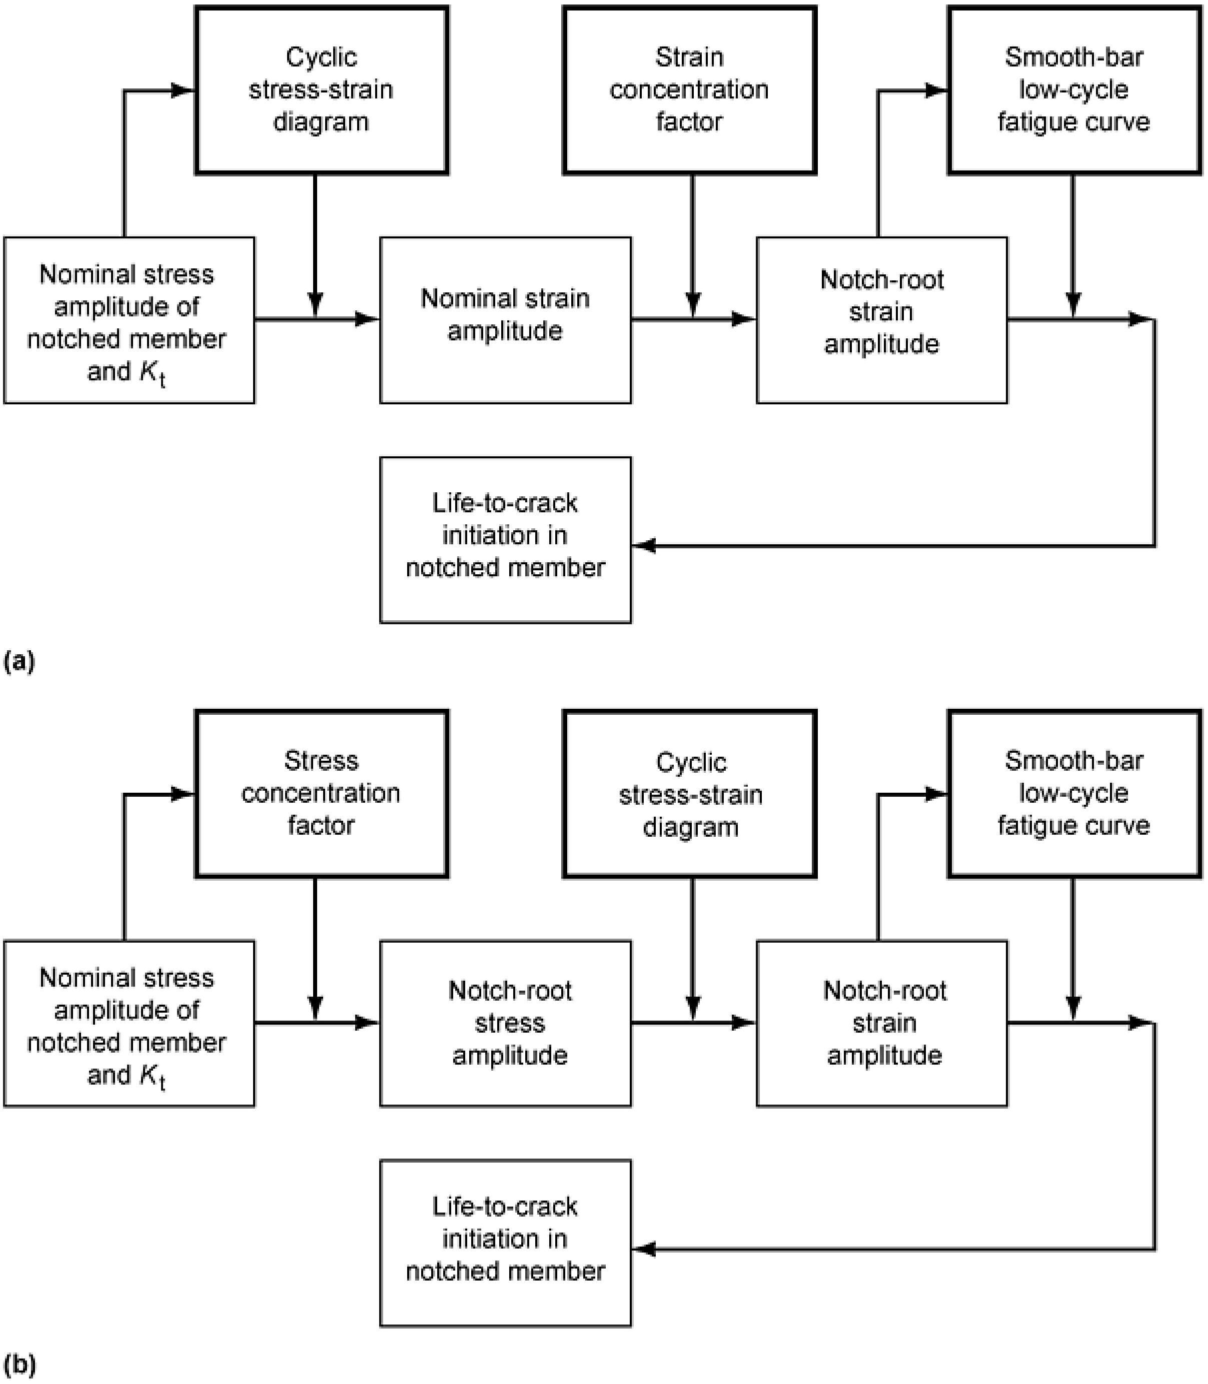

Fig. 23 Schematic showing how the life to crack initiation for notched members can be determined. (a) Strain approach. (b) Stress approach. Source: Ref 48

For the determination of the stress (strain) concentration factors the empirical Stowell-Ohman-Hardrath Method (Ref 49), or the approximate Neuber Method and variants are used (Ref 24, 28). The latter is preferred in applications.

The Stowell-Ohman-Hardrath Method yields (Ref 28):

$$K_\sigma = 1 + (K_t - 1)\frac{E_s}{E_N} \qquad \textbf{(Eq 18)}$$

where E_s and E_N are the secant moduli in a uniaxial stress-strain diagram evaluated at the maximum stress and strain and at the nominal stress and strain, respectively. They are given by $E_s = \sigma_{max}/\varepsilon_{max}$ and by $E_N = \sigma_N/\varepsilon_N$. From the definition of the stress and strain concentration factors, $K\sigma/K\varepsilon = E_s/E_N$. With this relation, the strain concentration factor is:

$$K\varepsilon = K_t - 1 + E_N/E_s \quad \textbf{(Eq 19)}$$

The strain concentration factor can be determined by an iterative solution using Eq 12 (or a stress-strain diagram) and Eq 19 (Ref 50).

The starting point for the Neuber Method is again the approximate relation:

$$K_t^2 = K\sigma K\varepsilon \quad \textbf{(Eq 20)}$$

This expression is freely applied to strain and stress ranges and to the cyclic stress-strain diagram to determine the notch root strain in a procedure similar to the one discussed above (see Ref 24).

These methods are all approximate and derived from empirical relations. Plasticity involves nonlinear behavior, and analytical solutions are only available for simple geometries. Elastoplastic finite-element methods are now available to calculate the maximum strain in the notch strain, analyses can be performed using the cyclic stress strain diagram.

For additional methods of the analysis of notched members and their life prediction, see Ref 24, 28, and 30.

Multiaxial Low-Cycle Fatigue

Deformation Behavior. The cyclic-hardening (softening) phenomena experienced in uniaxial loading are also encountered in multiaxial loading. While in uniaxial loading, the planes of maximum shear stress are stationary; this need not be the case for biaxial or multiaxial loading. This causes additional features of hardening to appear. Included are "extra" hardening in out-of-phase loading and sequence effects.

To demonstrate the latter tubular specimens of annealed type 304 stainless steel were cycled at an effective von Mises strain amplitude of 0.008 ($\varepsilon_e = (\varepsilon^2 + \gamma^2/3)^{1/2}$), where γ is the engineering shear strain at a constant effective strain rate of 3×10^{-4} 1/s. Pure axial cycling and pure torsional cycling tests were performed in the first and second test, respectively. In the third test, torsion and axial loading alternated. After each cycle, the stress and strain were returned to zero. The results were plotted using the von Mises effective stress:

$$\sigma_e = (\sigma^2 + 3\tau^2)^{1/2}$$

and the accumulated effective inelastic strain:

$$p = \int_0^t [(\dot{\varepsilon} - \dot{\sigma}/E)^2 + (\dot{\gamma} - \dot{\tau}/G)^2]^{1/2}\, d\eta$$

where τ is the shear stress, G is the shear modulus, and η is the integration variable. While the continuous cycling responses are reasonably correlated by the effective quantities, the intermittent axial/torsion test exhibits considerably more hardening, as seen in Fig. 24. Extrapolation of the hardening curves would indicate that the saturation stress level will be different for continuous and intermittent cycling.

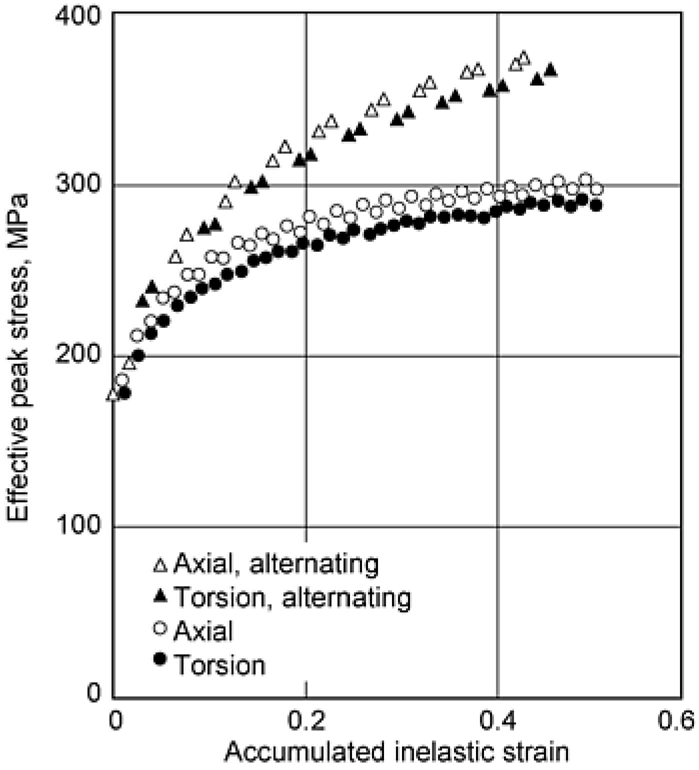

Fig. 24 Cyclic hardening of annealed type 304 stainless steel: Effective peak stress versus accumulated inelastic strain for pure axial and torsional cycling and intermittent axial/torsion cycling at an effective strain amplitude of 0.008. Source: Ref 51

The hardening is not only sequence dependent but also amplitude dependent as shown in Fig. 25. By plotting the results of uniaxial and 90° out-of-phase tests performed at different effective strain amplitudes, it is demonstrated that the hardening depends not only on the accumulated inelastic strain, but also on the amplitude. It is also observed that the 90° out-of-phase tests harden considerably more than the uniaxial tests. It is most interesting that the true effective stress in a tensile test hardens even more than the cyclic tests. In this case, the strain rate was cycled between 1.5×10^{-3} and 1.5×10^{-5} 1/s, which explains the steps in the graph.

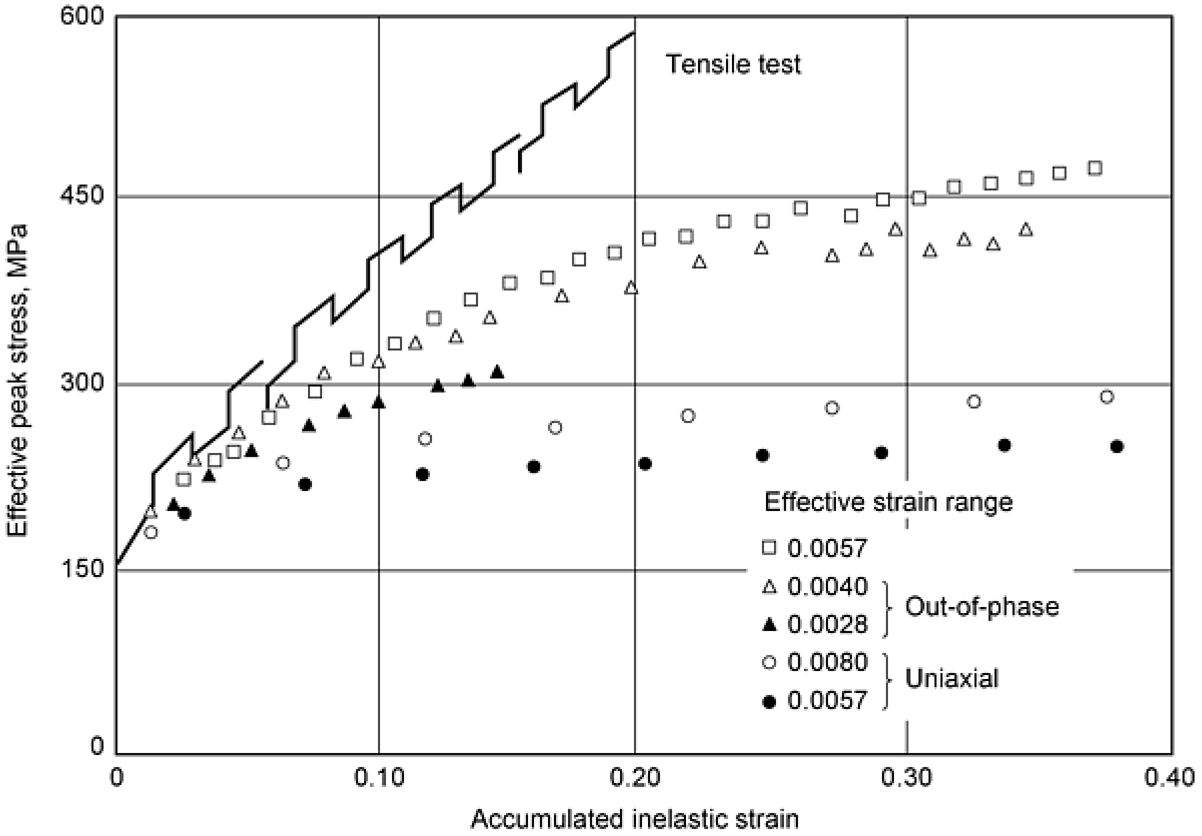

Fig. 25 Cyclic hardening of annealed type 304 stainless steel: True effective stress (for uniaxial monotonic loading with strain rate cycling between 1.5 × 10^{-3} and 1.5 × 10^{-5} 1/s), effective stress (uniaxial completely reversed strain controlled at two amplitudes and effective stress in 90° out-of-phase cycling (three amplitudes) versus accumulated inelastic strain. The effective strain rate is 3 × 10^{-4} 1/s in all cyclic tests. Source: Ref 51

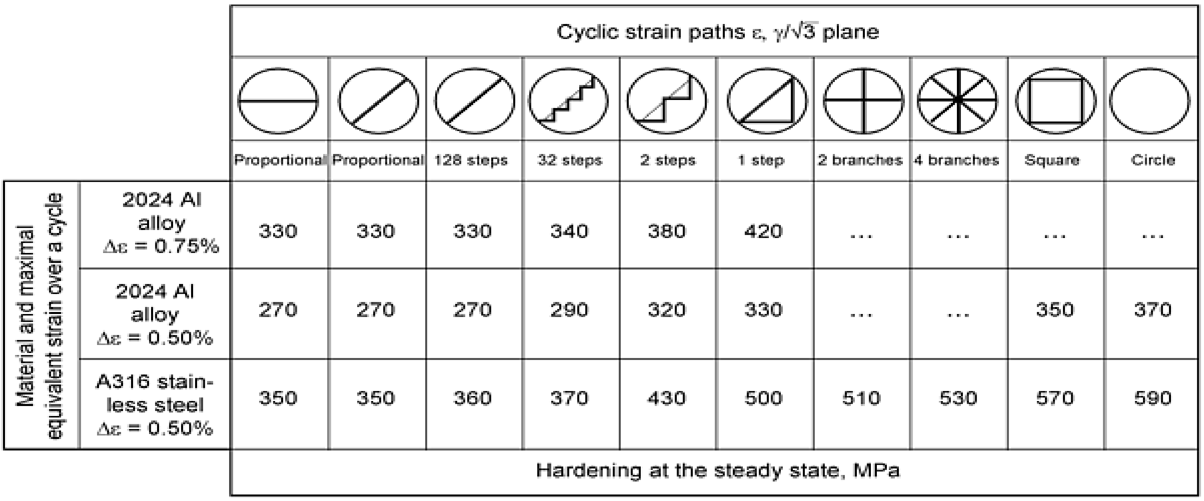
Finally, Fig. 26 demonstrates the path dependence of cyclic hardening for two materials. The top row has icons for the paths executed in strain control at the same effective stress amplitude as indicated in the left column. It is seen that the hardening as measured by the steady-state stress range is path dependent and that the 90° out-of-phase tests show the strongest hardening. The hardening that exceeds the one obtained in proportional loading is termed "extra hardening."



Material and maximal equivalent strain over a cycle	Cyclic strain paths ε, γ/√3 plane: Proportional	Proportional	128 steps	32 steps	2 steps	1 step	2 branches	4 branches	Square	Circle
2024 Al alloy Δε = 0.75%	330	330	330	340	380	420	...	...	...	...
2024 Al alloy Δε = 0.50%	270	270	270	290	320	330	...	...	350	370
A316 stain-less steel Δε = 0.50%	350	350	360	370	430	500	510	530	570	590
	Hardening at the steady state, MPa									

Fig. 26 The path dependence of cyclic hardening type 316 stainless steel and of 2024 aluminum alloy. It is seen that the hardening is path dependent and that the 90° out-of-phase loading generates the highest steady

stress range, the highest extra hardening. Source: Ref 52

The "extra hardening" is observed in annealed copper and stainless steels, but not all alloys investigated so far exhibit this effect. It appears that cyclic neutral materials do not (Ref 53). The almost cyclic neutral, age-hardenable, isotropic superalloy B1900 + Hf did not exhibit extra hardening at two elevated temperatures (Ref 54). Also, aluminum is reported to exhibit no extra hardening (Ref 55). This author is not aware of any investigation using cyclic-softening alloys in multiaxial loadings involving different strain paths.

A review of the microstructural investigations associated with multiaxial loading is presented in Ref 56. They report on the microstructural reasons of the "extra hardening" referred to as overstrengthening.

It is comparatively easy to model the effects of biaxial loading in the absence of extra hardening (Ref 57). However, the modeling of extra hardening has not been satisfactorily accomplished. For a review, see Ref 58. An energy-based approach is championed in Ref 28.

Even if finite-element calculations are used to calculate the cyclic response, an accurate modeling of these extra-hardening effects cannot be expected because a completely satisfactory constitutive model is not available. (For a finite-element model to be realistic, the appropriate material description has to be implemented into the program.)

Fatigue Life. Because out-of-phase loading can reduce the fatigue life by more than a factor of ten (Ref 59) and because it is assumed that the strain history determines fatigue performance, it is important to capture the actual strain history in a component or specimen. Increasingly, finite-element analyses are used to obtain the desired strain ranges and mean strain and stresses.

As in the uniaxial case, strain-based approaches are preferred in multiaxial low-cycle fatigue-life prediction. Rather than relying on strain invariants, such as effective strain or maximum shear strain, for correlation and prediction of multiaxial low-cycle fatigue life, the trend in the 1970s shifted to strain-based "critical-plane" approaches, which according to Ref 60, made the connections between fatigue crack initiation on specific planes on the surface of the material and the maximum shear strain range and/or normal strains on these planes. An overview is given in Ref 61 for constant amplitude loading. This approach deals in essence with the life to crack initiation, and crack growth is not included. Increasingly, the activity shifts toward inclusion of crack propagation in life prediction (Ref 62, 63).

According to Ref 64, multiaxial fatigue is best understood by examining crack propagation mechanics, because it is the physical growth of cracks that controls damage accumulation. This trend will undoubtedly continue, and the crack initiation and crack-propagation methods will have to be merged to arrive at a "complete" life-prediction method.

Thermal Fatigue

Many components in the power-generation and propulsion industry are subjected to the simultaneous action of mechanical loads and changing temperature. Examples are turbine blades and their coatings, first-stage shells in turbines and brakes of airplanes, cars, and railroads. In recent years failures of solder joints of electronic packages have been reported that can be attributed to thermal fatigue and are caused by the changing temperature in the devices.

Thermal cycles occur less than a few ten thousand times during the lifetime of the components. Frequently, the thermal stresses set up by these temperature changes can exceed the elastic region and inelastic deformation takes place. (At high temperatures, the linear elastic region may not exist and inelasticity can always be present.) After return to ambient temperature, residual stresses are present. Due to repeated cycles and due to the inelastic deformation, a low-cycle fatigue situation exists and cracking is experienced, especially at stress raisers, within the design lifetime of the component.

In many cases, the assumption is made that the life under thermal and mechanical cycling can be predicted by using the isothermal low-cycle fatigue life at the maximum temperature of the cycle. There is, however, no guarantee that this method leads to a conservative prediction.

Although thermal fatigue testing is more elaborate than isothermal low-cycle fatigue investigations, it can be performed using the test setup used in isothermal low-cycle fatigue tests. Suitable heating (induction heating is used mostly) and cooling facilities (mostly pressurized air) must be added. It should be mentioned that thermal fatigue investigations preceded isothermal low-cycle fatigue.

The lifetime analysis is also based on a strain approach as in low-cycle fatigue, and the methods of life prediction are similar.

Further details can be found in Ref 65, a recent, comprehensive overview.

High-Temperature Behavior

It is best to use homologous temperature θ (the ratio of test temperature over melting temperature, both measured in degrees Kelvin). For structural applications, θ is below 0.5. Higher homologous temperatures are used in processing.

High-Cycle Fatigue

In general, high-cycle fatigue strength is decreased as the temperature increases. This is demonstrated in Fig. 27, where most of the data show a decrease in fatigue strength with increasing temperature. There are, however, exceptions. The fatigue strength of 0.17% C steel has a maximum at about 350 °C. High-strength cast iron also exhibits an increase of fatigue strength with temperature before the decrease begins.

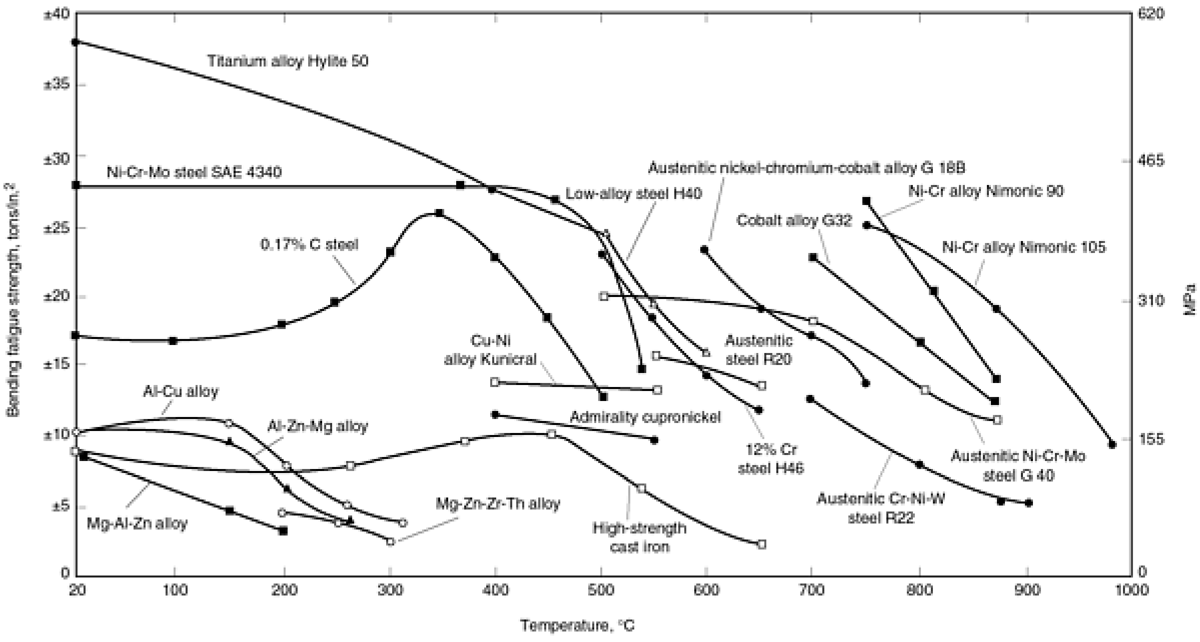

Fig. 27 The influence of temperature on the 10^7 cycle fatigue strength in bending. Source: Ref 22

This anomalous behavior is most likely caused by dynamic strain aging. According to Ref 66, when solute atoms are sufficiently mobile to catch up with mobile dislocations, a particular dynamic interaction takes place. Whenever this phenomenon is present, it tends to produce behavior that is opposite to the one expected; for example, the fatigue strength increases with a temperature increase. Strain aging is confined to certain temperature ranges that depend on the alloy, and "normal" behavior is frequently found outside these temperature ranges.

The results presented in Fig. 27 are for completely reversed bending. There is a mean stress effect at high temperatures that can deviate from the one shown in Fig. 8, 9, and 10. An example of such behavior is given in Fig. 28 for S-816 unnotched and notched specimens at three different temperatures at 2.16×10^7 cycles or 100 h life.

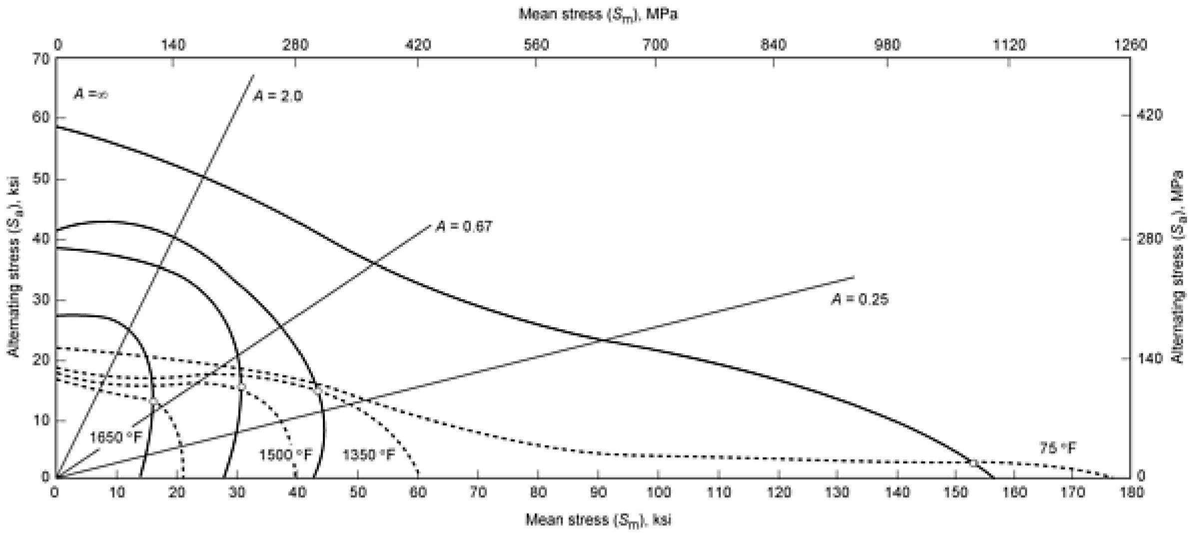

Fig. 28 Mean stress effects at high temperature for notched K_t = 3.4 (dashed lines) and unnotched (solid lines) specimens of S-816 alloy for 2.16 × 10^7 cycles or 100 h. Source: Ref 67

When a static stress is applied at high homologous temperature, creep and creep rupture can be experienced at stress levels below yield. This is not the case at low homologous temperature. Creep must be considered as an additional failure mechanism at high homologous temperature. To construct the diagrams showing the influence of mean stress, the following practice is adopted. An iso-time procedure is followed. The creep rupture strength corresponding to the time it takes (in this case 100 h) to complete the specified number of cycles to failure (in this case, 2.16 × 10^7 cycles) is entered on the abscissa if it is less than the yield strength. The abscissa then represents the creep rupture strength in most cases.

It is seen in Fig. 28 that the iso-cycles curve have a tendency to bow out; the presence of an alternating stress can allow for an increased mean stress when compared to pure static loading. This behavior is frequently observed at elevated temperature. (Compare with Fig. 9 to see the difference.)

When the notched and unnotched results are compared, it is seen that the rule of thumb expressed in Eq 7 is still valid. This result corresponds to other findings.

Low-Cycle Fatigue

Deformation behavior is characterized by the presence of rate (time)-dependent effects that are found in addition to plasticity. The majority of tests are conducted in strain control to simulate the effect of elastic stress fields surrounding inelastically deformed regions in the vicinity of stress raisers.

After initial changes from idle to operating conditions with attendant increases in temperature, steady-state conditions are reached for power-generation equipment, jet engines, and other high-temperature components. The power output and the temperature are nearly constant. During these times, creep processes will be operative that contribute to the damage inflicted on the material.

Hold or dwell times at constant strain are introduced in testing to simulate these periods of nearly constant power output. In strain control, relaxation sets in and the stress decreases. The amount of stress decrease changes from cycle to cycle and may not reach a steady-state condition.

A schematic showing the imposed strain conditions, the resultant stress response, and the crossplot of input and output--the hysteresis curve--is shown in Fig. 29.

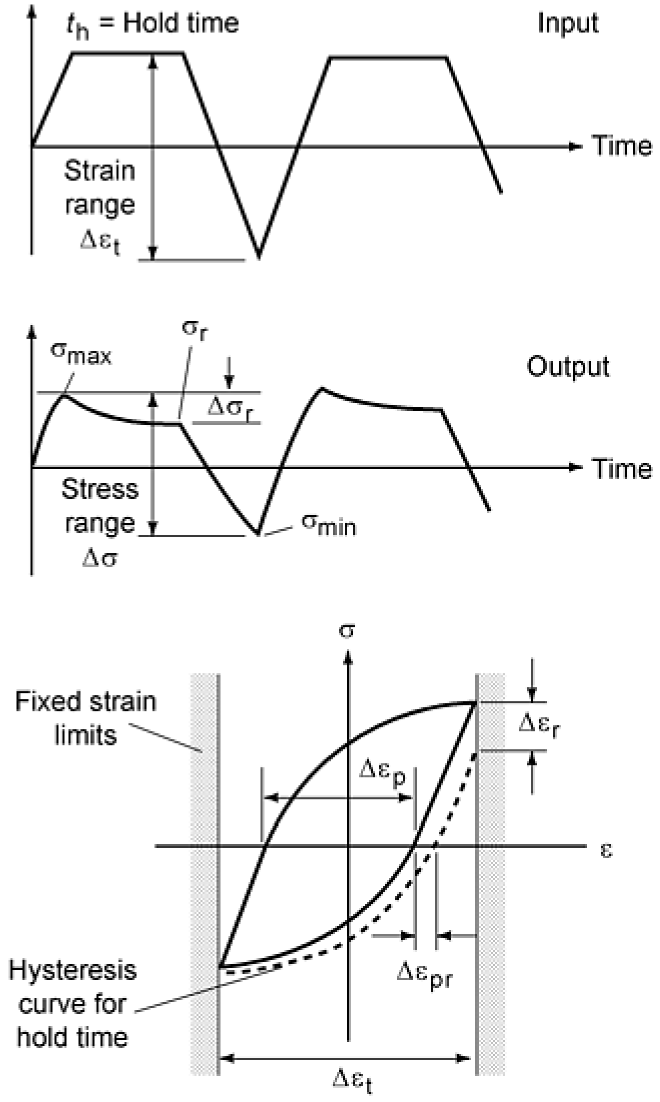

Fig. 29 Schematic showing imposed strain history, stress response, and hysteresis loop. Note that the drop in relaxation adds additional plastic strain labeled $\Delta\varepsilon_{pr}$ to the width of the loop at zero stress. Source: Ref 68

The variation of the peak stress with cycles for 316 stainless steel for three different hold times at a strain range of 3% is shown in Fig. 30. The tests show cyclic hardening at each hold time followed by a steady-state range before the incipient crack decreases the peak stress. The curve for the longest hold time of 480 min has the smallest peak stress, and the highest peak stress is obtained for the shortest hold time of 30 min. (Note that the hardening appears exaggerated due to method of plotting; also the strain range is quite high.)

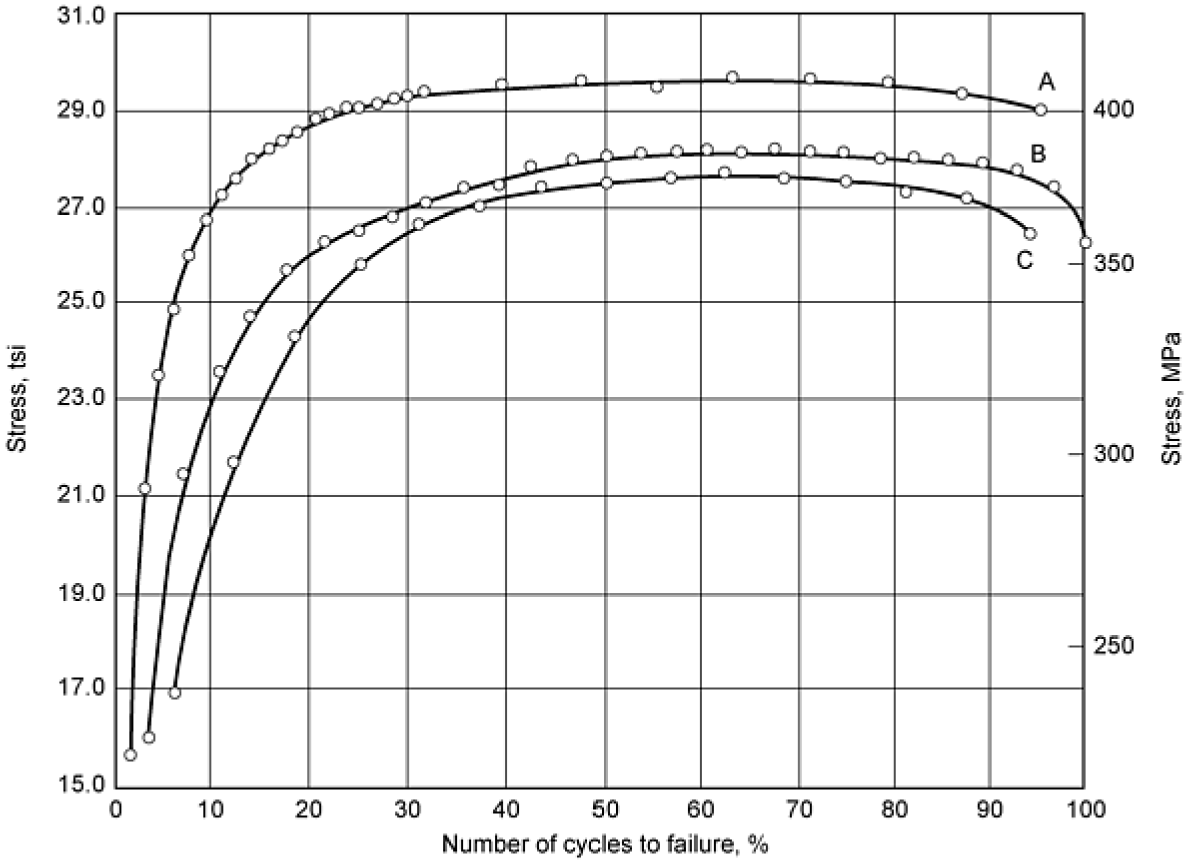

Fig. 30 The influence of hold time on the variation of the peak stress with cycles for 316 stainless steel at a strain range of 3% at 600 °C. Material A8; push-pull test. Dwell time: A, 63 cycles at 30 min; B, 28 cycles at 100 min; C, 16 cycles at 480 min. E_t = ±1.5%. Source: Ref 69

Figure 31 shows that the relaxation drop during hold time increases with cycles by more than a factor of two. As in Fig. 30, the strain range is quite high, and this fact tends to exaggerate the change in the relaxation drop with cycles. At a reduced strain range, the change in drop may not be as large.

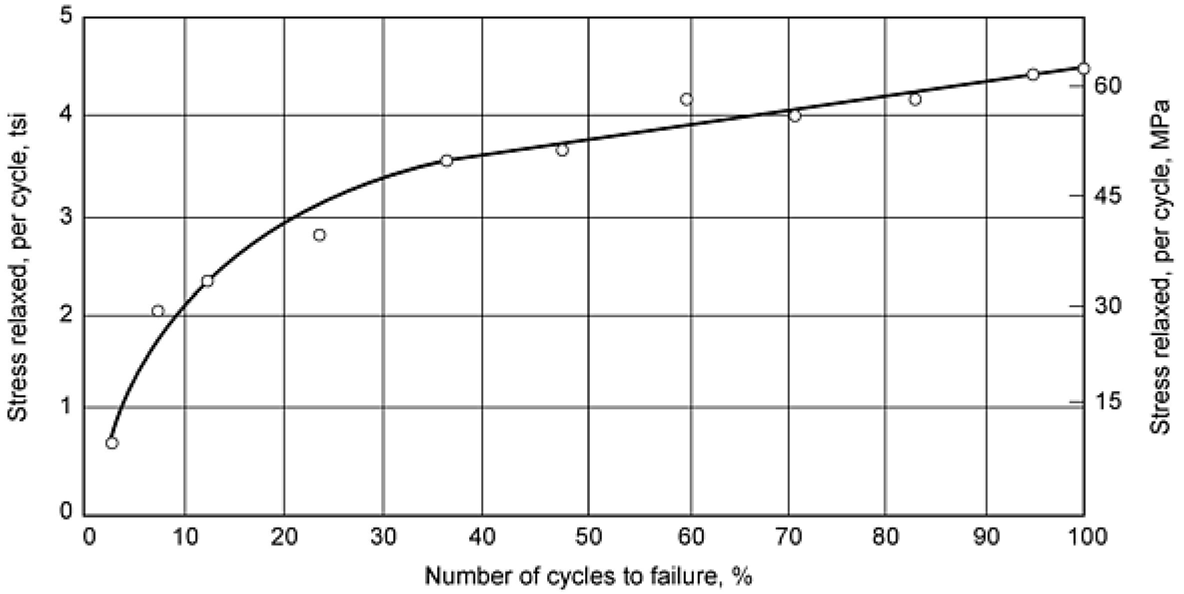

Fig. 31 The variation of the relaxation drop with cycles for a test with a strain range of 3% and a hold time of

100 min. Material A6; push-pull test. Dwell time: 42 cycles at 100 min. E_t = 1.49%. Source: Ref 70

When frequency is changed from test to test, the stress range for the highest frequency will be the highest if normal deformation behavior prevails (no strain aging). Reduced frequencies will have reduced stress ranges. Frequencies must be changed by at least an order of magnitude to have a noticeable effect on the stress range.

During relaxation the strain is constant and the inelastic strain is "traded" for elastic strain, and in this process damage is introduced.

If the tests are run in load control then creep periods are introduced directly as shown in Fig. 32. During each hold time, creep strain is accumulated, and the specimen can fail by excessive deformation before fatigue occurs. This phenomenon is known as ratcheting. It cannot be found in strain control.

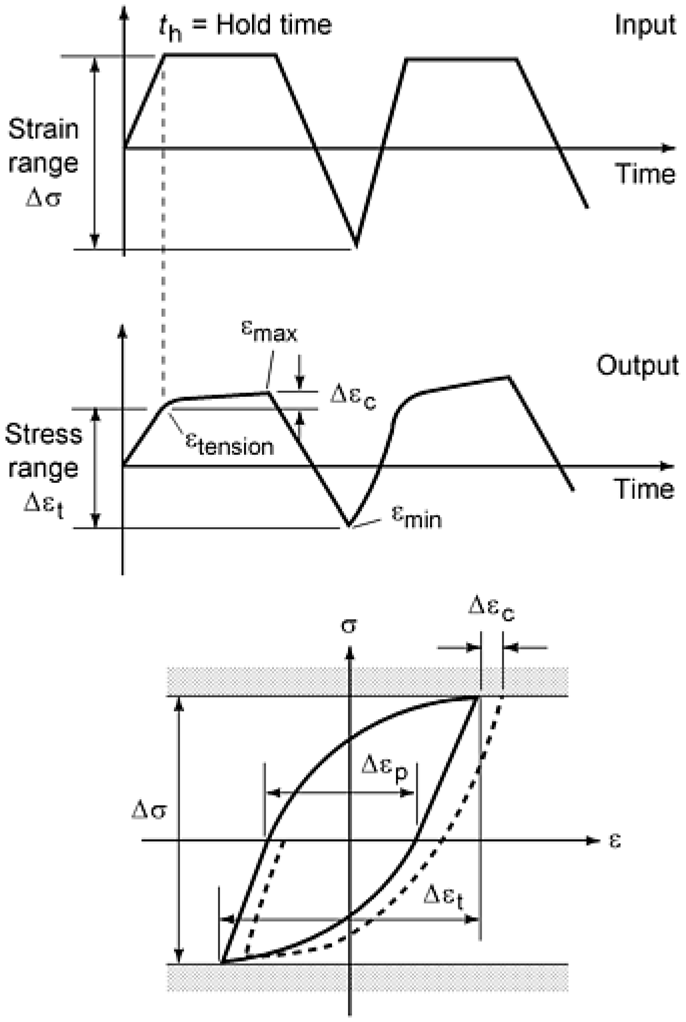

Fig. 32 Schematic showing the imposed stress history, the strain response, and the hysteresis loop. Note that the creep strain accumulated in each cycle can lead to failure due to excessive elongation (ratcheting) before failure due to fatigue. Source: Ref 68

For design purposes, the deformation behavior illustrated above in a cursory way must be captured in suitable material models, the constitutive equations. It is recognized that the changing internal state due to inelastic deformation must be accounted for in a realistic model. To this end, state variable models have been developed where the state variables represent the changing internal structure and where all inelastic deformation is considered rate (time)-dependent (see Ref 39). The state variable theories use incremental formulation so that they can be integrated for any loading history. The

differential equations are nonlinear, and a numerical integration scheme is needed. The recent advances in computing power make this easily possible.

The old design approach combined rate (time)-independent plasticity with separately formulated creep equations. But this formulation has led to many contradictions and is no longer used in advanced work. State variable constitutive equations were considered for design approaches, and their predictions were compared with experiments (Ref 71).

Lifetime. Similar to the deformation behavior, cycles to failure are also influenced by loading rate and hold time. In general, cycles to failure are determined as explained above by percentage of load drop, but early investigations may have adopted a different definition, especially when tests were run in bending.

When the strain rate is increased, fatigue life increases as seen in Fig. 33 for type 304 stainless steel. Note that the strain rate is changed by an order of magnitude at a time. The fatigue life changes by less than an order of magnitude.

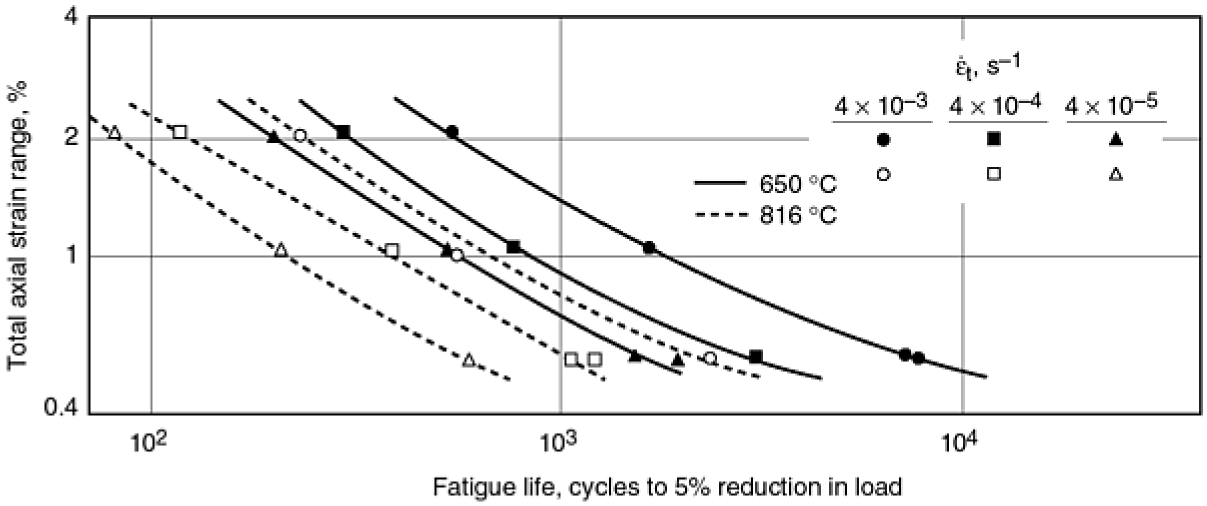

Fig. 33 The influence of strain rate on cycles to failure for type 304 stainless steel at 650 and 816 °C. Source: Ref 72

An increase in dwell time decreases fatigue life, as shown in Fig. 34 where the inelastic strain range is plotted versus cycles to failure. It is seen that the life reduction of tensile hold time is significant. At the low strain range, a 30 min tensile hold time can reduce the life by one order of magnitude. It is also seen that the introduction of hold times at other positions does not have the life-reducing effect as do tensile hold times.

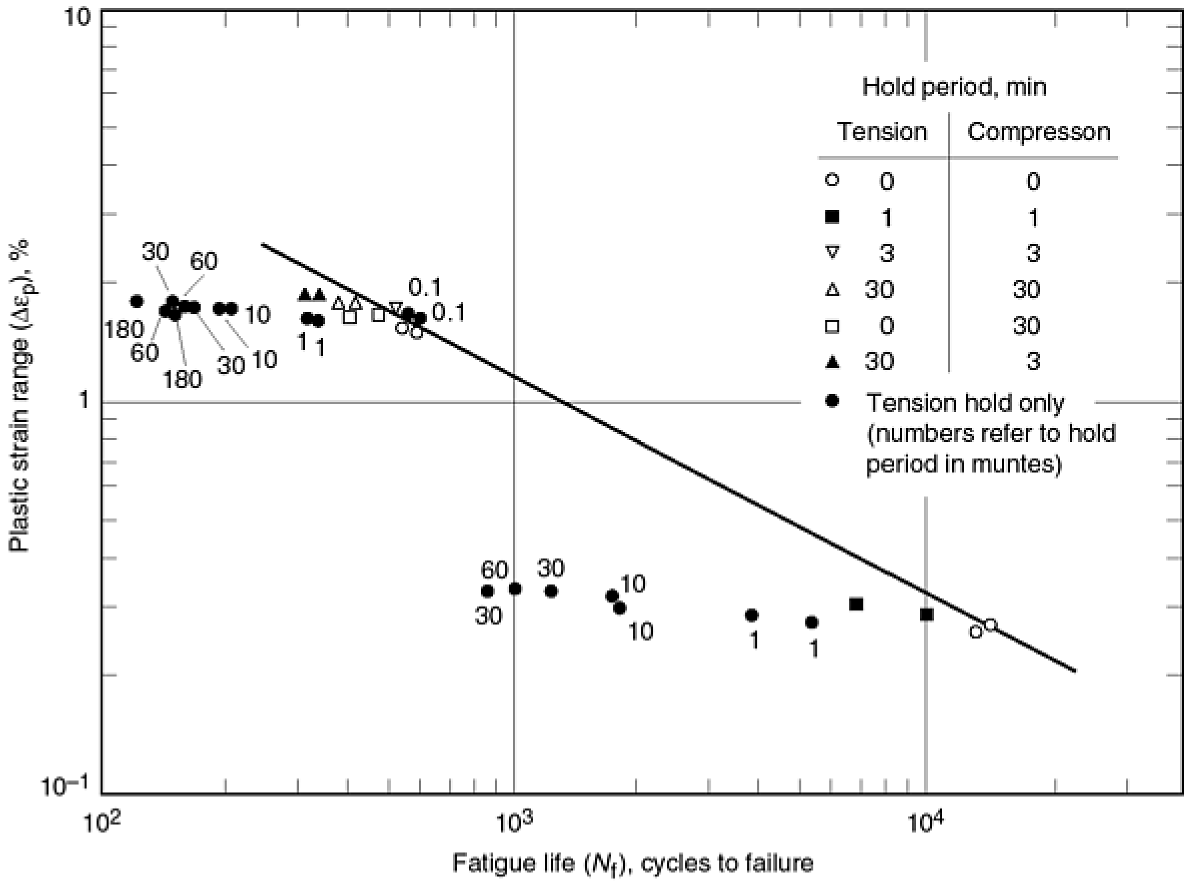

Fig. 34 Effect of hold period and position of hold period on fatigue life for type 304 stainless steel at 1200 °F and a strain rate of 4 × 10^{-3} 1/s. Source: Ref 73

Life-prediction methods have to model these effects, and it is clear that the methods given previously for room-temperature applications are not sufficient.

Detailed discussions of the methods applicable to high temperature including the frequency-modified strain range methods and strain-range partitioning methods are in use (see Ref 74, 75, 76).

These methods are all aimed at a typical cycle, and it is presumed that this cycle is representative of the actual loading. In high-temperature fatigue testing various wave forms are imposed (see Fig. 29 and 32, and Fig. 1.3 in Ref 75). It is then very difficult to find a representative cycle. Moreover in real applications, variable amplitude loadings are experienced, and a typical cycle is hard to define.

Following the developments of incremental constitutive equations that are in principle applicable to any history, incremental life-prediction laws have been developed (Ref 77, 78). These laws need to be integrated for each history to determine the lifetime and are ideally suited for a joint use with incremental constitutive laws.

In hold-time and slow-frequency tests, creep and fatigue damage interact as evidenced by the change from transgranular to intergranular cracking as the hold time increases. The subject of high-temperature fatigue and microstructure is discussed in depth in Ref 79.

Recently high-temperature fatigue considerations of electronic components have become important, especially for solder joints. These joints operate at high homologous temperature, and frequency and hold time have an important effect on lifetime. The reader is referred to Ref 80.

Effect of Environment. All the discussions so far were for test results obtained in laboratory air. It has been found out that other environments can have a significant influence on fatigue performance. Discussions of the effects of environment are given in Ref 81 and 82, to name just two sources.

Design for Fracture Toughness

M.P. Blinn and R.A. Williams, Materials Characterization Laboratory

Introduction

MODERN TECHNOLOGY has many challenges for the scientist, engineer, or designer of the machinery used by the people of the world. Because mechanical equipment is often used at or near design limitations, great care must be employed in selecting the proper materials to use for a particular design application. The need for high-performance materials in such industries as aerospace and power generation has advanced the use of design parameters in the evaluation of material behavior. In particular, fracture toughness is used as a design parameter to establish safe, efficient performance levels for mechanical equipment.

Fracture toughness, in the most general of definitions, is the ability of a material to withstand fracture in the presence of cracks. The American Society for Testing and Materials (ASTM) has numerous commonly accepted standards for fracture testing, and it defines fracture toughness as "a generic term for measures of resistance to crack extension" (Ref 1). In design, fracture toughness is used as a parameter to avoid the catastrophic failures often associated with fracture. When employing fracture toughness as a design criterion, the user must be well aware that historically, catastrophic fracture failures have occurred at nominal stresses far below the design stresses of the structures. To corroborate this point, the literature contains numerous examples of unanticipated mechanical and structural failures due to fracture (Ref 2, 3, 4, 5).

In the design process, the scientist, engineer, or designer should recognize that cracks, discontinuities, heterogeneities, or numerous other anomalies may exist in any "homogeneous" material used in manufacturing a product (Ref 6, 7). These cracks can exist at any stage in the life of the structure or machine component, and they should be accounted for not only after a part has been in service for a length of time, but also during the entire manufacturing process. Fracture mechanics provides a useful tool in planning for the occurrence of cracking; in particular, the use of fracture toughness as a design parameter (or limit) can alleviate the occurrence of fracture.

The focus of this article is on the use of fracture toughness as a parameter for engineering and design purposes. Although the subject of fracture mechanics is discussed in a general manner, most of the information in this article is related to the fracture behavior of metals. Both linear elastic and elastic-plastic fracture mechanics concepts are reviewed as they relate to fracture toughness and the design process. The article explores the use of plane strain fracture toughness (K_{Ic}), crack-tip opening displacement, and the J-integral as criteria for the design and safe operation of structures and mechanical components. In particular, the use of fracture toughness in damage-tolerant methods in aircraft and pressure vessel design are reviewed.

Design for Fracture Toughness

M.P. Blinn and R.A. Williams, Materials Characterization Laboratory

A Brief History of Fracture Mechanics

It is generally accepted that the study of fracture mechanics was pioneered by A.A. Griffith in the first half of the 20th century, although much earlier fracture studies have been attributed to da Vinci (Ref 3). Regardless of who was the earliest fracture experimentalist, the importance of Griffith's contributions to engineering was most pronounced in the new paradigm that he introduced to the world: a quantitative relationship for fracture by the use of fracture mechanics. The history of fracture mechanics is well documented in the literature (Ref 5).

In his seminal work in the 1920s on fracture mechanics (Ref 8), Griffith tested glass specimens that were scratched and unscratched and compared their respective breaking strengths. Griffith developed the following expression for the fracture strength of solids that met stringent boundary conditions:

$$\sigma_c = \sqrt{\frac{2\gamma E}{\pi a}} \quad \textbf{(Eq 1)}$$

where σ_c is the critical stress, *E* is the elastic modulus, γ is the surface energy, and *a* is the crack length.

From his findings, Griffith showed that assuming a material to be a homogeneous solid could lead to grave miscalculations in design. Further, Griffith advocated the use of more refined materials to increase strength, but cautioned that discrepancies in strength between scratched and unscractched specimens would still exist, regardless of how well the material was refined. In essence, Griffith established the concept of designing for fracture; however, it took years for the engineering and scientific community to fully appreciate (or understand) his findings.

Fracture mechanics became a more workable topic for most engineers due to the studies of Irwin in the late 1940s and 1950s (Ref 5, 9). Irwin proposed an energy approach to describe fracture mechanics, based on the work of Griffith. Irwin defined an expression for the energy release rate as:

$$G = -\frac{d\Pi}{dA} \quad \textbf{(Eq 2)}$$

where *G* is the energy release rate, $d\Pi$ is the change in potential energy of the cracked body, and *dA* is the change in crack-surface area.

Taking this equation out further, the elastic energy release rate of a plate can be described as:

$$G = \frac{\pi\sigma^2 a}{E} \quad \textbf{(Eq 3)}$$

where σ is the applied stress.

In order to obtain more workable engineering units, Eq 3 can be rearranged and rewritten as:

$$K = f\left(\frac{a}{W}\right)\sigma\sqrt{\pi a} \qquad \textbf{(Eq 4)}$$

where *K* is the stress intensity factor (in general form), which is a function of geometry ($f(a/W)$), stress, and crack length. The stress intensity factor is generally expressed in units of MPa$\sqrt{\text{m}}$ (ksi$\sqrt{\text{in.}}$).

Currently, it is the stress intensity factor that is most commonly used as a basis for the design and analysis of structures or mechanical components that contain cracks. The stress intensity factor is essentially a pseudostress; that is, it is calculated and used in design much the same as a stress, only the crack is now considered in the equation. Although very useful in design, the stress intensity factor as represented in Eq 4 is limited to elastic material behavior. It should be clearly understood that the stress intensity factor (K or K_I, as will be discussed later) described in this article is not the same as the stress concentration factor (also denoted by *K* in many texts). A stress concentration factor is generally used as a stress multiplier, applied to the calculated stress of the structure or component. For example, where there is a change in the component shape (geometry), such as at a sharp edge or hole, a stress concentration factor is applied to calculated stress to account for the geometric constraint.

The challenge in fracture mechanics in the 1960s and 1970s was to establish working models for materials that were too tough to be characterized by the Griffith-Irwin fracture mechanics approach, which was somewhat limiting to elastically behaving materials. In the early 1960s, Wells proposed a crack-tip opening displacement method (CTOD) based on his observations that the degree of crack-tip blunting was in proportion to the toughness of the material (Ref 5, 10). From this work, the following expression is one form that relates the elastic component of CTOD (δ) to the stress intensity factor (K_I):

$$\delta = \frac{4K_I^2}{\pi \sigma_{YS} E} \qquad \textbf{(Eq 5)}$$

where σ_{YS} is the yield stress.

To develop an alternative means to evaluate the fracture resistance of high-toughness materials, the *J*-integral was first proposed by Rice in 1968 (Ref 11) as a path-independent integral for measuring the stress and strain field ahead of cracks.The *J*-integral is expressed mathematically as:

$$J = \int_{\Gamma}\left(W dy - T_i \frac{\partial u_i}{\partial x} ds\right) \qquad \textbf{(Eq 6)}$$

where *J* is the contour integral, *W* is the strain energy density, T_i is the traction vector outward normal to the arc Γ, $T_i = \sigma_{ij} n_j$, u_i is the displacement vector, and *s* is the arc length along Γ.

Early experimental work by Begley and Landes in the 1970s (Ref 12, 13, 14) developed a multi-specimen method in the laboratory, with a proposal to use the *J*-integral to evaluate the onset of crack initiation (J_{Ic}). The early form of the *J*-integral expression that Begley and Landes worked with was:

$$J = -\frac{1}{B}\left(\frac{\partial U}{\partial a}\right) \qquad \textbf{(Eq 7)}$$

where *U* is the potential energy and *B* is the specimen thickness.

Adding to this early laboratory work, Andrews et al. (Ref 15) developed an unloading compliance method for a single-specimen test. Additionally, numerous investigators continued exploring mathematical expressions for the *J*-integral (Ref 5, 16, 17). Further discussion on the *J*-integral and elastic-plastic fracture mechanics is presented in the next section of this article.

Design for Fracture Toughness

M.P. Blinn and R.A. Williams, Materials Characterization Laboratory

Categories of Fracture Mechanics

Fracture mechanics is a broad subject, but there are fundamentally two categories: linear elastic fracture mechanics (LEFM) and elastic-plastic fracture mechanics (EPFM). LEFM, the more mature of the two categories, studies the behavior of materials where cracking is presumed to occur under essentially elastic conditions. Additionally, LEFM assumes that the crack tip is sharp, with a limited amount of plasticity. Some materials that are designed using LEFM concepts are high-strength steels, titanium, and aluminum alloys.

Although LEFM has been used in design and analysis with a measure of success, there are limitations to its applications. Lower-strength steels can behave in a relatively plastic manner, so they are not easily characterized by LEFM. To account for materials that do not fall within the limitations of LEFM, research has been actively pursued from the 1960s through the present to determine and refine different methods of characterizing the crack tip and the fracture process. For the study of more ductile materials, EPFM evolved from LEFM as a somewhat more complex science. In contrast to LEFM, EPFM assumes that the crack tip is not sharp and that there is a degree of crack tip plasticity (or blunting). Some materials that are designed using EPFM concepts are common structural materials, such as lower-strength, higher-toughness steels.

Linear Elastic Fracture Mechanics. Although some of the background work previously discussed in this article touched on the stress intensity factor (K_I), the concept was not fully developed. The stress intensity factor is at the heart of characterizing LEFM, and a general example is reviewed below. As further reference material for the solid mechanics approach to the stress intensity factor, the literature contains numerous texts (some older, but excellent background material) on LEFM theory (Ref 3, 4, 5, 9, 18, 19).

Consider a crack in a material as shown schematically in Fig. 1. The stress field ahead of the crack tip can be described by the following equations, assuming a linear elastic, isotropic material:

$$\sigma_{XX} = \frac{K_I}{\sqrt{2\pi r}} \cos\left(\frac{\theta}{2}\right)\left[1 - \sin\left(\frac{\theta}{2}\right)\sin\left(\frac{3\theta}{2}\right)\right] \quad \textbf{(Eq 8)}$$

$$\sigma_{YY} = \frac{K_I}{\sqrt{2\pi r}} \cos\left(\frac{\theta}{2}\right)\left[1 + \sin\left(\frac{\theta}{2}\right)\sin\left(\frac{3\theta}{2}\right)\right] \quad \textbf{(Eq 9)}$$

$$\pi_{XY} = \frac{K_I}{\sqrt{2\pi r}} \cos\left(\frac{\theta}{2}\right)\sin\left(\frac{\theta}{2}\right)\cos\left(\frac{3\theta}{2}\right) \quad \textbf{(Eq 10)}$$

$$\sigma_{ZZ} = \nu(\sigma_{XX} + \sigma_{YY}) \text{ (plane strain)} \quad \textbf{(Eq 11)}$$

$$\sigma_{ZZ} = 0 \text{ (plane stress)} \quad \textbf{(Eq 12)}$$

$$\tau_{XZ} = \tau_{YZ} \quad \textbf{(Eq 13)}$$

where K_I is the mode I stress intensity factor (explained below), τ is the shear stress, ν is the Poisson's ratio, and *r* is the radius.

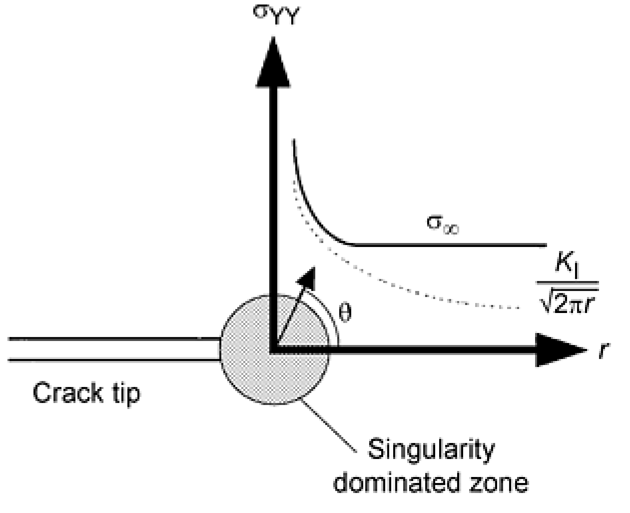

Fig. 1 Stress field normal to the crack plane in mode I, where θ = 0°. The far field stress is σ and the stress intensity factor is K_I. Source: Ref 5

It is important to note the sub used on the stress intensity factors, which refers to the loading mode. There are essentially three loading modes discussed in the literature that can be applied to a crack developing in a material, as shown schematically in Fig. 2. Mode I, the opening mode of loading, is by far the most commonly studied. Modes II and III are the in-plane and the out-of-plane shear modes, respectively, and are not further discussed in this article. These loading modes are less significant in fracture toughness testing, but they are described in ASTM E 616 and E 399 (Ref 1, 20).

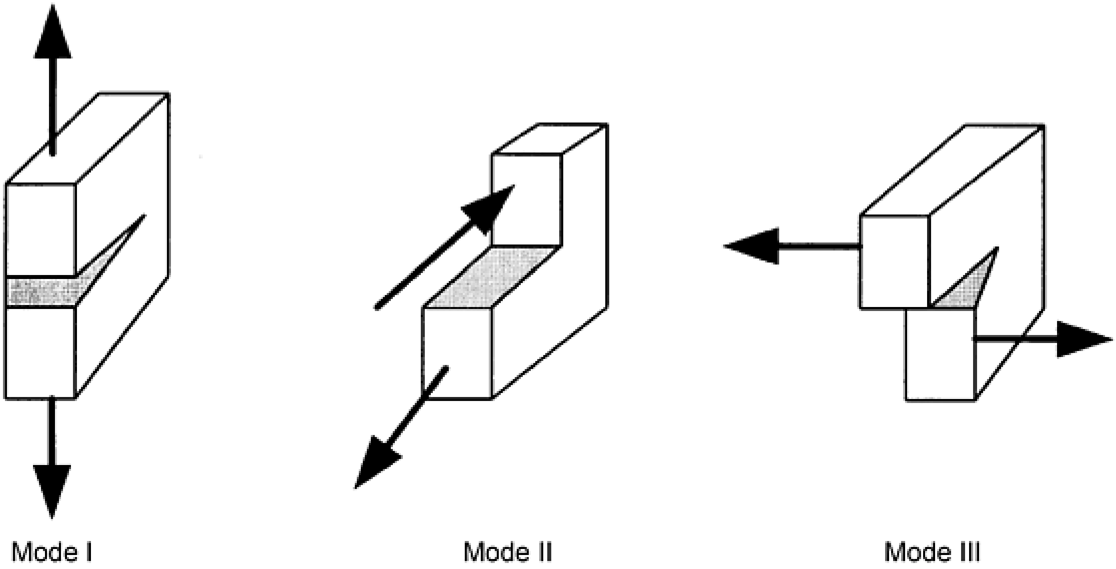

Fig. 2 The three modes of loading that can be applied to a crack. Mode I is the opening mode, mode II is the in-plane shear mode, and mode III is the out-of-plane shear mode. Source: Ref 5

Closed-form solutions exist for many stress intensity factor load-crack situations, and some of the more common expressions are given in Eq 14, 15, and 16 (Ref 5). These three stress intensity solutions are perhaps the most simplistic of the closed-form solutions. To accompany these equations, various schematics are shown in Fig. 3(a) to (c), each picture representing one of the three stress intensity factor load-crack situations. For the through crack in an infinite plate subjected to a remote tensile stress (Fig. 3a), the stress intensity factor is given as:

$$K_I = \sigma\sqrt{\pi a} \qquad \textbf{(Eq 14)}$$

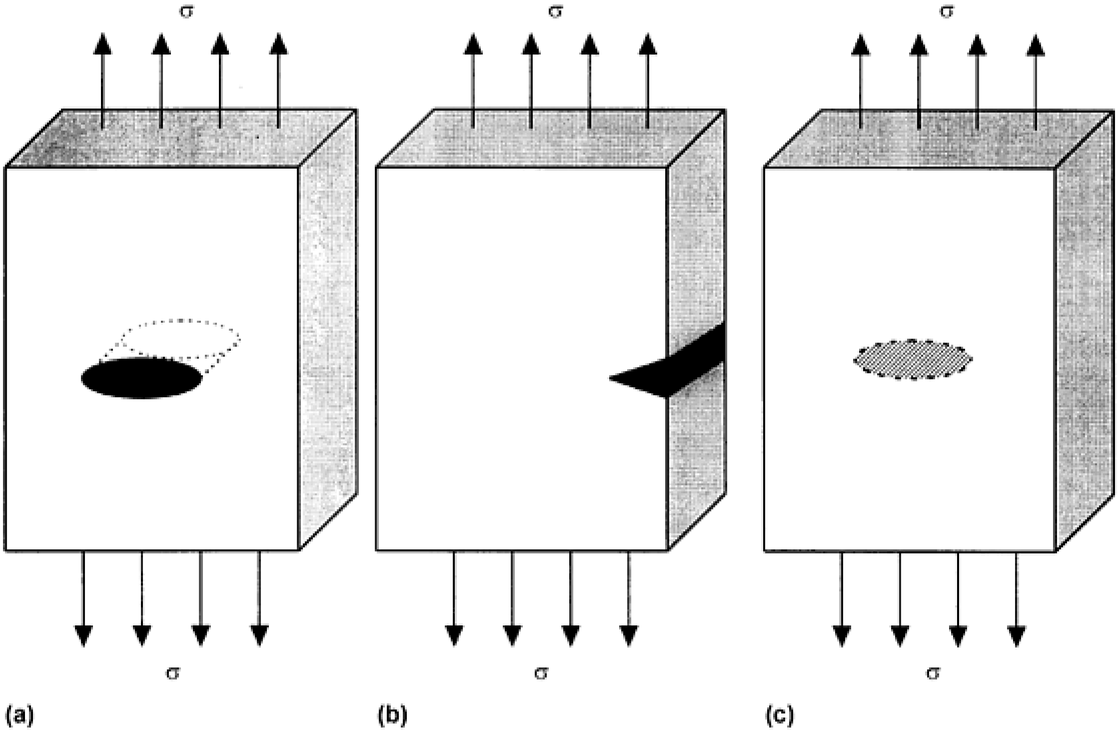

Fig. 3 Schematic of the three load-crack situations that have closed-form solutions in fracture mechanics. (a)

The through crack in an infinite plate subjected to a remote tensile stress. (b) The semi-infinite plate with an edge crack. (c) The penny-shaped circular crack embedded in a solid. Source: Ref 5

For the semi-infinite plate with an edge crack (Fig. 3b), the stress intensity factor is given as:

$$K_I = 1.12\sigma\sqrt{\pi a} \quad \textbf{(Eq 15)}$$

where 1.12 is a correction factor to account for the different boundary condition.

For the "embedded penny" crack in an infinite medium (Fig. 3c), the stress intensity factor is given as:

$$K_I = \frac{2}{\pi}\sigma\sqrt{\pi a} \quad \textbf{(Eq 16)}$$

where $2/\pi$ accounts for a radial crack.

Having described the stress intensity factor (K or K_I) used for LEFM, it is perhaps appropriate to define plane-strain fracture toughness (K_{Ic}), which is the material response characteristic that is often used in designing against fracture. K_{Ic} is a limiting value; that is, it can be used in static fracture mechanics design in much the same way as the yield strength (σ_Y) is used in static stress analysis. As the sub of K_{Ic} implies, it is a critical stress intensity factor for mode I cracking and is determined for a material by following a rigorous test procedure, as prescribed in ASTM E 399 (Ref 20). More detailed descriptions of K_{Ic} and ASTM E 399 are given in later sections of this article.

Elastic-Plastic Fracture Mechanics. Different approaches are used for evaluating materials that fracture (or behave) more plastically than in LEFM. In evaluating EPFM, the CTOD and *J*-integral methods are most often used to characterize fracture at the crack tip. The more current literature contains the best sources for additional review of EPFM (Ref 5, 16, 21, 22, 23). Closed-form CTOD and *J*-integral solutions are also available in these references.

To evaluate the use of the CTOD in essentially the elastic case, consider the through crack in an infinite plate subject to a remote tensile stress (Fig. 3a). The most general form of this load-crack situation is expressed as follows (Ref 5):

$$\delta = \frac{K_1^2}{m\sigma_{YS}E} = \frac{G}{m\sigma_{YS}} \quad \textbf{(Eq 17)}$$

where δ is the CTOD, and m is a constant (1.0 for plane stress, 2.0 for plane strain).

The concept of the CTOD and the crack-mouth opening displacement (CMOD) is shown schematically in Fig. 4, which shows a sample specimen before and after (hidden lines) deformation (Ref 16). Note that the CMOD is evaluated at the load line (centerline of the loading) and the CTOD is evaluated at the crack tip. Some test methods used for evaluating the CTOD are British Standard 7448, Part 1 and ASTM E 1290 (Ref 24, 25).

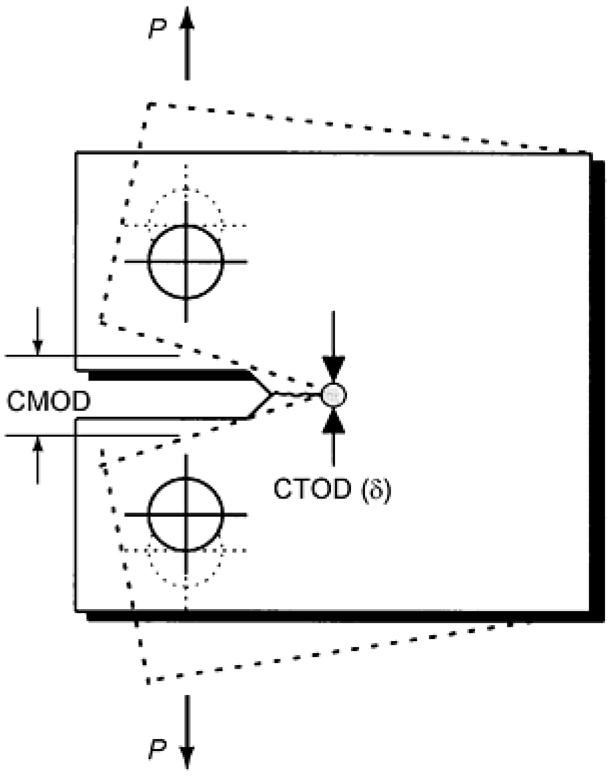

Fig. 4 Schematic of a sample specimen showing the definition of crack-mouth opening displacement (CMOD) and crack-tip opening displacement (CTOD). CTOD is the diameter of the circular arc at the blunted crack tip and should not be confused with the plastic zone. Source: Ref 16

The *J*-integral method is another means of characterizing the crack tip in an elastic-plastic type of material. The mathematical definition of the *J*-integral was previously given in Eq 6; the alternative definition is "a mathematical expression, a line or surface integral that encloses the crack front from one crack surface to the other, used to characterize the local stress-strain field around the crack front" (Ref 1).

To expand on the background work discussed above and summarize the link between the *J*-integral and Griffith-Irwin fracture concepts, a general (and simplistic) form of the *J*-integral may be given as follows (Ref 17):

$$J = J_{el} + J_{pl} \qquad \textbf{(Eq 18)}$$

$$J_{el} = \frac{K_I^2 (1 - \nu^2)}{E} \qquad \textbf{(Eq 19)}$$

$$J_{pl} = \frac{\eta A_{pl}}{B_N B_0} \qquad \textbf{(Eq 20)}$$

where J_{el} is the elastic portion of the *J*-integral, J_{pl} is the plastic portion of the *J*-integral, η is a factor based on the type of specimen used, A_{pl} is the area under the load against displacement plot, B_N is the specimen thickness, and B_0 is the uncracked portion of the specimen (ligament).

Note that Eq 18, 19, and 20 apply to specific specimen geometries and load-crack situations, as described in the ASTM test standards for fracture toughness testing (Ref 17, 25, 26). These expressions were given only as an example to show the link between *J* and *K*, and to further show how the *J*-integral is expressed in two parts: the elastic and the plastic components. Finally, Fig. 5 is presented to show schematically how the plane-strain fracture toughness (J_{Ic}) is obtained

after testing. Once a candidate *J* value (J_Q) is determined, it must pass through numerous validity criteria before it can be considered as a fracture toughness value to use in design.

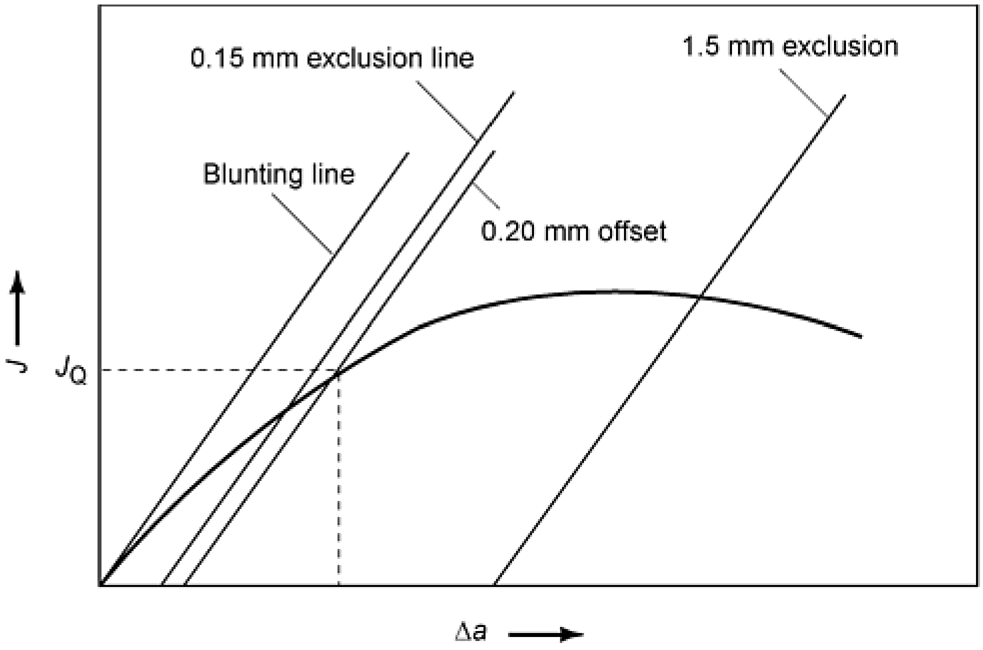

Fig. 5 Schematic of a *J*-Δ*a* plot showing the point at which J_Q is determined for evaluation as J_{Ic}. These plots are generated by first obtaining the plot of load against crack-mouth opening displacement (CMOD), and then determining the *J* and Δ*a* values accordingly. Only for compact tension specimens is *J* estimated from some function of CMOD. The blunting line approximates the apparent crack advance, due to crack-tip-blunting in the absence of slow stable crack tearing (Ref 1). The offset and exclusion lines are used in data qualification in the determination of J_{Ic}. Source: Ref 20

Dynamic and Impact Fracture Mechanics. Although dynamic and impact test methods, such as the Charpy and Izod tests (Ref 27), have been essentially overshadowed by LEFM and EPFM in the past few decades, they do have historical significance in fracture mechanics. In particular, the concept of transition temperature behavior in fracture is well grounded in impact testing (Ref 3, 4, 5).

The transition temperature is shown schematically in Fig. 6, where the Charpy V-notch energy (CVN) is plotted against temperature. Generally, numerous specimens are tested at various temperatures to establish plots that may reveal temperature effects in a material. Lower-strength steels tend to give an S-shaped plot, as shown in Fig. 6; higher-strength steels and aluminum alloys will give a flat, lower-energy plot (Ref 3). The lower, flat portion of the plot is generally referred to as the "lower shelf" region; the higher, flat portion of the plot is the "upper shelf" region. Additionally, there is a "transition" region between the upper and lower shelves. Metallurgically, early investigators studied the apparent "brittle" behavior of steels at the lower shelf and the "ductile" behavior at the upper shelf.

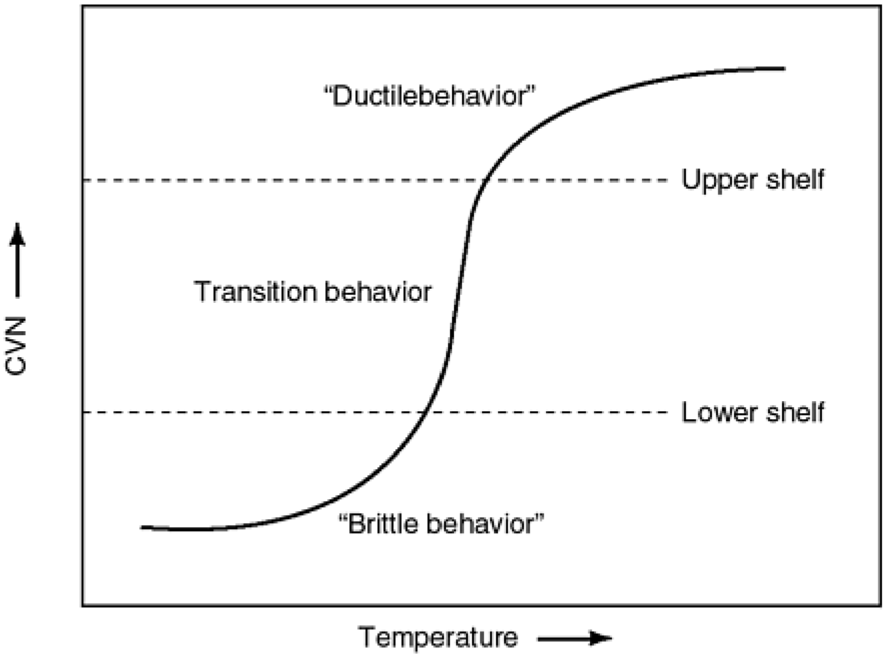

Fig. 6 Charpy V-notch energy (CVN) plotted against temperature, showing the three regions of material behavior ("brittle," transition, and "ductile"). This schematic approximates the S-shape of the curves for low-strength steel; other materials, such as aluminum alloys and high-strength steels, show a flat-shaped curve.

To elaborate on the use of a plot of CVN against temperature, it should be noted that in essence this plot is a toughness against temperature plot. For impact tests, Charpy energy can be replaced by percent shear fraction or percent lateral expansion as alternative measures of toughness. Additionally, plots of CTOD or J against temperature can be employed in similar fashion, to serve the same purpose. Results of these S-shaped plots can be translated from the left or right by varying the strain rate, thickness, cold forming, welding, or geometries associated with testing. That is to say, "ductile" (or tough) materials may behave in a "brittle" (or less tough) manner if any (or all) of these parameters are varied. Conversely, a less tough material can be used successfully by careful attention to these parameters.

In tandem with the transition temperature effects, many early investigators proposed correlations between fracture toughness and CVN values (Ref 3, 4, 28). This information was especially important in the upper shelf region, where LEFM methods to determine fracture toughness become impractical. One such correlation was reported by Begley and Logsdon (Ref 3, 29) who proposed a three-point correlation for rotor steel alloys (NiCrMoV, NiMoV, CrMoV) of the entire transition temperature regime with the following three equations:

$$(K_{Ic})_1 = 0.45\sigma_{YS} \text{ (at 0\% shear fracture)} \quad \textbf{(Eq 21)}$$

$$(K_{Ic})_2 = \sigma_{YS}\left[5\left(\frac{CVN}{\sigma_{YS}} - 0.05\right)\right]^{1/2} \quad \textbf{(Eq 22)}$$

(at 100% shear fracture)

$$(K_{Ic})_3 = \frac{1}{2}\left[(K_{Ic})_1 + (K_{Ic})_2\right] \quad \textbf{(Eq 23)}$$

(at 50% shear fracture)

Equations 21, 22, and 23 are not intended to be used for all materials (or design applications); they apply only to the rotor steels described in the literature (Ref 3, 29). No CVN-K_{Ic} correlation is universal; it may vary with product form, temper, and numerous other material parameters. Additionally, the variability in CVN-K_{Ic} correlations can be quite large, so these equations should be used with caution.

Design for Fracture Toughness

M.P. Blinn and R.A. Williams, Materials Characterization Laboratory

Variables Affecting Fracture Toughness

Fracture toughness is highly dependent on many variables, many of which can dramatically alter the fracture resistance characteristics of a structure, mechanical component, or test specimen. During analysis and design, consideration of yield strength, loading rate, temperature, thickness, and orientation should all be addressed. When fracture toughness data are generated, laboratory conditions for testing should model actual service conditions, as practically as possible. Although not a complete list, some of the more important variables that affect fracture toughness are presented in this section. These variables can be studied in greater detail in some of the numerous texts on fracture mechanics (e.g., Ref 3, 4, 5, 9, 19).

Yield Strength. A general phenomenon with many (but not all) steels and high-strength alloys is that: increasing the fracture toughness of the material lowers the yield strength. Conversely, increasing the yield strength of the material lowers the fracture toughness. This consideration of yield strength, in tandem with fracture toughness, is especially important in design applications where the material will be taken to the upper limits of stress. Table 1 presents a compilation of yield strength and corresponding fracture toughness values for various aircraft structural materials (Ref 18).

Note: These values are dependent on other factors, such as the actual plate thickness that specimens are cut from. Source: Ref 18

The general relationship between toughness and yield strength may not be the case for structural steels used in various other applications. Modern steelmaking techniques can routinely increase the yield strength of the material, with little or no sacrifice in toughness. In some cases, an increase in toughness may be achieved in tandem with an increase in yield strength. The important point is that the user of a material should be careful not to enhance one material quality (such as yield strength) at the expense of another material quality (such as toughness).

Loading Rate. There is a tendency for many materials, such as steels, to exhibit different values of fracture toughness at different loading rates. In terms of stress intensification rates (*K*), impact tests are done at relatively fast rates in the range of 10 to 10^4 MPa$\sqrt{m}$/s (9.1 to 9.1 × 10^3 ksi$\sqrt{in.}$/s), as opposed to the quasistatic fracture test rates of less than 2.75 MPa$\sqrt{m}$/s (2.5 ksi$\sqrt{in.}$/s) (Ref 30). In general, impact test fracture toughness results tend to be lower (more conservative) than fracture toughness results determined with a test done according to ASTM E 399 or E 813.

Impact loading and rapid loading rate are not the same thing; in fact, a rapid loading rate can have strain rates an order of magnitude less than those of an impact test. Some examples of rapid loading are dynamic bridge loading and ship slamming, although they are often thought to be impact loading situations. This misunderstanding arose from early observations of steam locomotives crossing bridges and feeling the "hammering" of the counterweights on the driving wheels.

Temperature. Fracture toughness is highly dependent on temperature, and an effort should be made early in the design process to establish characteristic temperatures that model the service applications of the structure or mechanical component under consideration. Many design applications, such as aircraft, pressure vessels, and turbines, run at varying temperatures, and it may be necessary to generate a spectrum of fracture toughness information regarding temperature.Various articles and texts relate the issues of testing at different temperatures (Ref 3, 4, 21, 31) and discuss the transition temperature phenomenon, as well as the use (and misuse) of terminology such as "ductile" and "brittle" behavior in fracture.

The greatest challenge in assessing fracture toughness at a range of temperatures is determining what test method is appropriate. Modern structural steels used in land and marine vehicles and structures (high-strength low-alloy steel, quenched and tempered steel, carbon steel, etc.) exhibit significant plasticity to invalidate plane-strain toughness testing at

any temperature. For other materials, such as the higher-strength materials used in aerospace applications, plane-strain fracture toughness testing may be appropriate at lower to moderate temperatures, but not for higher service temperatures. Methods such as *J*-integral, CTOD, and even CVN testing are available for higher-temperature testing, but the test method should be carefully chosen.

As a general description of temperature effects in fracture of steels, it is instructive to paraphrase from Ewalds and Wanhill (Ref 9). In general, at low temperatures the crack tip is sharp, the material yield stress is high, and at failure the plastic zone size is small (as is K_{Ic}). Conversely, at higher temperatures the crack tip blunts, the material yield stress decreases, and there is a larger plastic zone (K_{Ic} is larger too).

Material Thickness (Plane Stress and Plane Strain). Material thickness is an especially important consideration in the design for fracture, as thicker sections can lead to a decrease in the fracture toughness of the structure or component part under consideration. What this means is that as the thickness of a plate (or section) is increased, the fracture toughness value can decrease, at least to a limiting value. This is important for the designer to note, as a design "fix" to a highly stressed component may be to increase the cross-sectional area of the part, thus reducing the nominal stress. However, the fracture toughness of the component may be decreased by the change in geometry, and it should be reevaluated in terms of adequacy for design.

Material thickness is linked with plane-stress and plane-strain behavior in fracture mechanics, due to the dependency of the stress state at the crack tip on the thickness. When a component (or test specimen) is thin, there is essentially no lateral constraint (in the direction of the thickness), and plane-stress conditions will dominate (Ref 4). Conversely, when a component is very thick, there is a great deal of lateral constraint, and plane-strain conditions can prevail.

The effects of plane stress and plane strain can be explained by the use of a stress cube and sample specimen, as shown schematically in Fig. 7. If the thickness of the specimen is minimal, then σ_z will be essentially zero, with σ_x, σ_y, ε_x, ε_y, and ε_z all having a magnitude (value). This situation is considered to be plane stress (σ_x and σ_y have a magnitude and are "in-plane"). Conversely, if the thickness of the specimen is increased substantially, then σ_z, σ_x, σ_y, ε_x, and ε_y all will have magnitudes and ε_z will be essentially zero. This situation is considered to be plane strain (ε_x and ε_y have a magnitude and are "in-plane"). Plane stress and plane strain also affect the plastic zone size; the plane-stress and plane-strain plastic zones can be simply modeled (along the *x*-*y* plane) as:

$$r_y = \frac{1}{2\pi}\frac{K^2}{\sigma_{YS}^2} \quad \text{(plane stress)} \qquad \textbf{(Eq 24)}$$

$$r_y = \frac{1}{6\pi}\frac{K^2}{\sigma_{YS}^2} \quad \text{(plane strain)} \qquad \textbf{(Eq 25)}$$

where r_y is the radius of the plastic zone. It should be noted that r_y decreases along the *z*-axis from the outside surface to the center of the specimen.

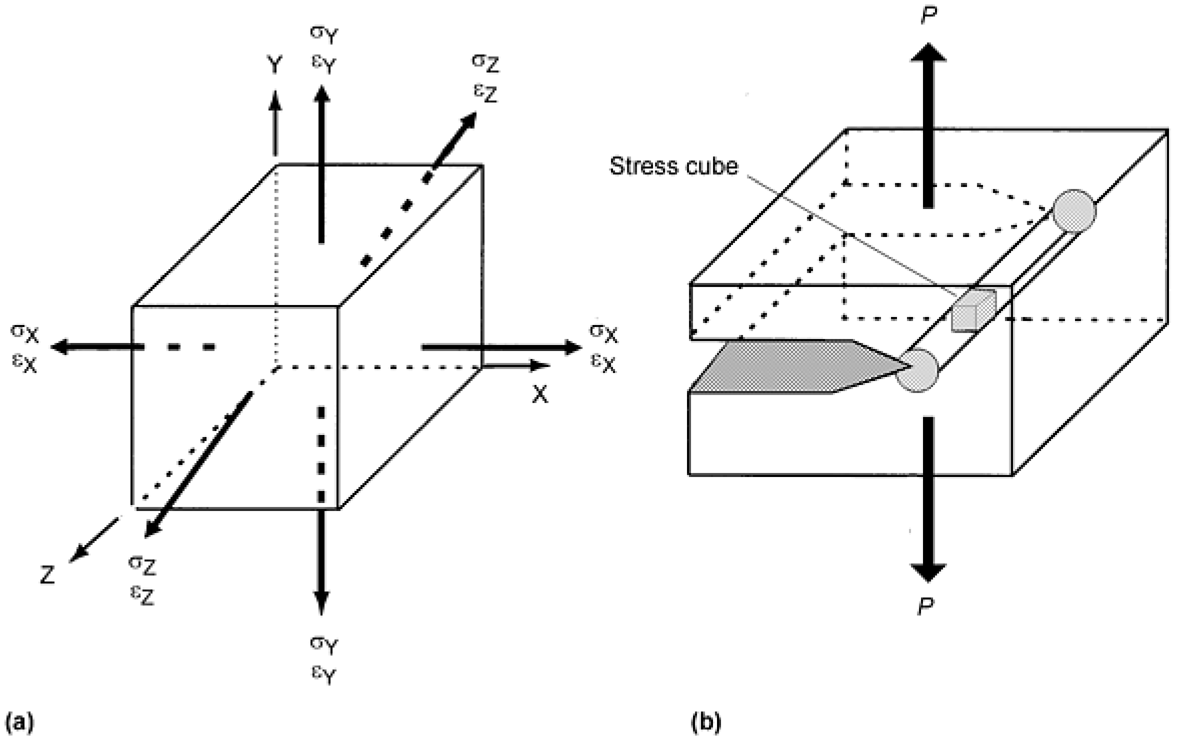

Fig. 7 Solid mechanics type approach to the description of stress and strain using a stress cube. (a) An expanded stress cube, with the normal stress (σ) and strains (ε) depicted. (b) Schematic of a plate with a crack, loaded in tension. The gray circular "cylinder" in the plate represents the plastic zone, which will vary in size and shape with thickness (it is not a perfect cylinder as shown). The radius of the plastic zone decreases along the *z*-axis from the outside surface to the center of the specimen.

Figure 8 summarizes the effects of loading rate, temperature, and material (specimen) thickness in a somewhat simplistic plot. In general, increasing the specimen thickness will decrease the fracture toughness value to a limiting (critical) value.Additionally, increasing the temperature and decreasing the loading rate will shift upward the curve of fracture toughness versus specimen thickness.

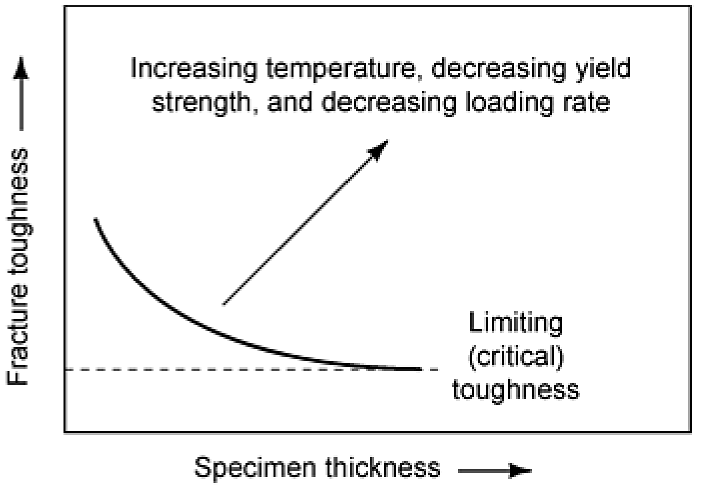

Fig. 8 Effect of specimen thickness, loading rate, and temperature on fracture toughness. In general, increasing the specimen thickness will decrease the fracture toughness to a limiting (or critical) value. Additionally, increasing the temperature and decreasing the loading rate will shift upward the curve for fracture toughness vs. specimen thickness.

Material Orientation and Anisotropy. The forming process of a material, such as drawing, extruding, rolling, or forging, can have a great effect on the microstructure and texture (preferred grain orientation) of the material. Additionally, the fracture toughness of a material is affected by the microstructural and mechanical changes a material undergoes through processes such as heat treating. These changes in the material fracture toughness properties can be advantageous to the scientist, engineer, or designer who is aware of their discrepancies. For the unaware and unknowing, these changes in material fracture toughness behavior can have disastrous consequences.

Material anisotropy (or simply anisotropy) is a term used to describe the dependence of material properties, such as fracture toughness, yield strength, and elastic modulus, to the texture.When a material has mechanical properties that are independent of direction, it is said to be *isotropic*. Conversely, if the material has mechanical properties that depend on a particular (or preferred) orientation(s), it is said to be *anisotropic* (Ref 32).

To provide a common scheme for describing material anisotropy, ASTM has standardized the following 6 orientations: L-S, L-T, S-L, S-T, T-L, and T-S (Ref 1). As shown in Fig. 9, the first letter denotes the direction of the applied load; the second letter denotes the direction of crack growth. In designing for fracture toughness, consideration of anisotropy is very important, as different orientations can result in widely differing fracture toughness values. Table 2 shows how fracture toughness can vary among materials, as well as orientation (Ref 33).

Design for Fracture Toughness

M.P. Blinn and R.A. Williams, Materials Characterization Laboratory

Analysis, Detection, and Design Criterion

The fundamental basis for designing a structure or mechanical component to be fracture resistant is to explore the interrelationship among the important elements in fracture. The most basic fracture prevention model contains three elements, as shown in Fig. 10: applied stress, crack length, and fracture toughness. Stated another way, the basic fracture prevention model should account for the applied stress (analysis), crack length (detection), and fracture toughness (design criterion).

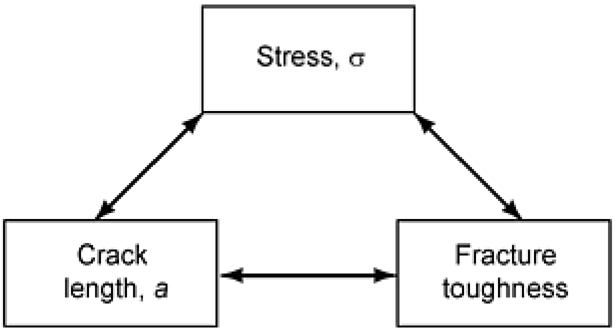

Fig. 10 The fundamental relationship between applied stress, crack length, and fracture toughness in fracture mechanics design

Analytical methods for fracture mechanics have been thoroughly studied in both LEFM and EPFM, and many closed-form solutions can be found in fracture mechanics textbooks (e.g., Ref 3, 4, 5, 9, 19, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48). With regard to stress intensity factors, small samples of some of these closed-form solutions were presented in Eq 14, 15, and 16. Additionally, some handbooks and codes show K and J solutions that are used in various industries, such as the military aircraft and nuclear pressure vessel industries (Ref 49, 50, 51, 52, 53, 54, 55, 56, 57, 58). Finite element methods in fracture mechanics, which came into vogue in the 1980s, are most commonly found in journal articles. Several popular fracture mechanics journals are good sources for all types of analytic procedures: *Engineering Fracture Mechanics, International Journal of Fracture Mechanics,* and the ASTM *Special Technical Publications.*

Cracks and Methods of Detecting Cracks. It is not an overstatement to say that defining and detecting cracks is just as important as computing the stress intensity factor. What has to be resolved in the initial phase of a fracture-resistant design is what defines the crack, either in terms of constitution, geometric size, or measurability (what is practically detectable). In the literature, various terms or phrases are used to describe a crack (or nucleation site of a crack), such as flaw, defect, discontinuity, heterogeneity, or anomaly, to name just a few. Regardless of which term is used, what is important to note goes back to Griffith (as paraphrased from Hoeppner, Ref 6): "all materials contain inherent discontinuities and heterogeneities and at times they can be crack-like." Building on this thought, it is instructive to look at what types of cracks may exist in a component or structure and where these cracks might nucleate, at least from

a metallurgical viewpoint. Table 3 contains a list of typical defects in alloys and shows various means by which a crack can nucleate in a material (Ref 59).

Table 3 Typical "defects" in alloys

Metallurgical microstructure	Processing defects	Operations defects
Inclusions (oxides, sulfides, constituents)	Casting pores	Corrosion pits
Large precipitates (carbides, intermetallics, dispersoids)	Powder contaminants (hairs, ceramics, other metals)	Wear/fretting damage
Clusters or bands (inclusions, precipitates)	Weld defects	Surface oxidation and carburization
Brittle surface coatings	Forging/extrusion "cracking" and geometry discontinuities	Hydrogen attack
Local "soft spots" (precipitate-free zones)	Tool marks and dents	Creep voiding/cracking
Local "hard spots" (solute-enriched phases)	. . .	. . .

Note: In this table, the term "defect" is defined as "a feature, sized between 1 μm and 1 mm, that impairs the mechanical integrity and performance of a component." Source: Ref 59

As defined in Table 3, a defect may be too small to be detected, especially in a large structure such as an aircraft. It is the role of the scientist, engineer, and designer to determine the practical limitations of the available detection methods, both physically and statistically. Further, the scientist, engineer, and designer must judiciously employ these detection methods, in agreement with the fracture strength of the material (fracture toughness), for the safe operation of structures and mechanical components (Ref 60). Table 4 provides a sample of some of the crack detection methods that are commonly used by industry (Ref 19).

Table 4 Inspection techniques used for cracks

Technique	Principles	Applications and notes
Direct		
Visual	Naked eye, assisted by magnifying glass, low-power microscope, lamps, mirrors	Only at places easily accessible. Detection of small cracks requires much experience.
Penetrant	Colored liquid penetrant is brushed on material and allowed to penetrate into cracks. Penetrant is washed off and a developer is applied. Remnants of penetrant in crack are extracted by developer and give colored line.	Only at places easily accessible. Sensitivity on the same order as visual inspection.
Magnetic	Part to be inspected is covered with a layer of a fluorescent liquid containing iron powder. Part is placed in a strong magnetic field and	Only applicable to magnetic materials. Parts have to be dismounted and inspected in a special

particles	is observed under ultraviolet light. At cracks, the magnetic field lines are disturbed.	cabin. Notches and other irregularities give indications. Sensitive method.
X-ray	X-rays emitted by portable x-ray tube pass through structure and are caught on film. Cracks, absorbing less x-rays than surrounding material, are delineated by black line on film.	Has great versatility and sensitivity. Interpretation problems arise if cracks occur in fillets or at edge of reinforcement. Small surface flaws in thick plates are difficult to detect.
Indirect		
Ultrasonic	Probe (piezoelectric crystal) transmits high-frequency wave into material. The wave is reflected at the ends and also at a crack. The input-pulse and the reflections are displayed on an oscilloscope. Distance between first pulse and reflection indicates position of crack. Interpretation: Reflections of crack disappear upon change of direction of wave.	Universal method since a variety of probes and input pulses can be selected. Information about the size and nature of the defect (which may not be a crack) are difficult to obtain.
Eddy current	Coil induces eddy current in the metal. In turn this induces a current in the coil. Under the presence of a crack the induction changes; the current in the coil is a measure for the surface condition.	Cheap method (no expensive equipment) and easy to apply. Coils can be made small enough to fit into holes. Sensitive method when applied by skilled person. Provides little or no information about nature and size of defect.
Acoustic emission	Measurement of the intensity of stress waves emitted inside the material as a result of plastic deformation at crack tip, and as a result of crack growth.	Inspection must be done while structure is under load. Continuous surveillance is possible. Expensive equipment is required. Interpretation of signals is difficult.

Design Criterion--Determination of Fracture Toughness Values. The fracture toughness value of a material is determined in the laboratory, with the most generally accepted test methods following standards published by ASTM. Currently, ASTM has standards E 23 for notch toughness testing, E 399 for plane-strain fracture toughness testing, and E 813, E 1737, and E 1290 for elastic-plastic fracture toughness testing (Ref 17, 20, 25, 26, 27). Other standard fracture test methods have been developed, such as British Standard 7448, Part 1 (Ref 24).

The importance of laboratory testing in determining material design parameters, such as fracture toughness, should never be underestimated. The users of a material in a design application must communicate with the testing laboratory in order to choose the appropriate test for the specific application. A structure or mechanical component may encounter a plethora of variables that affect fracture toughness, besides those discussed above. Further, any number of possible combinations of these variables can occur, leading to potentially synergistic effects.

Laboratory testing for fracture toughness is well documented in the literature, and the literature provides an excellent supplement to the test descriptions provided in the ASTM standards (Ref 3, 4, 5, 61, 62, 63). A summary of fracture tests and their comparisons is presented in Table 5 (Ref 16).

Table 5 Fracture toughness tests

Method	Advantages	Disadvantages
K_{Ic}, ASTM E 399	This method is the most reliable to get fracture toughness values at lower temperatures. The success of all other methods is based on their ability to give data comparable to this method.	The high cost of testing the large specimens required for higher temperature tends to reduce the number of data points. Linear extrapolation from valid K_{Ic} at lower temperature to higher temperature produces conservatism. No valid K_{Ic} values at higher temperature.
***J*-integral, ASTM E 813**	Provides fracture toughness values that agree with K_{Ic} method. Yields realistic fracture toughness data at higher temperature. Has the advantage (over CTOD) of a sound theoretical basis, which permits evaluation of stable crack growth. Determination of dJ/da is a measure of the resistance to continued crack propagation. Testing many small J specimens provides an indication of material toughness variation.	Not able to evaluate irregular crack propagation due to residual stress or at HAZ near welds. Not accurate enough at low temperatures. Measurements are inaccurate due to irregular crack fronts. Not valid for thin materials where K_J is 2.5 K_{Ic}. When heat tinting is used, the additional number of specimens adds to testing costs.
CTOD, BS 7448, ASK-AAN 220	Provides fracture toughness values that agree with ASTM K_{Ic} method. Yields realistic fracture toughness data at higher temperatures. CTOD results have shown good consistency and comparability with toughness values using other methods. Simultaneous measurement of CTOD and J-int. is possible for a minor extra cost.	Variations in the measurement of δ results in variations of K_{Ic} of up to a factor of 2. This method restricted to temperatures above -60 °C.
Simple equal energy	Provides fracture toughness values that agree with ASTM K_{Ic} method. Yields realistic fracture toughness data at higher temperatures. Toughness data are identical or closely similar to J-int. data.	Limitations similar to those of the J-int. method. This method is more empirical in nature, so J-int. testing is preferred.
Instrumented Charpy testing	Requires small specimens. Practically suited for determination of toughness variations in small regions of complex parts, in HAZ of welds, and in other locally embrittled zones. Error in K_{Ic} is small (in comparison to ASTM K_{Ic} method) for predominantly brittle failure.	Can provide very pessimistic values, particularly at higher temperatures. K_{Ic} is slightly underestimated at low temperatures, but considerable scatter of measurements exists above the brittle-transition temperature within a factor of 3 due to small size of specimens. Difficulty in separating the crack-initiation and crack propagation components of fracture.
Empirical methods per Begley and Logsdon	Requires small specimens. Offers a rapid and inexpensive technique to estimate K_{Ic} for wrought ferritic steels. This method indicates that Charpy K_{Ic} values are scattered and lie entirely below ASTM K_{Ic} data. Conservative by a factor of up to 3. K_{Ic} by this method provides narrow scatter band with the results below ASTM K_{Ic} by a factor of 2.	Can provide very pessimistic values, particularly at higher temperatures. Cannot give information relevant to small regions such as HAZ at welds, castings, or materials other than the ferritic steels.

CTOD, crack-tip opening displacement; HAZ, heat-affected zones. Source: Ref 16

Charpy Impact Testing. Although perhaps more of an impact energy test than a true fracture toughness test, the Charpy impact test is often used to obtain fracture toughness results. The history and early uses of this easy-to-use and relatively inexpensive test method are well described in the literature (Ref 3, 4, 5, 28). The Charpy impact test as described in ASTM E 23 (Ref 27) uses a hammer on the end of an arm to strike a CVN specimen, supported on an anvil. The pendulum motion of the hammer striking the CVN specimen results in an energy transfer to the specimen, which is measured with a visual indicator. Charpy energy, percent shear fracture, or percent elongation is generally plotted against a range of temperatures, as shown in Fig. 6.

Compliance-Based Fracture Toughness Testing. Laboratory testing for fracture toughness has become increasingly reliant on servohydraulic equipment, and a synthesis of mechanical test apparatus with sophisticated computer data acquisition and controls is becoming the fracture toughness test standard. Compliance-based fracture testing employs a displacement (CMOD) gage. DC signals are amplified and conditioned to control and monitor the test, as shown schematically in Fig. 11. The load is generally monitored by the use of a load cell, mounted within the test frame in the load train.

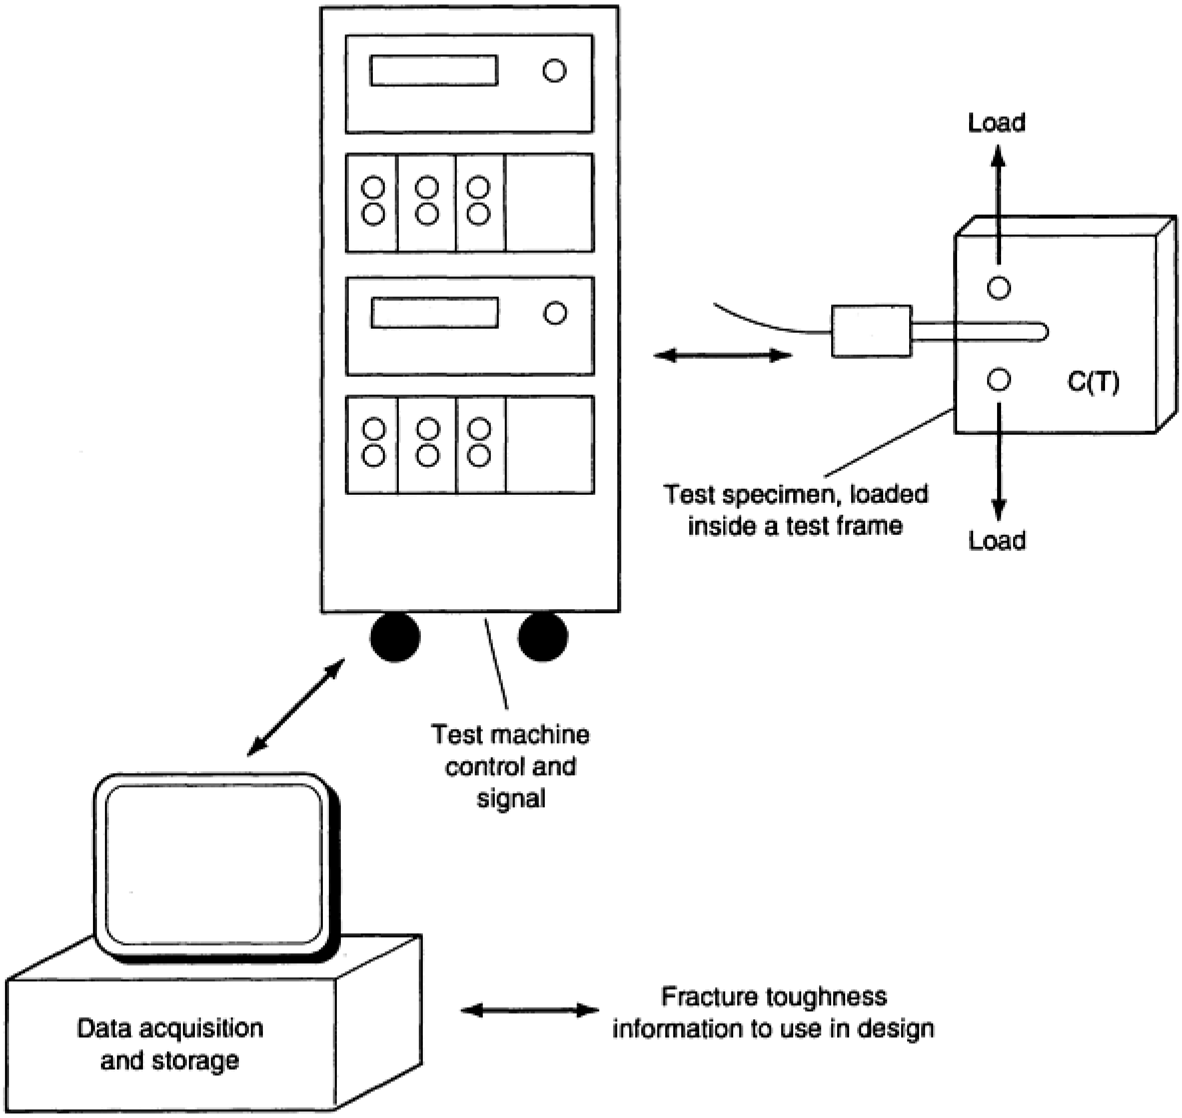

Fig. 11 Common fracture toughness testing setup, showing the interaction of the specimen tested to the control and data acquisition. Current systems generally employ servohydraulic test systems; this schematic shows a gage of crack-mouth opening displacement mounted in the compact tension (C(T)) specimen.

Compliance-based fracture testing employs the relationship between compliance, which is the reciprocal of the load-displacement plot generated during testing, and the crack length. For example, the equation for the crack mouth opening compliance of a compact tension specimen for LEFM (following ASTM E 399) can be expressed as follows (Ref 20):

$$C = \frac{EvB}{P} \quad \textbf{(Eq 26)}$$

where C is the compliance, v is the displacement of the clip gage, B is the specimen thickness, and P is the load.

The relationship between compliance and crack length has been verified in the literature (Ref 64), and these relationships are generally good for specific specimen geometries, such as compact tension (C(T)) and single-edged notch bend specimens (SE(B)), as found in ASTM E 399, E 813, and E 1737 (Ref 20, 26, 17). With reference to Fig. 12, and using the C(T) specimen for an example, the elastic compliance relationship (following ASTM designation E 399) works as follows:

1. The clip gage records a displacement and the load cell records the load, both values of which are input into the compliance equation (Eq 26).
2. The compliance is input into an equation of the form:

$$u_x = \{\sqrt{C} + 1\}^{-1} \quad \textbf{(Eq 27)}$$

3. where u_x is a value to use for a polynomial expression.
4. Continuing, u_x is input into a fifth-order polynomial expression with various constants as follows:

$$\frac{a}{W} = c_0 + c_1 u_x + c_2 u_x^2 + +c_3 u_x^3 + c_4 u_x^4 + c_5 u_x^5 \quad \textbf{(Eq 28)}$$

5. where W is the specimen width and c_i are various constants. Multiplying both sides of the equation by W obtains the crack length.
6. Finally, the stress intensity factor can be determined by the following expression:

$$K = \left(\frac{P}{B\sqrt{W}}\right) f\left(\frac{a}{W}\right) \quad \textbf{(Eq 29)}$$

7.

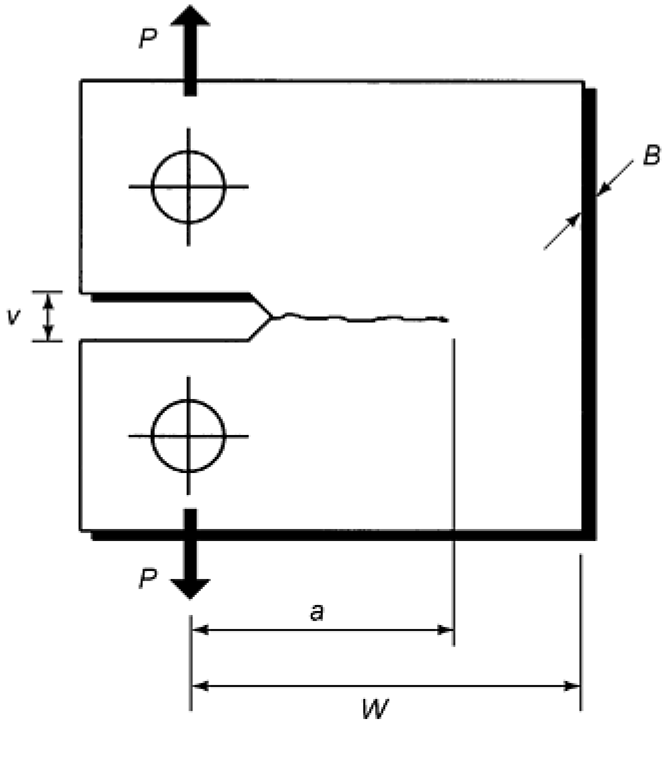

Fig. 12 Schematic of a compact tension specimen used for fracture testing. *P*, load; *W*, width; *B*, thickness; *v*, displacement; *a*, crack length

It should be noted that the compliance-based procedure just developed describes only LEFM testing in detail. For EPFM testing the procedure is essentially the same, except that plasticity must be accounted for in the determination of J and CMOD. For information on that topic, see ASTM E 813 and E 1737, and some of the more current fracture mechanics texts (Ref 5, 17, 23, 26, 44, 45).

The direct current electric potential (DCEP) technique for fracture toughness testing is being recognized as a viable alternative to compliance-based testing, and it has recently been incorporated into ASTM E 1737 as Appendix A (Ref 17). Higher-temperature applications are well suited for the DCEP technique, as the electrical wiring involved is less cumbersome than CMOD gages, especially in an environmental chamber, and more cost effective. The DCEP technique is not particularly well suited for relatively large or thick specimens.

The DCEP technique is relatively simple, generally consisting of a direct current source, voltmeter, amplifier, and recording device. A constant direct current is passed through the specimen, which acts as a resistor in the circuit. During testing, the crack in the fracture specimen increases, reducing the remaining uncracked portion of the specimen (the ligament). Reduction in the cross-sectional area of the specimen ligament constricts the current flow and increases the resistance of the specimen. Hence, during a DCEP fracture toughness test, the electric circuit can be modeled by the following simple equation:

$$V = IR \qquad \textbf{(Eq 30)}$$

where V is the electric potential, I is the direct current, and R is the specimen resistance.

A reference voltage (U_0) is established at the start of the test, with the subsequent voltages (U_i) recorded at predetermined intervals. Crack length is determined using a calibration procedure, as described in ASTM E 1737, and the ratio of U_0 and U_i is an important input in the crack length calculations. The calculations of the stress intensity factors are the same as in the unloading compliance method; it is the method of establishing the crack length that differs.

Design for Fracture Toughness

M.P. Blinn and R.A. Williams, Materials Characterization Laboratory

Fracture Toughness and Design Philosophies

It was not until the second half of the 20th century that scientists and the engineering community at large embraced fracture mechanics for design. Slightly earlier to (and nearly concurrent with) the advances made in fracture design was the progress in the study of fatigue. It is interesting to note that just as a great deal of fracture failures nucleate from fatigue cracks, fracture design evolved from fatigue design. To fully appreciate the use of fracture toughness in design, it is instructive to follow the evolution of fatigue and fracture in design, from infinite-life design to modern damage-tolerant design philosophies.

Infinite-life design is perhaps the oldest fatigue design philosophy, where the design stress of the structure or component is established below the fatigue limit of the material. This philosophy relies on stress-life plots of uncracked specimens to determine the fatigue limit of a material. It is still in use, although more contemporary fatigue and fracture design philosophies predominate. What can be called into question about this design philosophy is the initial premise that the material is crack free; Griffith disproved this premise long ago.

Safe-life design developed as a logical progression away from the inherent conservatism of infinite-life design. Many structures and mechanical components are intended to be in service for a specified length of time, rather than indefinitely. Hence, the restrictions of a safe-life design can be relaxed by the use of "finite-life" design. Instead of establishing the design stress below the fatigue limit, the design stress is based on the stress associated with the design number of cycles, with an appropriate safety factor applied. This design philosophy is the basis for some of the ASME boiler and pressure vessel codes and the ground vehicle industry. In modern aircraft design, the safe-life design approach is used for components whose failure would result in the loss of the aircraft in service, such as the landing gear (Ref 18).

Safe-life design assumes a macrocrack-free structure, and the structure (or component) under consideration must remain macrocrack-free during service. A macrocrack-free component is not the same as a crack-free component; a macro-crack can be detected during inspection.

Fail-safe design ensures that the structure will support load after any single member fails, or after there is partial damage to an extensive structure. While there is nothing implicit about the presence or absence of cracks, some fail-safe designs account for the "possibility" of cracks by incorporating crack arresters, crack stoppers, and crack deflectors. In aircraft design, a complete fail-safe design provides for failure of a single component or for partial damage to the structure, while maintaining adequate stiffness in the structure for control.

Damage tolerance is the ability of a structure to sustain anticipated loads in the presence of fatigue, corrosion, or accidental damage until such damage is detected through inspections or malfunctions and repaired. Damage tolerance techniques can be applied to safe-life and fail-safe design. However, with respect to fracture mechanics, damage tolerance is a more contemporary approach to the design of structures and mechanical components, where the initial basis for design is the belief that cracks "will" exist in the structure or mechanical component. Taken a step further, the "complete" damage-tolerant design assumes that cracks may occur at any stage in the manufacturing process or service life of a product. Further, damage-tolerant design is intended to be intimately linked with periodic inspections of the structure or

mechanical component under consideration, ensuring that repair or replacement of a damaged item is performed in a safe, timely manner.

As a summary of the different fatigue and fracture mechanics design philosophies and their relationship with fracture toughness, an example from aircraft design is shown in Table 6 (Ref 33). To show their significance in design, items related to fracture toughness are shown in bold print.

Table 6 Design criteria for sizing aircraft, showing how fracture toughness is used in damage-tolerant design

Mode of failure	Design criteria	Allowable data
Static strength of undamaged structure	Structure must support ultimate loads without failure for 3 s	Static properties
Deformation of undamaged structure	Deformation of the structure at limit loads may not interfere with safe operation	Static properties and creep properties for elevated-temperature conditions
Fatigue crack initiation of undamaged structure	Fail-safe structure must meet customer service life requirements for operational loading conditions. Safe-life components must remain crack-free in service. Replacement times must be specified for limited life components.	Fatigue properties
Residual static strength of damaged structure	**Fail-safe structure must support 80-100% limit loads without catastrophic failure, a single member failed in redundant structure or partial failure in monolithic structure.**	Static properties and **fracture toughness properties**
Crack growth life of damaged structure	**For fail-safe structure, inspection techniques and frequency must be specified to minimize risk of catastrophic failures. For safe-life structure, must define inspection techniques and frequencies and replacement times, so that probability of failure due to fatigue cracking is extremely remote.**	Crack growth properties and **fracture toughness properties**

Design for Fracture Toughness

M.P. Blinn and R.A. Williams, Materials Characterization Laboratory

Examples of Fracture Toughness in Design

The use of fracture toughness in design is extensively covered in numerous articles, textbooks, and handbooks related to aircraft design and damage tolerance (Ref 65, 66, 67, 68, 69, 70, 71). Additionally, there are various articles, texts, handbooks, and codes related to pressure vessel design (Ref 72, 73). Fracture mechanics is pertinent to other disciplines as well, such as the automotive and aerospace industries (Ref 74, 75).

Other excellent sources of literature on fracture mechanics are failure analysis studies. Some of these are contained in fracture texts (Ref 4); others are found in complete texts covering the subject of failure analysis (Ref 76, 77). A rigorous failure analysis gives good insight into how a fracture failure can occur and what the scientist, engineer, and designer should consider for a damage-tolerant structure or material component.

The reader also should be aware of the use of various engineering "tools" to assist in LEFM and especially EPFM analysis of structures or components. Some of these tools are the Welding Institute CTOD design curve, the failure assessment diagram (FAD), and the deformation plasticity failure assessment diagram (DPFAD). The use of these

approaches in the design against fracture is well documented, and some excellent articles related to their use (including case studies) may be found in the literature (Ref 78, 79, 80). Another general reference book on fracture mechanics is *Fatigue and Fracture,* Volume 19 of *ASM Handbook.*

Example 1: LEFM Analysis of a Cracked Jacketed Pressure Vessel.

The following example summarizes the use of LEFM in the analysis of a jacketed thick-walled pressure vessel, subjected to high pressures above 69 MPa (10 ksi). This case study, originally published as a journal article (Ref 81), is a straightforward example of the use of fracture toughness and damage tolerant methods in design. What is especially interesting is the magnitude of the pressures involved, and the application of a unique technology in controlling these pressures: high-pressure engineering.

Many large, vintage 1945 pressure vessels were returned to service in the late 1980s and were subjected to repeated pressurizations. It was observed that some of these pressure vessels developed long, shallow cracks at the inside diameter (ID) in the longitudinal direction. A damage tolerance assessment was performed to determine three important quantities: the fracture toughness of the material, the applied stresses during service (stress intensities in service), and the critical flaw size (crack length). Note that these are the same quantities discussed in the fundamental fracture mechanics relationship diagram (Fig. 10).

The geometry of the pressure vessel is shown schematically in Fig. 13, where a is the inside radius (IR) of the liner, b is the outside radius (OR) of the liner (and the IR of the jacket), and c is the OR of the jacket. The dimensions of the pressure vessel were as follows: a is 20.32 cm (8.00 in.), b is 25.81 cm (10.16 in.), and c is 62.23 cm (24.50 in.). The k ratio (ratio of c/a), an important measure in high-pressure engineering (Ref 82), was calculated as 3.06. It is interesting to note, from the standpoint of damage tolerance, that the liner in a pressure vessel served as a crack arrestor.

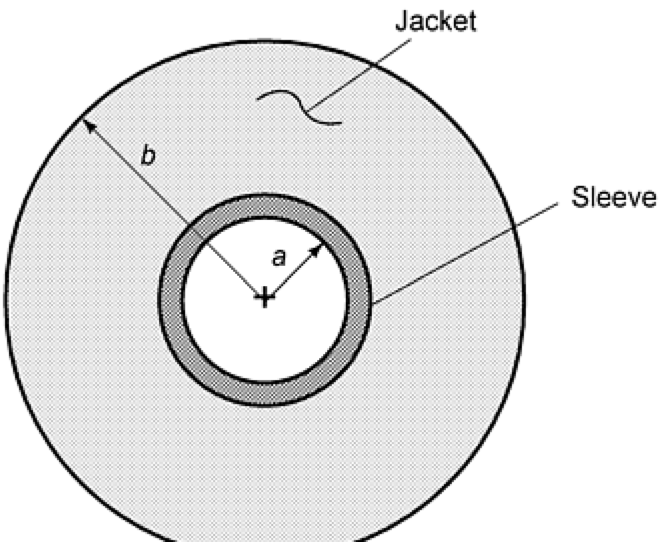

Fig. 13 Schematic of the pressure vessel example, showing the pertinent dimensions for analysis. Source: Ref 81

Metallurgical examination of the liners revealed two microstructures to consider in a damage tolerance analysis. Plane-strain fracture toughness tests were conducted according to ASTM E 399 on two different materials, one containing a pearlitic microstructure and one containing a ferrite/bainite microstructure. Further, to evaluate temperature effects, two temperatures were selected: -40 and +25 °C (-40 and +70 °F). The results of the fracture toughness tests, presented in Table 7, determined the first part of the damage tolerance assessment.

Table 7 Fracture properties of the pressure vessel liner material in Example 1

Specimen	Test temperature		Fracture toughness		Microstructure	Validity
	°C	**°F**	**MPa** $\sqrt{m}$	**ksi** $\sqrt{in.}$		
A-4	25	77	99.4	90.4	F/B	No
A-2	25	77	117.3	106.7	F/B	No
B-1	25	77	99.4	90.4	P	Marginal
B-4	25	77	90.1	82.0	P	Marginal
B-2	-40	-40	69.4	63.1	P	Yes
B-3	-40	-40	64.7	58.9	P	Yes
A-1	-40	-40	119.7	108.9	F/B	No
A-3	-40	-40	98.6	89.7	F/B	Marginal

The stress analysis was performed using finite element models and evaluating the effects of shrink fitting the liner into a much thicker jacket. This was the second step of the damage tolerance assessment. The basic tangential stresses ($\sigma\theta$) at the ID and the stress intensity factor used in the fracture toughness analysis were calculated as follows (Ref 82):

$$\sigma_\theta = \frac{2pk^2}{k^2 - 1} \quad \text{(internal pressure)} \qquad \textbf{(Eq 31)}$$

$$\sigma_\theta = \frac{-2b^2}{b^2 - a^2}\frac{E}{\delta}\left(\frac{(c^2 - b^2)(b^2 - a^2)}{2b^2\,(c^2 - a^2)}\right) \qquad \textbf{(Eq 32)}$$

(shrink fit)

$$f\left(\frac{l}{W}\right) = 1.12 - 0.175\left(\frac{l}{W}\right) - 0.515\left(\frac{l}{W}\right)^2 + 1.43\left(\frac{l}{W}\right)^3 \qquad \textbf{(Eq 33)}$$

(internal pressure)

$$f\left(\frac{l}{W}\right) = 1.12 - 0.217\left(\frac{l}{W}\right) - 0.268\left(\frac{l}{W}\right)^2 + 0.943\left(\frac{l}{W}\right)^3 \qquad \textbf{(Eq 34)}$$

(shrink fit)

$$K = \sigma_\theta\,(\text{ID})\,\sqrt{\pi l}\,f\left(\frac{l}{W}\right) \qquad \textbf{(Eq 35)}$$

(internal pressure and shrink fit)

where $\sigma\theta$(ID) is the stress at the ID, *l* is the crack length, and *f* (*l*/*W*) is the geometric shape factor.

Finally, by establishing the relationship among internal pressure, interference fit, tangential stress, and fracture toughness, a critical crack length was determined by graphical analysis. Essentially, the equation for the stress intensity factor (Eq 35) was rearranged for both the internal pressure and shrink fit cases and plotted as *K* against crack length. From these plots, a third plot, the algebraic sum of the two plots, determined the combined solution. For this analysis, the critical crack lengths were evaluated at two internal pressures, 296.5 and 342.7 MPa (43 and 49.7 ksi). Table 8 shows estimates of the critical crack sizes for both internal pressure cases, evaluated at various fracture toughness values. For example, a high-pressure vessel loaded at 342.7 MPa (49.7 ksi) internal pressure and having a material fracture toughness of 551.2 MPa (80 ksi) would have a critical crack length of 6.4 mm (0.25 in.). This is the final step in this basic damage tolerance model, and from the critical crack size, service life and inspection techniques can be reviewed.

Table 8 Calculated value of the critical crack length in Example 1

Internal pressure $\sigma\theta$ (ID)	Critical crack length at indicated fracture toughness (K_{Ic}) value				
	137.8 MPa (20 ksi)	**275.6 MPa (40 ksi)**	**413.4 MPa (60 ksi)**	**551.2 MPa (80 ksi)**	**689.0 MPa (100 ksi)**
296.5 MPa (43.0 ksi)	0.5 mm (0.02 in.)	2.0 mm (0.08 in.)	5.3 mm (0.21 in.)	4.57 mm (0.36 in.)	. . .

The Future Direction of Fracture Toughness in Design

Although fracture mechanics is a relatively mature science, there is still a great deal of refinement that can be made to the use of fracture mechanics in design applications. In the 1960s and 1970s, the focus was on LEFM analysis and testing methods; from the 1970s to the present, EPFM analysis and testing methods have been of greatest interest. LEFM and EPFM will be the paradigm for fracture mechanics into the next century, and they will surely be improved upon. Additionally, in the next few decades, with the trend towards maintaining longer service lives of structures such as military and commercial aircraft, there will undoubtedly be improvements in crack (flaw) detection.

Finally, there will be constant challenges for the scientist, engineer, and designer of damage-tolerant structures. Materials will be taken to their limits, and each new prototypic structure will contain some "exotic" or modified material(s) that will have to be characterized for fracture resistance. Another development, advocated by Griffith as early as the 1920s, will be the refinement of engineering materials to improve fracture strength. This approach should be viewed in terms of microdiscontinuities (which can be addressed by advancements in material refining techniques) and macrodiscontinuities (which can be alleviated by careful attention to the manufacturing and fabrication processes). The metallurgist may have a role in developing an engineering material for a component or structure; the mechanical, civil, or structural engineer may have a role in designing a workable component or structure using this material. Regardless on what level people work, everyone in the manufacturing and design process should always look towards improving the product.

Design for Fracture Toughness

Design for Corrosion Resistance

F. Peter Ford and Peter L. Andresen, General Electric Corporate Research and Development Center; Peter Elliott, Corrosion and Materials Consultancy, Inc.

Introduction

THE ANNUAL COST OF CORROSION in the United States in 1949 (Ref 1) was 2.1% of the gross national product (GNP), or $5 billion. Subsequent analysis (Ref 2) in 1975 indicated an increase to 4.2% GNP ($70 billion), with an estimate of $126 billion by 1982. Similar values have been quoted in other countries, including the United Kingdom (Ref 3) and Taiwan (Ref 4). These figures are associated with the direct cost of replacement of the corroded structure; additional costs are associated with maintance, increased regulatory demand (e.g., environment control), and lost production.

Not only is there a direct and indirect financial burden, but corrosion also has a considerable societal impact. Crucial industries such as energy, aerospace, transportation, food, agriculture, electronics, marine, and petrochemical rely on the safety and availability of their infrastructures. In many instances, these requirements have been compromised by corrosion events that have led to loss of life, environmental pollution, and loss of power to industry. However, between 25 and 50% of the economic impact (depending on the specific industry) could have been prevented by the use of well-accepted materials selection and corrosion prevention measures. The purpose of this article is to give the reader a concept of the principles of corrosion and the basis of the various prevention measures that can be taken for the different corrosion modes. Reference may be made to numerous textbooks, handbooks, and articles for specific material/environment systems for more detailed discussions (see Ref 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28 and the "Selected References" listed at the end of this article).

Design for Corrosion Resistance

F. Peter Ford and Peter L. Andresen, General Electric Corporate Research and Development Center; Peter Elliott, Corrosion and Materials Consultancy, Inc.

Basic Principles of Aqueous Corrosion

Aqueous corrosion phenomena are largely understood in terms of the electrochemical reactions that occur at the metal-environment interface. The metal surface can be in elemental form (e.g., copper or gold), as an alloy perhaps containing a mixture of phases, but more often the metal surface will have an oxide, compound, or salt layer between it and the environment. The role of this layer is discussed later in this section. The environment is usually water and its dissociation products H^+ (or H_3O^+) and OH^-, plus ionic impurities such as Na^+, Cl^-, or SO_4^{2-} and dissolved gases (e.g., oxygen, carbon dioxide). The amounts of these impurities can range from parts per billion to highly concentrated conditions; even at the lowest levels, however, these impurity levels can significantly affect certain corrosion events.

Metal atom (M) "removal" from the surface occurs primarily by reactions of the general type

$$M + zH_2O \rightarrow M^{n+} \cdot zH_2O + ne^- \quad \textbf{(Eq 1)}$$

$$xM + yH_2O \rightarrow M_xO_y + 2yH^+ + 2ye^- \quad \textbf{(Eq 2)}$$

where *n* is the number of electrons involved in the overall oxidation of an atom of metal and *z* is the hydration number.

For instance, bare surface corrosion occurs by a series of individual atomic steps that may be described overall by Eq 1. In essence, a metal atom combines with *z* solvating water molecules (zH_2O) and goes into solution as a solvated cation ($M^{n+} \cdot zH_2O$), liberating *n* electrons into the underlying metal substrate. Alternatively, the metal atom may interact with the water molecules to form a metal oxide (M_xO_y) on the surface by the solid-state reaction described overall by Eq 2. Because both of these reactions involve the liberation of electrons, they are known in electrochemical terms as "oxidation" reactions that occur at "anodic" sites on the metal.

Under natural corrosion conditions the electrons liberated by these oxidation reactions will be consumed by "reduction" reactions occurring at adjacent "cathodic" sites (Fig. 1). Such reactions may be of the type

$$2H^+ + 2e^- \rightarrow 2H_{ads} \rightarrow H_2 \uparrow \quad \textbf{(Eq 3)}$$

where, in acid solutions, hydrogen ions are reduced to form adsorbed hydrogen atoms (H^+) on the surface. These adsorbed hydrogen atoms may then either be absorbed into the metal (discussed below) or, as shown in Eq 3, combine with adjacent atoms to form hydrogen gas, which may bubble off as gas, allowing corrosion to proceed, or remain as a film that eventually slows or halts corrosion. In more neutral or alkaline solutions, the reduction reaction (because of the dissociation relationships between H_2O, H^+, and OH^-) is of the form

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \quad \textbf{(Eq 4)}$$

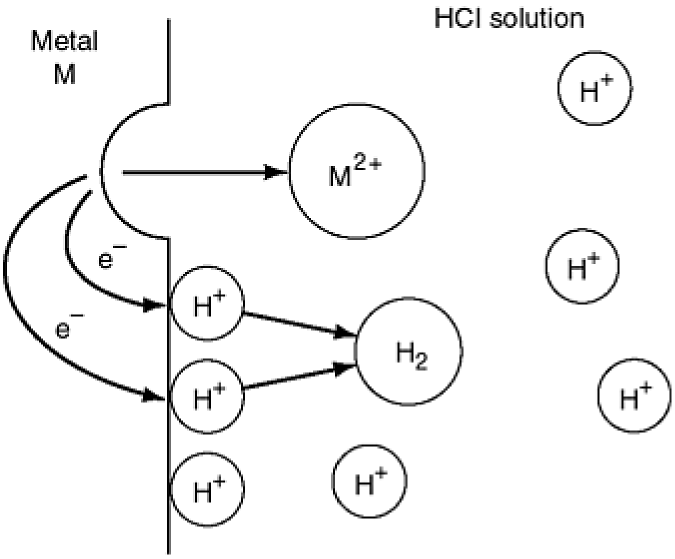

Fig. 1 Schematic representation of oxidation and reduction reactions occurring on a corroding metal surface. Source: Ref 5

In solutions containing dissolved oxygen, the electron consumption at the cathodic site in alkaline solutions is usually achieved by the reduction reaction

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \qquad \textbf{(Eq 5a)}$$

or in acid solutions by:

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O \qquad \textbf{(Eq 5b)}$$

In other instances where reducible cations are present, the cathodic reaction may be:

$$Fe^{3+} + e^- \rightarrow Fe^{2+} \qquad \textbf{(Eq 6)}$$

or

$$Cu^{2+} + e^- \rightarrow Cu^+ \qquad \textbf{(Eq 7)}$$

Thus, in summary, the metal corrosion (or oxidation) reactions are always associated with one or more reduction reactions. In order to conserve charge, the sum of these oxidation and reduction rates must be equal. Thus, in simplistic terms, the corrosion of, say, zinc in a deaerated acid solution would be described by Eq 1 and 3 to give:

$$Zn + 2H^+ \rightarrow Zn^{2+} + H_2 \qquad \textbf{(Eq 8)}$$

that is, zinc dissolution with hydrogen evolution.

Because these oxidation and reduction reactions involve a transfer of charged species adjacent to the surface, an equivalent capacitor is formed for which there is an associated electrode potential across the metal/solution interface (Fig. 2). Under "equilibrium" (reversible) conditions, the oxidation and reduction reactions shown in Eq 9, which are associated with metal dissolution (the forward reaction) and metal deposition (the backward reaction), occur at equal rates, and the

equilibrium potential is given by a function of the free energies of formation of the relevant species and their activities (this relationship is discussed later in this section):

$$M + zH_2O \leftrightarrow M^{n+} \cdot zH_2O + ne^- \qquad \textbf{(Eq 9)}$$

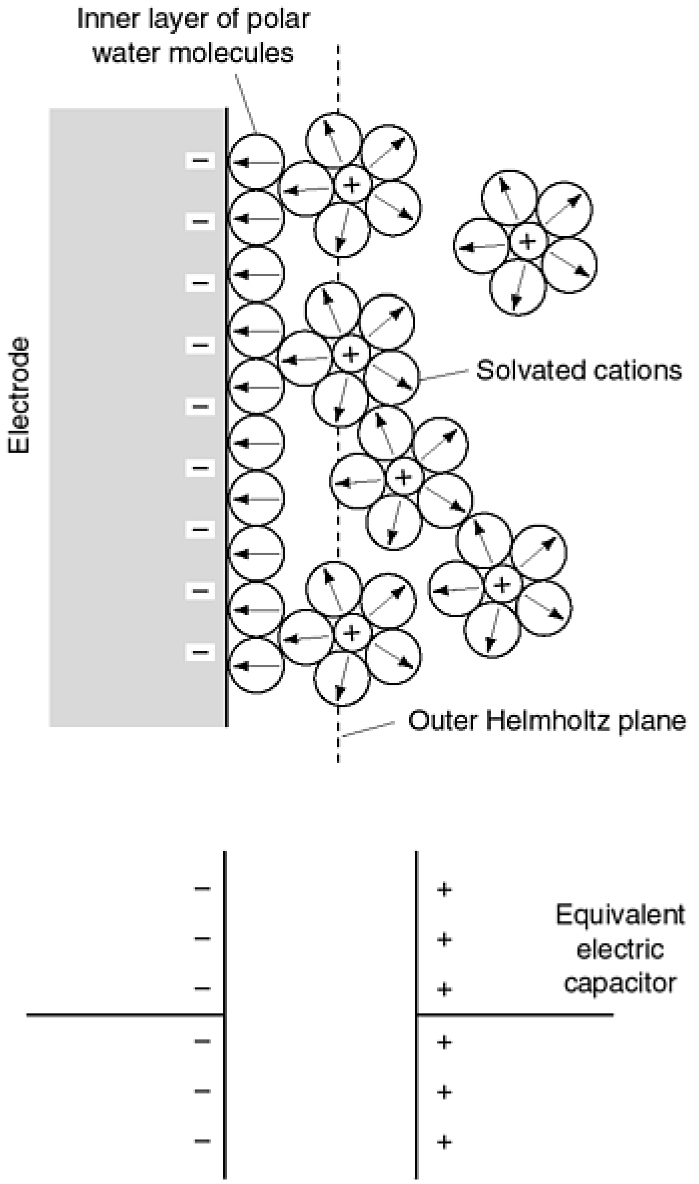

Fig. 2 Schematic electrode surface structure with equivalent electric capacitor. The circles containing arrows represent water molecules; the direction of arrows indicates the orientation of the hydrogen atoms in the molecule. Source: Ref 5

Note that, if the metal/solution potential is moved either way from the equilibrium potential, there will be a net increase in oxidation rate (i.e., dissolution) or reduction rate (metal deposition). Because these reactions involve electron movement, the rates of reaction may be quantified in terms of current that can often be measured. Because the reaction rates occur over a specific area, the unit of practical significance is the current density (*i*). Faraday's law relates this current density to the amount of metal being uniformly dissolved or reduced, in unit time:

$$CR = \frac{M}{n\rho F} i_a \qquad \textbf{(Eq 10)}$$

where CR is the corrosion rate (cm/s), i_a is the oxidation current density (amps/cm^2), *n* is the number of electrons (or "equivalents") involved (e.g., in the oxidation reaction of Eq 1), ρ is the density of corroding metal (g/cm^3), F is the Faraday constant (96,500 coulombs/"equivalent"), and *M* is the atomic weight of corroding metal (g).

As a point of reference, an anodic current density of 1 μA/cm^2 corresponds to approximately 0.4 to 0.5 mils/year (mpy) metal removal rate for many ferrous, aluminum, copper, and nickel-base alloys.

The relationships between the rates of oxidation and reduction reactions shown in Eq 9 and the electrode potential (known as "polarization" relationships) are shown schematically in Fig. 3. The most fundamental relationship between the oxidation reaction rate for Eq 9 and the overpotential (η_a), which is defined as the difference between the electrode potential and the equilibrium potential, is given by:

$$\eta_a = \beta_a \log \frac{i_a}{i_o} \quad \textbf{(Eq 11)}$$

where i_o is known as the "exchange current density" and β_a is the Tafel coefficient for the anodic reaction, which is the slope of η_a vs. log i_a. The oxidation (or reduction) rate may rise exponentially with increasing overpotential (Fig. 3a). This increase is not endless, however, for eventually the reaction rate will become controlled by the diffusion of reactants to, or the reaction products from, the metal/solution interface region. This mass transfer will be dependent on convection considerations as well as on the bulk concentration of the relevant dissolved species, and it will be evidenced by a reaction rate that is not directly dependent on potential (Fig. 3b). In systems where an oxide can form on the reacting surface in certain potential ranges (e.g., Eq 2), the dissolution rate (i_a) may abruptly drop due to "passivation" to an extremely low value (Fig. 3c); however, at higher potentials the passive film may lose its protective nature because of its dissolution (or "transpassivity") or to localized degradation due to aggressive anions (e.g., pitting in saline solutions). Thus, the polarization curves may change with different alloy/environment conditions, and, as will be seen later, this behavior will give the possibility of a large combination of corrosion responses.

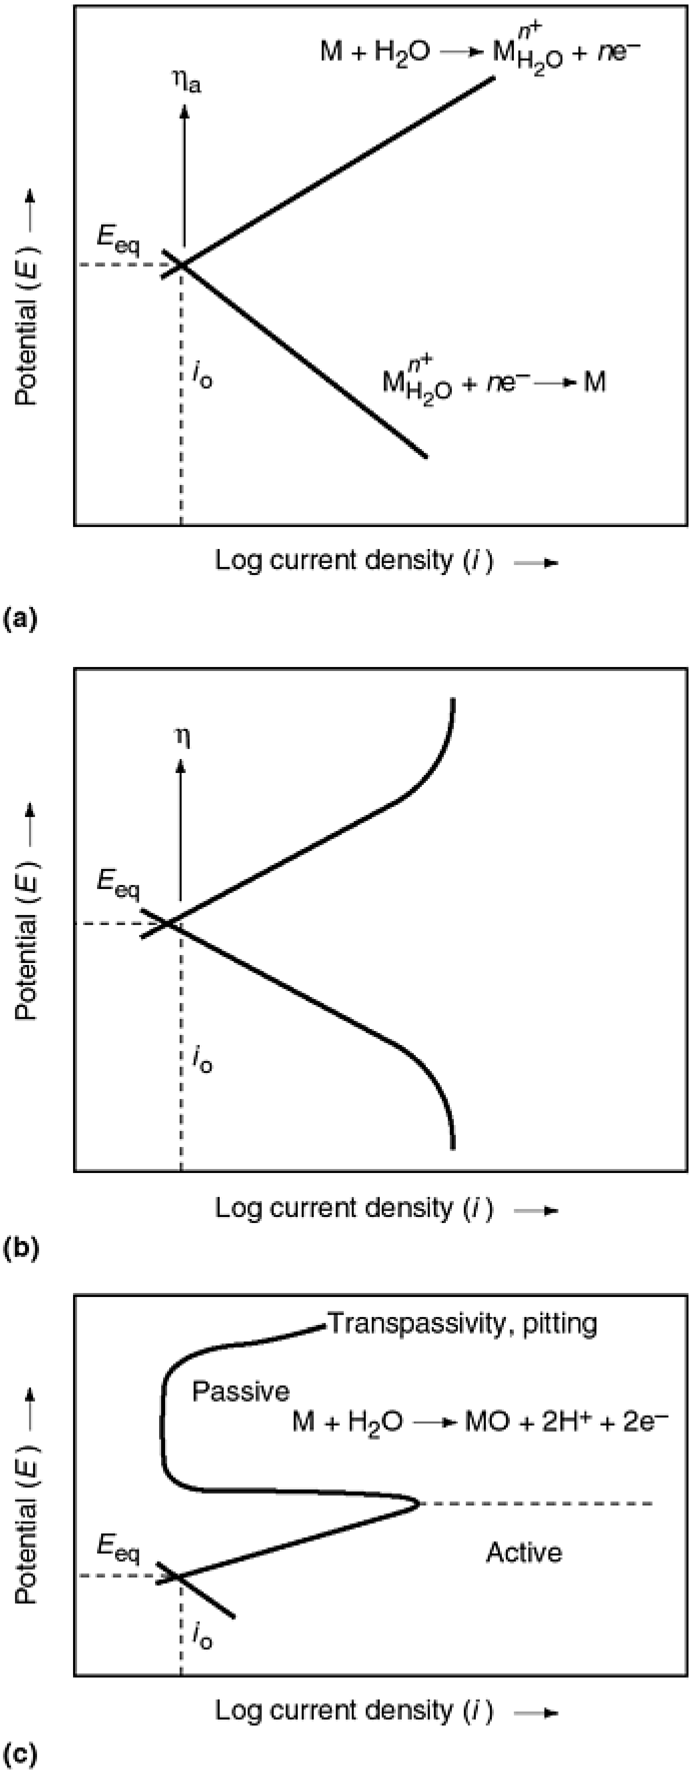

Fig. 3 Schematic Evans diagrams showing polarization relationships between electrode potential (*E*) and current density (*i*) indicating: (a) activation control, (b) onset of mass-transport (diffusion) control at higher overpotentials, and (c) active-to-passive transitions due to formation of surface oxide, followed by breakdown

or dissolution of oxide at higher overpotentials. E_{eq}, equilibrium potential

Bearing in mind that several reactions may be possible at a given metal/solution interface, a composite reaction rate diagram can be developed. For instance, the two-reaction system shown in Fig. 4 illustrates the oxidation reaction associated with the corrosion of a metal (Eq 1) and the corresponding reduction of H^+ ions in an acid environment (Eq 3). Based on this reaction rate construction (known as an Evans diagram), and bearing in mind that the net oxidation and net reduction reaction rates must be equal, the corrosion current density (i_{corr}) can then be predicted, and this result can be converted to uniform dimensional loss by Eq 10.

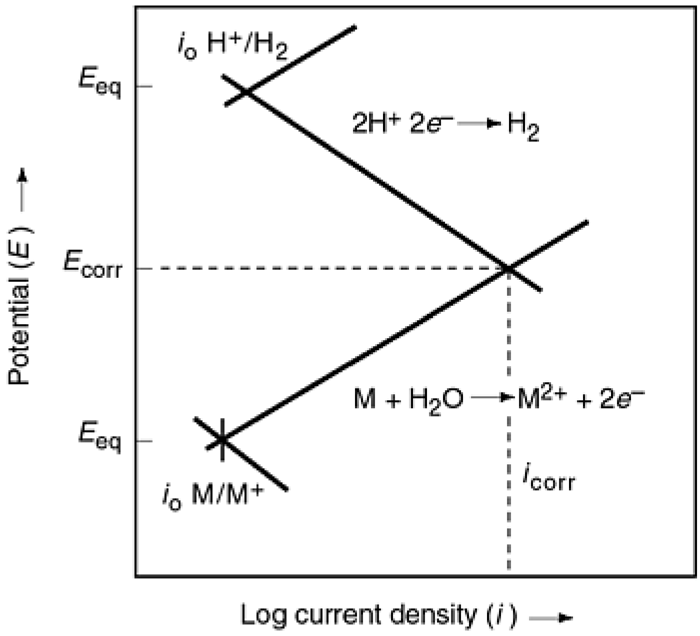

Fig. 4 Schematic Evans diagram showing oxidation and reduction reactions associated with, for instance, M → M^+ and H^+ → H_2 reactions, illustrating the fact that when the relevant oxidation and reduction reaction rates are in dynamic equilibrium, the metal/solution interface will attain the measured corrosion potential (E_{corr}) and the metal will corrode at a rate corresponding to i_{corr}

As indicated in Fig. 4 for a naturally corroding system, the potential between the metal and solution will have a value known as the "corrosion potential " (E_{corr}), defined by the balance of the net oxidation and reduction reaction rates. The relative difference between E_{corr} and the equilibrium potentials for the various possible reactions is of importance in determining potential corrosion mitigation actions. Thus, a brief review of the equilibrium thermodynamics at the metal/solution interface is given below, because it is relevant to the arguments that are given in a later section of this article, "Forms of Corrosion and General Mitigation Approaches."

When computing the metal/solution potential associated with the various half-cell reactions (e.g., Eq 1, 2, 3, 4, 5a, 5b, 6, 7), it is conventional to formulate the reactions as reduction processes, for example:

$$Ni^{2+} + 2e^- \rightarrow Ni \qquad \textbf{(Eq 12)}$$

The "reduction" potential (E) associated with the metal/solution interface (Fig. 2) will be related to the free-energy changes (ΔG) in the reaction shown in Eq 12:

$$E = -\frac{\Delta G}{nF} \qquad \textbf{(Eq 13)}$$

Since ΔG of a reaction can be expressed as RT ln (products/reactants) and a ΔG^0 (and, therefore, E^0) is used to define ΔG under standard conditions, an overall relationship, known as the Nernst equation, can be formulated for the Ni^{2+}/Ni reaction:

$$E = E^0 + \frac{RT}{nF} \ln (a_{Ni^{2+}}) = E^0 + 0.03 \log (a_{Ni^{2+}}) \quad \textbf{(Eq 14)}$$

where E^0 is the "standard potential" for Ni^{2+}/Ni, and $a_{Ni^{2+}}$ is the chemical activity of Ni^{2+} cations in the solution. Standard potentials are those realized when the relevant species are in their "standard" states of unit activity (for dissolved species) or unit fugacity (for gaseous species) usually at 25 °C.

These metal/solution potentials cannot be directly measured experimentally (because measurement automatically requires a second metal/solution half-cell electrode); therefore, they are defined in relation to the standard H^+/H_2 half-cell reaction (often measured on inert platinum):

$$2H^+_{(\text{unit activity})} + 2e^- \leftrightarrow H_{2\,(\text{unit fugacity})} \quad \textbf{(Eq 15)}$$

whose standard potential is, by convention, defined as zero at all temperatures. Thus, all metal/solution potentials are measured with respect to this standard hydrogen electrode (SHE) or to an equivalent, well-defined half-cell reaction (reference electrode) that has been calibrated against the SHE. Table 1 lists the standard (reduction) potentials for several metals and nonmetals with respect to their dissolved form. This table illustrates (bearing in mind that the potential is related to free energy changes) that the stability of the elements with respect to their dissolved cations ranges from the very stable noble metals (gold, platinum) to the very unstable elements (sodium, potassium). However, it is important to recognize that Table 1 does not *necessarily* give the relative ranking of metal corrosion resistance, because this ranking will depend on the specifics of the environment, the extent of elemental alloying, and the formation of surface oxides. These specific factors are covered in the section "Forms of Corrosion and General Mitigation Approaches" in this article.

Table 1 Standard electromotive force potentials (reduction potentials)

Reaction	Standard potential, E^0 (volts vs. SHE)
Noble (more cathodic)	
$Au^{3+} + 3e^- = Au$	+1.498
$Cl_2 + 2e^- = 2Cl^-$	+1.358
$O_2 + 4H^+ + 4e^- = 2H_2O$ (pH 0)	+1.299
$Pt^{2+} + 3e^- = Pt$	+1.118
$NO_3^- + 4H^+ + 3e^- = NO + 2H_2O$	+0.957
$O_2 + 2H_2O + 4e^- = 4OH^-$ (pH 7)	+0.82
$Ag^+ + e^- = Ag$	+0.799
$Hg_2^{2+} + 2e^- = 2Hg$	+0.799
$Fe^{3+} + e^- = Fe^{2+}$	+0.771
$O_2 + 2H_2O + 4e^- = 4OH^-$ (pH 14)	+0.401
$Cu^{2+} + 2e^- = Cu$	+0.342
$Sn^{4+} + 2e^- = Sn^{2+}$	+0.15
$2H^+ + 2e^- = H_2$	0.000
$Pb^{2+} + 2e^- = Pb$	-0.126
$Sn^{2+} + 2e^- = Sn$	-0.138
$Ni^{2+} + 2e^- = Ni$	-0.250
$Co^{2+} + 2e^- = Co$	-0.277
$Cd^{2+} + 2e^- = Cd$	-0.403
$2H_2O + 2e^- = H_2 + 2OH^-$ (pH 7)	-0.413
$Fe^{2+} + 2e^- = Fe$	-0.447
$Ce^{3+} + 3e^- = Cr$	-0.744
$Zn^{2+} + 2e^- = Zn$	-0.762
$2H_2O + 2e^- = H_2 + 2OH^-$ (pH 14)	-0.828

$Al^{3+} + 3e^- = Al$	-1.662
$Mg^{2+} + 2e^- = Mg$	-2.372
$Na^+ + e^- = Na$	-2.71
$K^+ + e^- = K$	-2.931
Active (more anodic)	

Thus, the equilibrium potential for, say, a Ni^{2+}/Ni half-cell reaction shown in Eq 12 can be defined as:

$$E = -0.25 + 0.03 \log (a_{Ni^{2+}}) \text{ volts (SHE)} \quad \textbf{(Eq 16)}$$

This particular equilibrium potential relationship is independent of the activity of H^+ ions (i.e., the pH). However, this is not the situation for other technically important reactions. For instance, the formation of an oxide by a solid-state reaction (e.g., Eq 2) will be dependent on the pH of the solution, e.g.:

$$Ni + H_2O \leftrightarrow NiO + 2H^+ + 2e^- \quad \textbf{(Eq 17)}$$

and the equilibrium potential will be defined by $E = +0.11 + 0.03 \log (a_{H^+})^2$, and because pH = -log (a_{H^+}):

$$E = +0.11 - 0.06 \text{ pH} \quad \textbf{(Eq 18)}$$

Alternately, there will be an equilibrium between the activity of the solvated metal cations ($Ni^{2+} \cdot zH_2O$) and the precipitation of an oxide or hydroxide in the solution, due merely to the fact that the solubility of the oxide/hydroxide has been exceeded. In such instances, depending on the specific solid-phase components being formed, the equilibrium dissolved metal activity may be independent of potential and be solely dependent on pH. For example, for the Ni^{2+}/NiO equilibrium:

$$Ni^{2+} + H_2O \leftrightarrow NiO + 2H^+ \quad \textbf{(Eq 19)}$$

the equilibrium relationship will be given by:

$$\log (a_{Ni^{2+}}) = 12.18 - 2 \text{ pH} \quad \textbf{(Eq 20)}$$

Note that the dependence of a reaction on pH is explicitly shown by the presence of H^+ or OH^- in the reaction, and its dependence on potential is shown by the presence of electrons.

Based on such various equilibria considerations, it is possible to define the relative stabilities of the metal, its dissolved species (e.g., Ni^{2+}, $HNiO_2^-$), solid-state oxides (NiO, Ni_3O_4, Ni_2O_3, NiO_2) and hydroxides $Ni(OH)_2$ as a function of potential and pH. Such a composite potential/pH diagram, known as a Pourbaix diagram, is shown in Fig. 5 for Ni/H_2O. Superimposed on these stability regions are the equilibrium relationships for the H_2O/H_2 (Eq 4) and O_2/H_2O reactions (Eq 5a, 5b), illustrated by the lines marked "a" and "b," respectively. The insertion of these latter relationships onto the Pourbaix diagram are important for corrosion assessments, as described below.

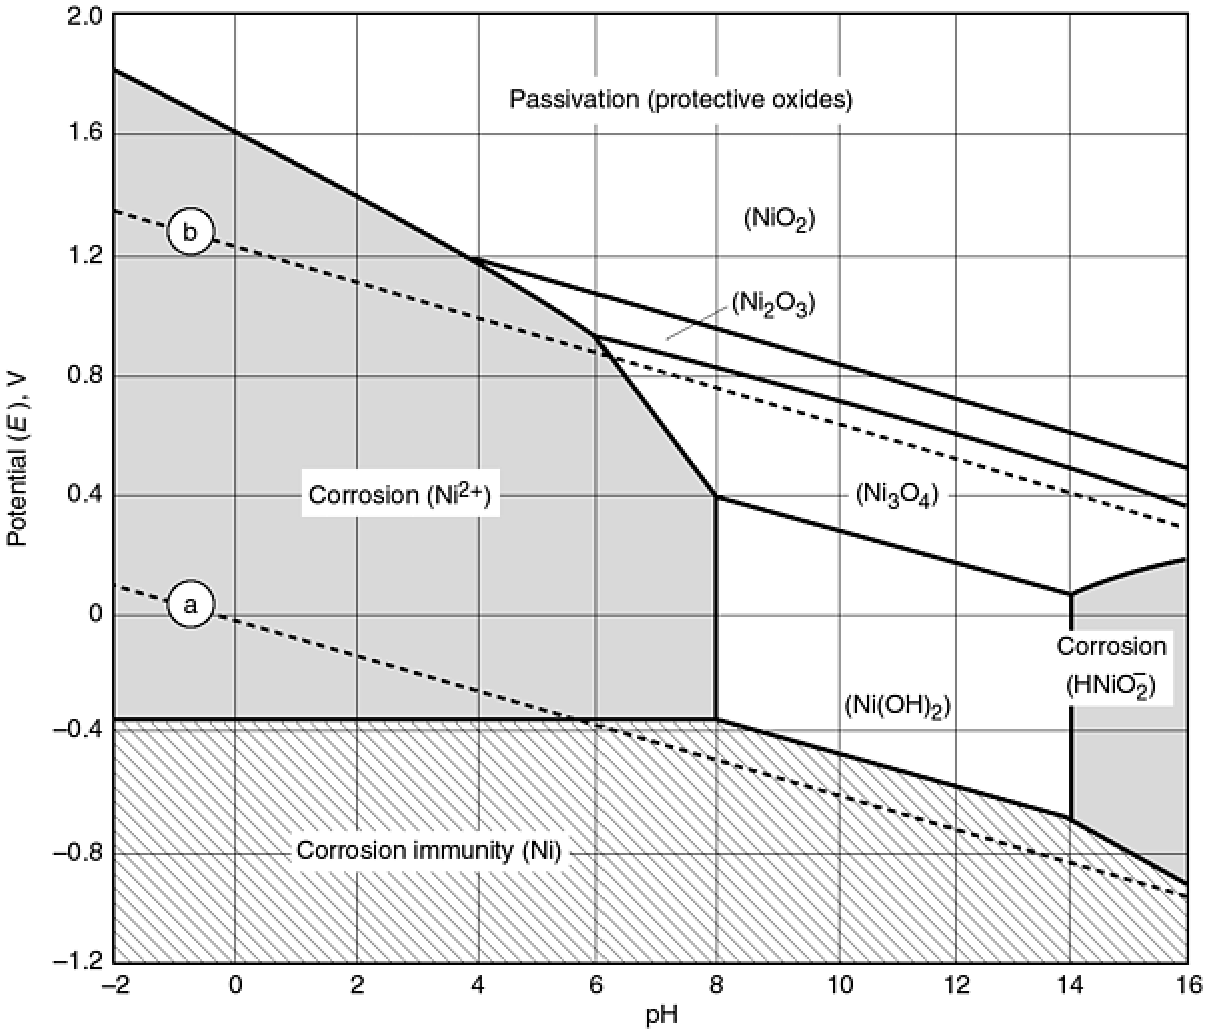

Fig. 5 Pourbaix diagram for the nickel/water system, indicating the *E*/pH regions of thermodynamic stability of various dissolved and solid species and the regions of "corrosion immunity," "passivation," and "active corrosion." Dashed lines show the equilibrium potentials for the (a) H_2/H_2O and (b) O_2/H_2O systems

If we arbitrarily assume that "corrosion" is defined by dissolution in solutions containing an activity of dissolved metal cations of 10^{-6} moles/L (i.e., ~0.06 mg/L (ppm) for iron, copper, or zinc), then the Pourbaix diagram can be divided into regions denoted as "corrosion immunity" (where, thermodynamically, the metal cannot undergo net dissolution), "corrosion" (where the metal will be oxidized to a soluble species), and "passivation." In this latter region, an oxide can form at the metal/solution surface, and, depending on its properties, it *may* confer protection against corrosion. Regions of "corrosion immunity," "corrosion," and "passivation" for Ni/H_2O are shown in Fig. 5.

There is, as was pointed out earlier, a further criterion for corrosion to occur, and that is the fact that a corresponding reduction reaction must occur. In water, these reactions are often associated with water reduction (Eq 4) and oxygen reduction (Eq 5a, 5b). Thus, referring to Fig. 5, corrosion of nickel in deaerated acids will be confined thermodynamically to the *E*/pH "space" between line "a" and the line described by Eq 12 and 16 (at about -0.35 V_{SHE} in Fig. 5), whereas in aerated acids the corrosion region will be extended up to line "b." Thus, the Pourbaix diagrams are important tools for defining the *E*/pH regimes where corrosion *might* occur and the regions where, thermodynamically, corrosion *cannot* occur. It is important to recognize, however, that Pourbaix diagrams do not give information on the rates of corrosion.

Forms of Corrosion and General Mitigation Approaches

From the previous section, it is seen that there are four conjoint requirements for corrosion of metals in aqueous environments to occur. They are:

- A metal oxidation (or "corrosion") reaction is thermodynamically possible under the given potential and pH conditions (Fig. 5).
- A corresponding reduction reaction is thermodynamically possible given the presence of various reducible species (Eq 3, 4, 5a, 5b, 6, 7) under given potential and pH conditions.
- There is an electronic path in the metal between the anodic and cathodic sites where the oxidation and reduction reactions are occurring (compare with Fig. 1).
- There is an ionic path in the environment between the anodic and cathodic sites.

With this background, the specific forms of corrosion will now be discussed.

General Corrosion

General corrosion occurs more or less uniformly over the whole structure area. This generally implies that the surface is fairly uniform metallurgically, and that the environment is relatively constant throughout the system. General corrosion often results from atmospheric exposure (especially polluted industrial environments), marine exposure, or exposure in chemical plants involving relatively concentrated aqueous environments. The mechanisms of degradation are reasonably well understood, and the problem usually occurs because of poor materials choice or changes in process chemistry.

Alloy Choice and Design. There is no question that, from a thermodynamic viewpoint, materials can often be selected that can withstand even highly aggressive conditions. For instance, the noble metals (e.g., gold, silver, and platinum) are resistant to most concentrated acids. These metals, however, are hardly materials of widespread use, and for most engineering materials, general corrosion protection is achieved by the presence of a surface film or oxide that has very limited solubility in the environment. Thus, material choices have to be based on the specific environment under consideration.

Alloying is generally needed for engineering-strength purposes, and knowledge of corrosion mechanisms can facilitate the design of alloys that also have adequate corrosion resistance. For instance, based solely on examination of the Pourbaix diagram, nickel and its alloys are normally a good choice for use in alkaline environments, given the fact that this metal has a relatively small stability region for the dissolved $HNiO_2^-$ anion in high-pH solutions; hence, the use of nickel electrodes in alkaline batteries (Fig. 5). Conversely, aluminum and its alloys would *not* be good candidates for alkaline environments, given the relatively wide stability range for the AlO_2^- anion at pH values greater than ~8.5 (Fig. 6).

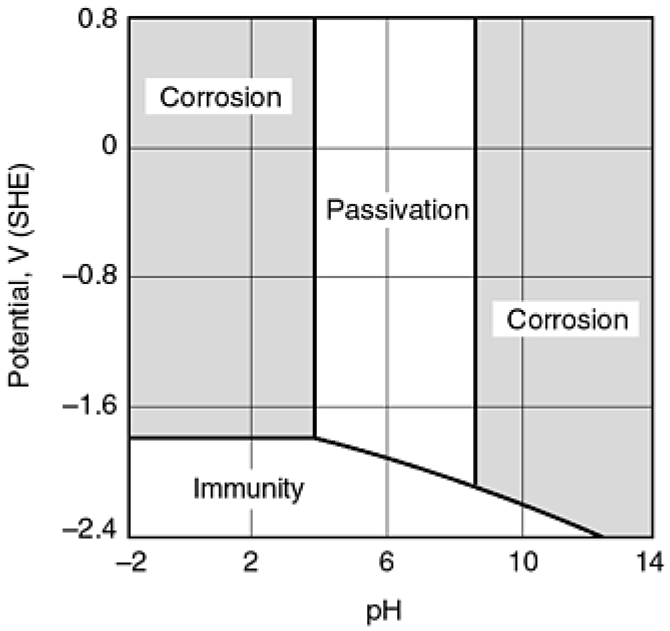

Fig. 6 Pourbaix diagram for aluminum/water

The general corrosion resistance of many alloys is increased by elements that enhance the passivation region on the Pourbaix diagram due to the formation of mixed surface oxides:

Base metal	Alloying element	Alloy
Fe	Cr	400-series ferritic stainless steels (11-23% Cr)
Fe	Cr, Ni	300-series austenitic stainless steels (16-26% Cr, 6-22% Ni)
Ni	Cr	Alloy 600 (16% Cr, 0.2% Cu, 8% Fe)
		Nimonic 75 (20% Cr)
Ni	Mo, Cr	Hastelloy B (28% Mo, 1.5% Fe, 1.5% Cr)
		Hastelloy C (17% Mo, 5% Fe, 15% Cr), Hastelloy C-22
		Hastelloy C-276 (16% Mo, 16% Fe, 15% Cr)
Ni	Si	Hastelloy D (10% Si, 3% Cu)
Ti	Mo, Ta, Al	3-6% Al, 2.5-4% V
Zn	Al	35-50% Al

The increase in the corrosion resistance associated with alloying may be indicated by the Pourbaix diagrams for the major elements in the alloy. For instance, the superposition of the Cr_2O_3 stability domains onto the Pourbaix diagram for iron-water (Fig. 7) or the MoO_4 and Cr_2O_3 stability domains onto the Pourbaix diagram for nickel-water (Fig. 8) indicate that, in both instances, the "passivation" domains are reinforced in neutral/alkaline environments and are increased in acidic environments. This behavior gives some rationale for the corrosion resistance improvement observed in, for instance, the ferritic and austenitic stainless steels and in the Nichrome and Hastelloy types of nickel-base alloys.

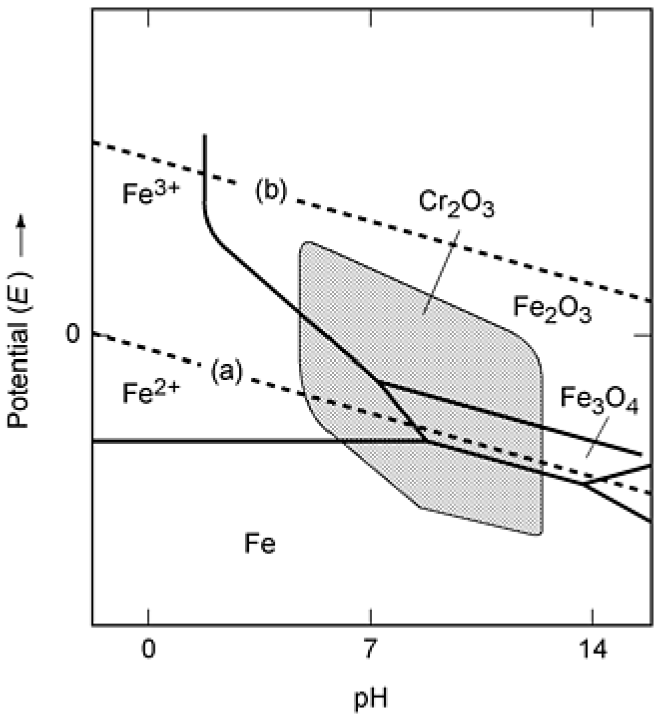

Fig. 7 Superposition of the Cr_2O_3 stability regions (shaded) on the iron/water Pourbaix diagram, to illustrate the *E*/pH regions where chromium alloying might confer added corrosion resistance. Dashed lines show the equilibrium potentials for (a) H_2/H_2O and (b) O_2/H_2O

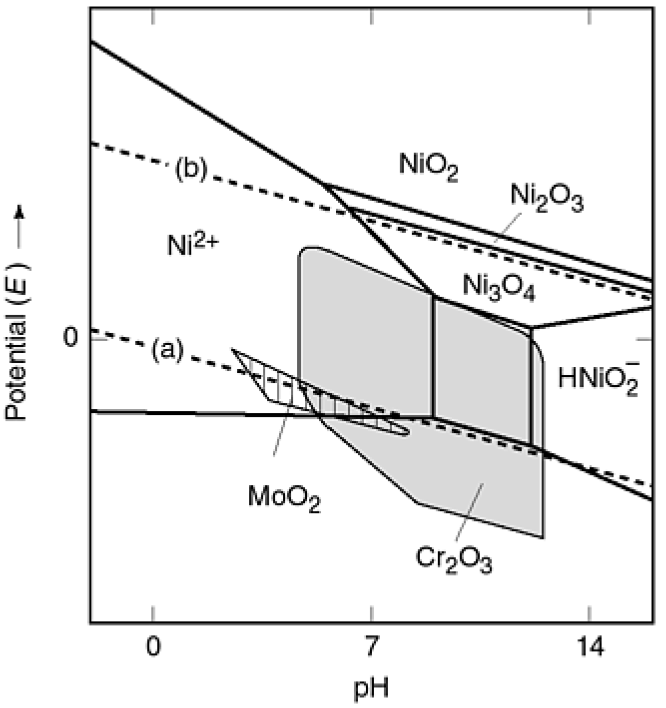

Fig. 8 Superposition of the MoO_4 and Cr_2O_3 stability regions (shaded) on the nickel/water Pourbaix diagram, to illustrate the thermodynamic reason for the improved corrosion resistance of various nickel alloys in neutral and acid environments

It should be emphasized again that such material-design analysis based on thermodynamic considerations does not give a direct prediction of the corrosion rates. However, when considering the anodic polarization curves for iron and iron-

chromium alloys in deaerated sulfuric acid (Fig. 9), it is not surprising that, at low overpotentials, the dissolution rate increases with increasing polarization (compare with the schematic Evans diagram, Fig. 3a), followed by a decrease at a potential associated with the formation of a protective "passivating" film (Fig. 3c). Moreover, the marked decrease in corrosion rate due to the chromium alloying and the resultant formation of a low-solubility iron-chromium spinel oxide is understandable. Similar polarization curves for nickel-base alloys in deaerated sulfuric acid are shown in Fig. 10 to illustrate the combined effects of different alloying additions. As would be expected from Fig. 8, molybdenum has only a mild effect on the passivation characteristics in acidic conditions and, hence, alloying nickel primarily with molybdenum in Hastelloy B does not significantly reduce the dissolution kinetics under these particular environmental conditions. However, Fig. 8 also indicates that the passivation domain for nickel is considerably increased in acidic environments by further alloying with chromium, and the effect of this observation is reflected in Fig. 10 by the vastly reduced oxidation rates for the chromium-containing Hastelloy C family of alloys. Thus, under deaerated acid conditions, where the corrosion potential will be about -0.250 V (versus the standard calomel electrode, or SCE) in Fig. 10, there is little difference in corrosion current densities (~10 μA/cm^2) between the three alloys. Under aerated or oxidizing acid conditions, however, when the corrosion potential will be at more positive potentials, there is a considerable benefit in choosing the chromium-containing (and more expensive) Hastelloy C grades. The combination of the high molybdenum and chromium alloying contents also confers enhanced corrosion resistance in environments other than oxidizing acids. For instance, the increased general and pitting resistance of the molybdenum- and chromium-containing nickel-base alloys allow their satisfactory long-term use in desalination plant and seawater heat exchangers.

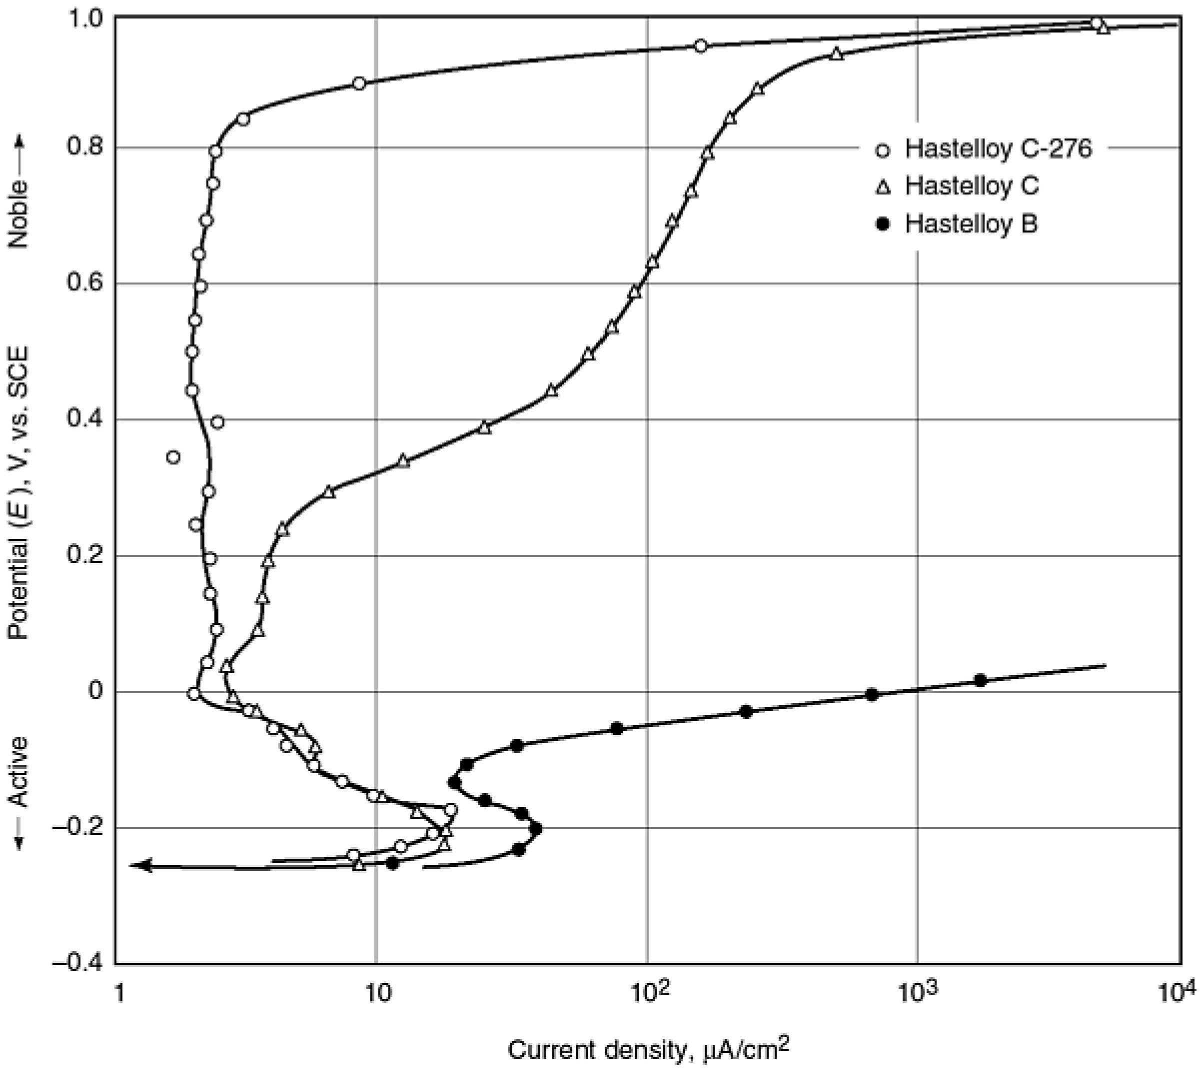

Fig. 10 Evans diagram showing the comparison of potentiostatic anodic polarization of nickel alloys in H_2SO_4 at ambient temperature. Source: Ref 5, with courtesy of F.G. Hodge, Haynes International

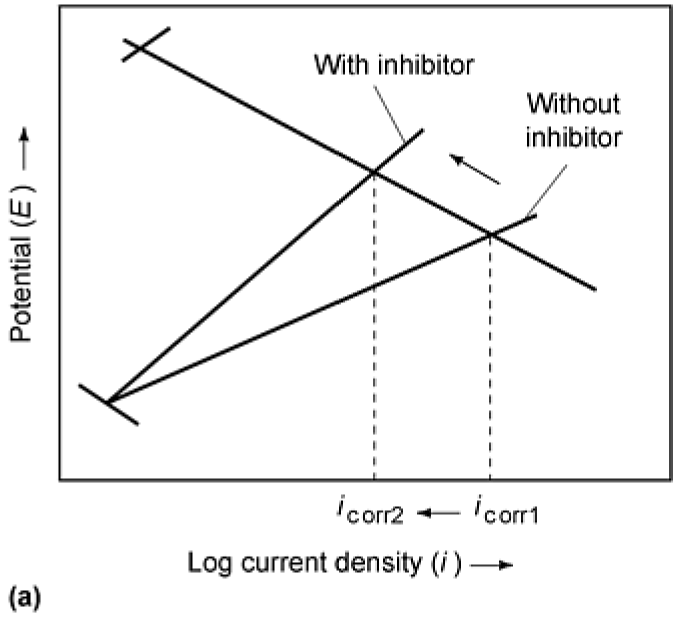
The increase in corrosion resistance due to alloying elements need not, however, necessarily be confined to increasing the passivation region on the Pourbaix diagram. This behavior is illustrated by the copper-base alloys, where the corrosion resistance in aqueous environments at room temperature is primarily due to the cuprous oxide (Cu_2O) film. This oxide is a *p*-type semiconductor and, therefore, its growth by an oxidation reaction similar to Eq 2 depends on the transport of copper cations and electrons through the oxide. Thus, alloying elements that form divalent or trivalent cations will reduce the ionic and electronic conductivity of the oxide and decrease the oxidation kinetics. This result is the fundamental basis for the development of aluminum bronze (5-12% Al), brasses (30% Zn), cupronickels (10-30% Ni), and the mixed brasses and bronzes (admiralty and naval brass, Cu-Zn-Sn; aluminum-brass, Cu-Zn-Al; phosphor bronze, Cu-Sn-P).

Inhibitors. Mitigation of general corrosion by adding inhibitors to the aqueous environment relies on an alteration of the oxidation or reduction kinetics and/or the creation of an adsorbed film between the metal and the corrosive environment. This approach is practically limited to closed environment systems that have good circulation, so that an adequate and controlled concentration of inhibitor is ensured. Such conditions can be met, for instance, in industrial cooling systems, oil production, the refining industry, and acid pickling of steel components.

In their simplest form, inhibitors may be large organic molecules, such as ureas, mercaptans, pyridenes, and benzoates, which chemisorb on the metal surface and thereby hinder the access of the reactants to the corrosion process. In many instances, however, effective inhibition of the corrosion process is achieved by the use of either "anodic" inhibitors or "cathodic" inhibitors that quite specifically decrease the kinetics of the oxidation and reduction processes, respectively, and thereby (Fig. 11) decrease the corrosion current density.



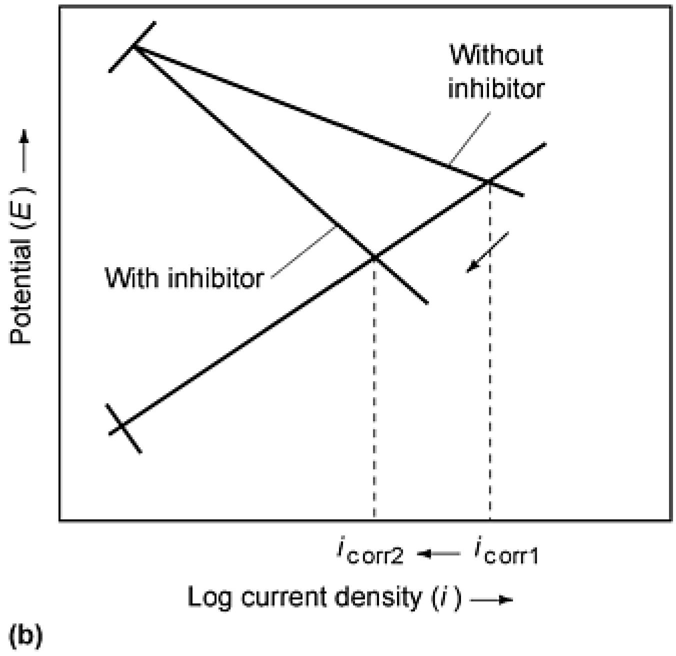


Fig. 11 Schematic Evans diagrams similar to that in Fig. 4, illustrating (a) anodic inhibition and (b) cathodic inhibition where changes in the oxidation or reduction reaction kinetics alter the corrosion potential (E_{corr}) and corrosion rate (i_{corr})

Examples of anodic inhibitors include chromates, nitrites, molybdates, and phosphates. For instance, chromates derive their effectiveness in protecting ferrous and nonferrous metals by forming protective mixed oxides at the anodic sites. It is important to recognize, however, that because these inhibitors rely on the creation of a thermodynamically stable oxide or compound, their use might be dependent on the presence or absence of additional species. For instance, nitrites require deaerated conditions, or else the nitrite is oxidized to nitrate at the more positive potentials in aerated solutions. Conversely, molybdates, phosphates, and borates all require the presence of an oxidant, usually oxygen, in order to ensure that the metal/solution interface is at a potential where the protective film can form. Furthermore, the critical concentration of anodic inhibitor that is required may depend on the presence of other corrosive anions (such as chloride) that may degrade the passivity of the protective film (discussed below). If this critical inhibitor concentration is not maintained, then excessive localized corrosion attack can occur. Moreover, because the efficiency of this type of inhibitor depends on a specific type of protective film, the choice of a given inhibitor might be good for one alloy system but not for another. For instance, nitrites can be extremely effective for mitigating general corrosion in low-carbon steels, but

they are ineffective on zinc and are deleterious for copper and for lead-tin solders. Thus, it is common to have quite complicated inhibitor mixtures for mixed alloy systems.

Thus, "anodic" inhibitors can be classified as dangerous if there is not continual monitoring of water composition (below a minimal concentration of inhibitor, the corrosion rate is dramatically increased), whereas "cathodic" inhibitors are generally regarded as safer, if somewhat less powerful. An obvious method of inhibiting the reduction reactions occurring at the cathodic sites is to lower the activity of the reactant. Thus, sulfites and hydrazine are both commonly used cathodic inhibitors in industrial boilers because they remove oxygen (Eq 5a, 5b). For example:

$$N_2H_4 + O_2 \rightarrow 2H_2O + N_2 \quad \textbf{(Eq 21)}$$

Similarly, excessive corrosion in acid systems (e.g., pickling baths) can be controlled by the use of additives such as arsenic that poison the adsorbed hydrogen atom recombination step in Eq 3 and hence lower the overall reduction reaction rate (e.g., Fig. 11b).

Inhibitors may also rely on the alkalinity produced at cathodic sites in aerated environments due to the reactions in Eq 5a, 5b. For instance, the addition of calcium bicarbonate will cause a reaction with the hydroxide produced during the reduction reaction to precipitate calcium carbonate, which then prevents further oxygen diffusion to the cathodic site. Similar cathodic inhibition due to precipitate formation is achieved by various zinc salts, where the inhibiting efficiency is increased over that due to zinc hydroxide by combinations of zinc chromates, phosphates, or polyphosphates.

Coatings. Paint or metallic coatings can be applied to a metal surface to act as a physical barrier between the metal and an aqueous environment and/or have a further role in mitigating electrochemical corrosion. In contrast to inhibitors, however, where the coating may be of molecular dimensions, paint and metallic coatings often range from 25 to 100 μm to millimeters in thickness.

Paint. The primary role of paint coatings is to act as a physical barrier to the diffusion of water, oxygen, and aggressive anions (Cl^-, SO_4^{2-}, etc.) to the metal surface. However, very few, if any, paint systems are completely impermeable, and thus some further means of mitigating electrochemical corrosion is necessary for longer-term protection. There are numerous organic paint systems available, each with very specific applications (Table 2). In general, however, the paint will comprise three components: the "vehicle," such as linseed oil, which confers fluidity during application; a "pigment," generally a solid suspension of 30 to 90 vol%, which not only gives color but, more importantly, imparts extra corrosion resistance via inhibition or sacrificial mechanisms; and an "additive" that accelerates the drying process by evaporation, polymerization, or oxidation to give a binder that holds the pigment to the surface. The entire paint system may comprise three or more coatings, with the first (primer) coat applied to the clean, grease-free surface. The primer coat provides corrosion suppression due to the presence of, for instance, sacrificial zinc or aluminum metallic particles, or zinc chromate or phosphate inhibitors. The outer (top-coat) paint layer may contain additives for specialty purposes such as quartz for wear resistance or copper for antifouling purposes in marine environments.

Table 2 Organic coating classifications and characteristics

Resin Type	Estimated chemical and weather resistance					Comments
	Acid	**Alkali**	**Solvent**	**Water**	**Weather**	
One-component systems						
Alkyd (oil base)	F	P	P	F	VG	Excellent adhesion to poorly prepared surfaces. Adequate for mild chemical fumes. Not chemically resistant.
Modified alkyd						
Silicon	F	F	F	F	VG	Improved durability, gloss retention, heat resistance.
Amino	F	F	F	G	VG	High humidity resistance.
Phenolic	F	F	F	VG	VG	Suitable for immersion service.
Epoxy ester	F	F	P	F-G	P-F	Similar to alkyds. Somewhat better chemical resistance. More expensive.
Vinyl	VG	VG	P	VG	G	Widely used industrial coating. Easily recoated. Low toxicity, tasteless. High volatiles content--possible fire hazard.
Chlorinated rubber	G	G	P	G	VG	Good vapor barrier. Poor resistance to sunlight.

Acrylics (solvent base)	F	G	G	G	VG	Automotive topcoats.
Two-component systems						
Phenolic	F	F	G	VG	VG	Immersion service.
Polyamide	F	VG	VG	P	G	Tough, flexible, abrasion resistant. Difficult to topcoat.
Coal tar epoxy	VG	VG	G	VG	G	Can be applied without primer. Very adherent. Excellent chemical resistance.
Polyester urethane	F-G	G	VG	F-G	VG	Can be designed for wide range of service depending on modifying groups.

(a) VG, very good; G, good; F, fair; P, poor

Numerous organic compounds can be used in the paint formulation, such as oil-base alkyds, silicon-modified alkyds, epoxy esters, acrylics, and polyurethanes. More recently, solvent-free paints have been developed to conform to environmental control regulations. These latter paints are basically coatings of nylon, polyvinyl chloride, or polytetrafluoroethylene, that are deposited by dipping, electrostatic or airless spraying, or, more recently, by thermal spraying. The corrosion protection of the various paints is due to the formation of a plastic insulating barrier between the metal and the aqueous environment.

Metal Coatings. Corrosion protection can also be obtained via metallic coatings deposited by electroplating, hot dipping, thermal spraying, overlay cladding (explosive, rolling, welding), or diffusion coating. The utility of most such coatings is due to the fact that they are relatively impermeable (compared to paints) and may protect the underlying metal even if the coating is mechanically ruptured. The mechanism of this latter property relates to the fact that the corrosion potential of any corroding system is determined by the dynamic equilibrium between all the oxidation and reduction reactions (e.g., Fig. 4). Thus, referring to the schematic Evans diagram in Fig. 12, it is seen that an uncoated metal (M) in, for example, an aerated environment where the reduction reaction is given by Eq 5a, 5b, will be corroding at a rate controlled by the current density, i_{corr1}, and the corrosion potential will be E_{corr1}. If the surface is completely covered with a metallic coating (C), then the corrosion potential on the coating surface will be E_{corr2}. If the coating is now ruptured, then (because of the ratio of the areas of the coating to the exposed metallic substrate) the corrosion potential of the exposed metallic substrate will be decreased from E_{corr1} to E_{corr2} and the current density at the exposed metal substrate will be correspondingly decreased from i_{corr1} to i_{corr2}. In other words, the underlying metal surface will be protected even if the outer metallic coating is ruptured. The area of the surface defect that can be protected will be dependent on the conductivity of the environment. For instance, in distilled water the maximum defect dimension that can be protected may be <3 mm, whereas in seawater these dimensions may be an order of magnitude greater.

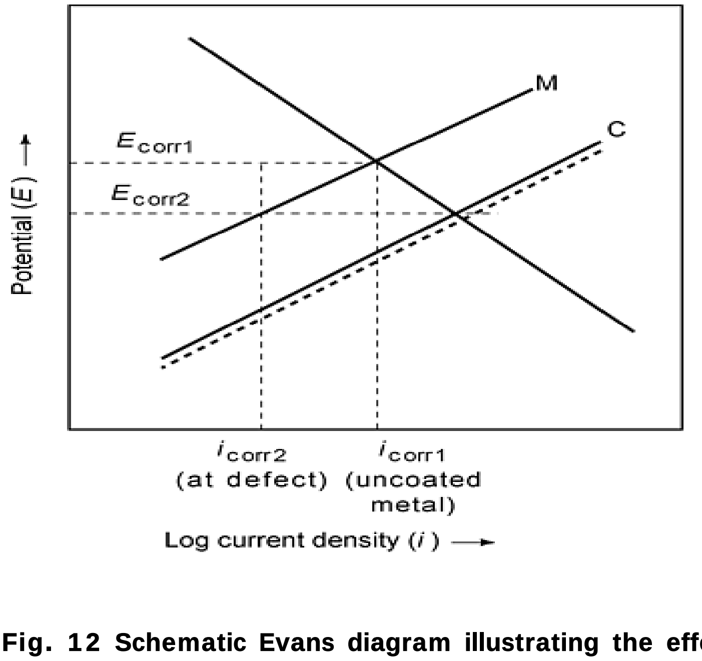

Fig. 12 Schematic Evans diagram illustrating the effect of a metallic coating (C) in galvanically protecting a metal (M) that is exposed at a defect in the coating. Mechanism relies on the effective drop in corrosion potential on the exposed metal from E_{corr1} to E_{corr2}, with a resulting drop in current density i_{corr1} to i_{corr2} and a corresponding drop in corrosion rate.

Specific protective metallic coatings for a given metallic substrate can now be designed based on this understanding. For instance, the metallic coating must have a corrosion potential more negative than the substrate to be protected. An indication of whether this criterion can be met for protection of metals in seawater can be gained from the galvanic series (Fig. 13), which indicates the corrosion potentials of various alloys in flowing seawater. Thus, low-carbon steel with a corrosion potential of about -650 mV (vs. SCE) will be protected by, for instance, cadmium-, aluminum-, zinc- or magnesium-base coatings, even if there is a defect in the coating that exposes the underlying low-carbon steel to the seawater. Examination of the galvanic series indicates that tin would not be expected to provide galvanic protection for low-carbon steel, and this situation is true for flowing, aerated environments. However, this is not true in ***deaerated*** solutions where the relative positioning of the corrosion potential for tin and low-carbon steel are reversed. This combination gives the rationale for the use of tin as the protective coating for the inside of sealed beverage and food containers, and it explains why protection is lost once the container is opened and the inside of the can is exposed to air.

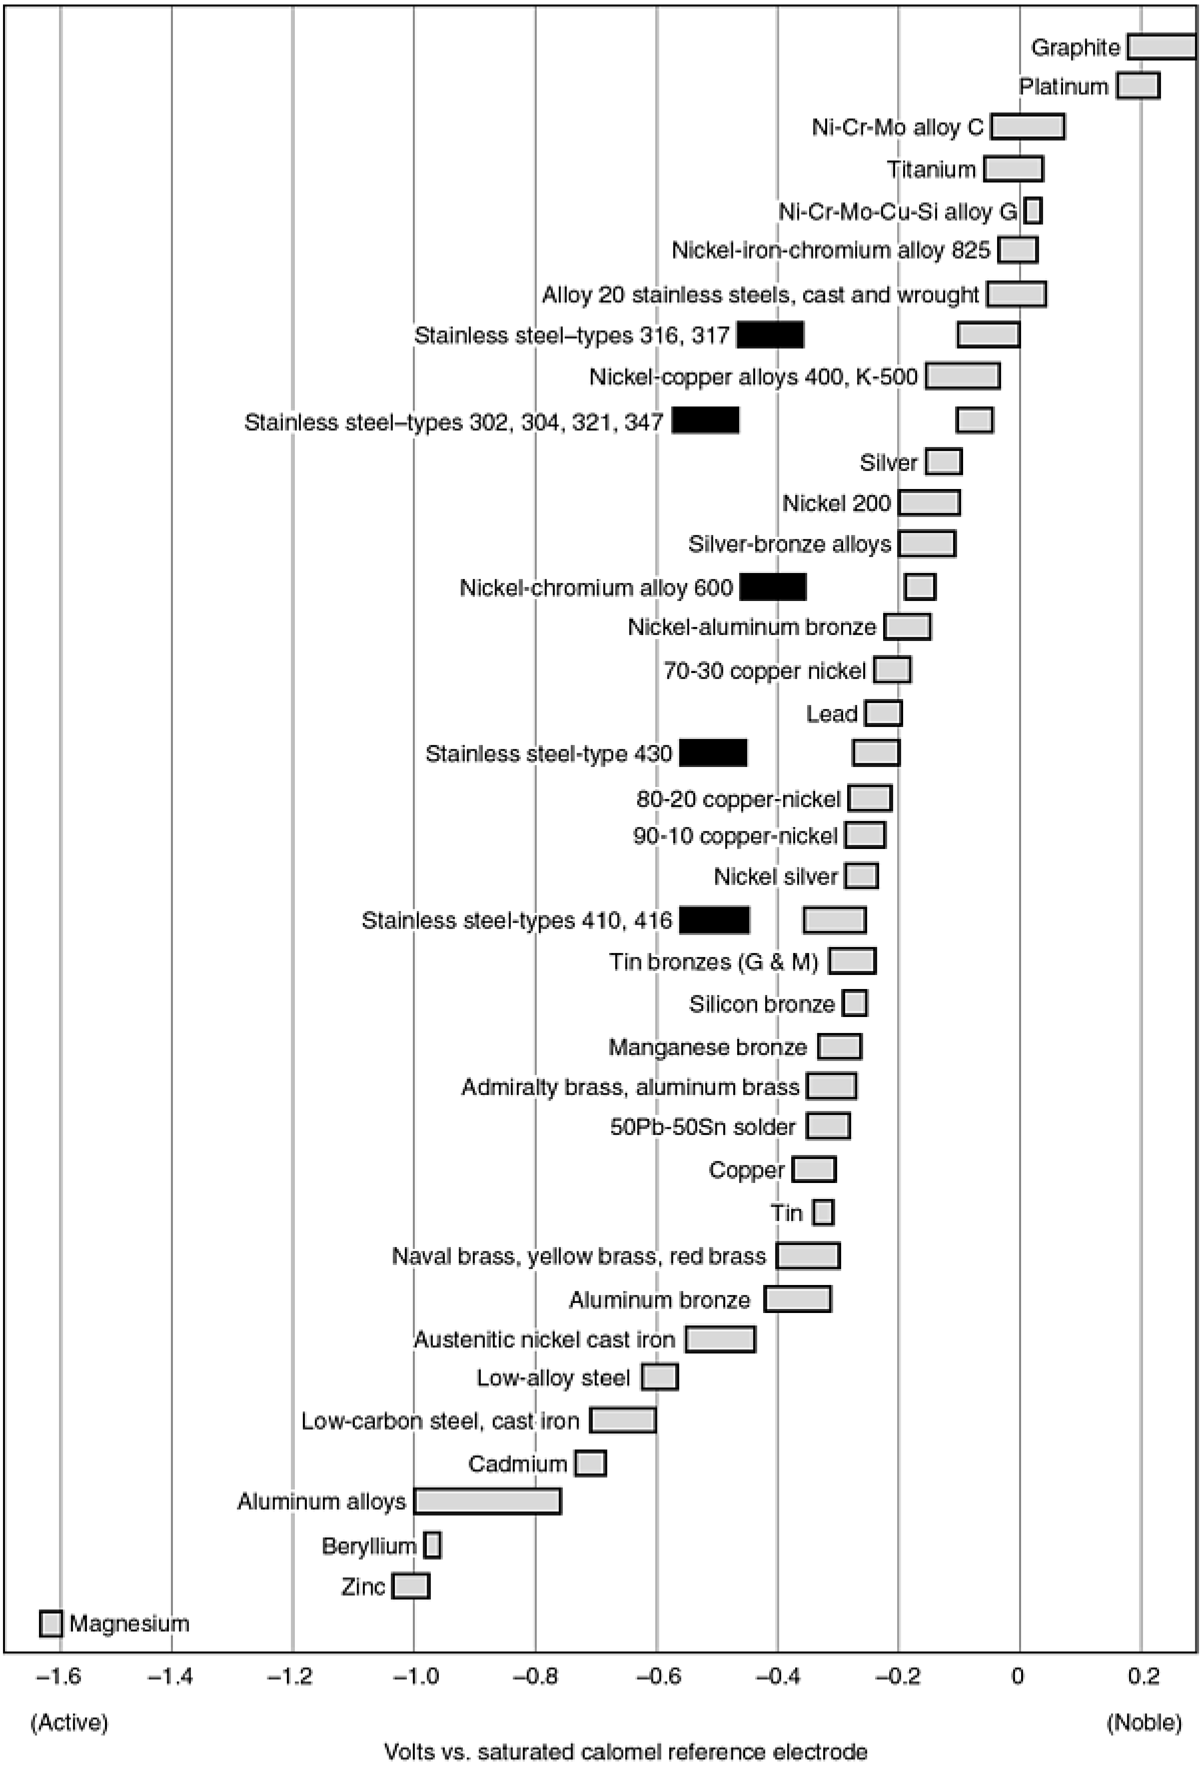

Fig. 13 Galvanic series for seawater. Dark boxes indicate active behavior for alloys that exhibit both active and passive behavior.

Because the coating is the main component to corrode, its effective life as a protection to the underlying metal (even if that is exposed at defects in the coating) depends on the thickness of the coating and the environment. For instance a 100 μm thick zinc coating on low-carbon steel might offer protection in seawater for 5 years, but its lifetime in a nonpolluted inland environment might be 35 years. Conversely, the useful lifetime in seawater might be extended to 15 years by increasing the zinc coating thickness to 300 μm or replacing the coating with 55% Al-Zn.

Other metallic coatings might not give galvanic protection to the underlying metal substrate, and excessive attack at defects in the coating can occur unless other design features are employed. A good example of this is chromium plating on low-carbon steel, which has decorative purposes as well as being hard and wear resistant; however, the chromium plating can easily crack and thereby expose the underlying steel to the environment. Because of the very large area of "noble" chromium surface, excessive attack will occur on the small area of low-carbon steel exposed at a crack in the coating. The solution to this situation is to place two intermediate layers of nickel and nickel-sulfur alloy between the chromium coating and the steel. The nickel is thus potentially attacked, although slowly, and the integrity of the steel substructure is maintained.

Cathodic and Anodic Protection. Examination of the Pourbaix diagrams for, for instance, iron (Fig. 7) or nickel (Fig. 5) indicates that, in mildly acidic or neutral environments, corrosion protection can be attained either by ensuring that the metal/solution potential is depressed below the equilibrium potential for Fe^{2+}/Fe or Ni^{2+}/Ni, or by elevating the potential to a value where a protective passivating oxide is formed. Such corrosion mitigation actions are known respectively as "cathodic" and "anodic" protection.

Cathodic protection can theoretically be applied to virtually all metal/water systems, but it has the widest commercial use for steels in aerated soil or seawater (e.g., the oil/petrochemical and marine industries). There are two approaches to lowering the metal/solution potential, involving the use of either an impressed current or a sacrificial anode. In the first method, a direct current (such as from a rectified ac power source or solar power cells) is passed between the structure to be protected and an adjacent inert anode (Fig. 14a). This anode can be inert graphite, high-silicon iron, platinized titanium, lead-platinum alloy, or lead-silver alloy, depending on the environment. In the second method (Fig. 14b), the structure to be protected is directly connected to a sacrificial anode, such as magnesium, zinc, aluminum, or their alloys. The fundamentals of these approaches are clear by examination of the relevant Evans polarization diagram (Ref 5). For instance, for cathodic protection by impressed current of low-carbon steel in acidic solutions, the relevant reduction reaction is H^+/H_2 (Eq 3) and the oxidation reaction is:

$$Fe \rightarrow Fe^{2+} + 2e^- \qquad \textbf{(Eq 22)}$$

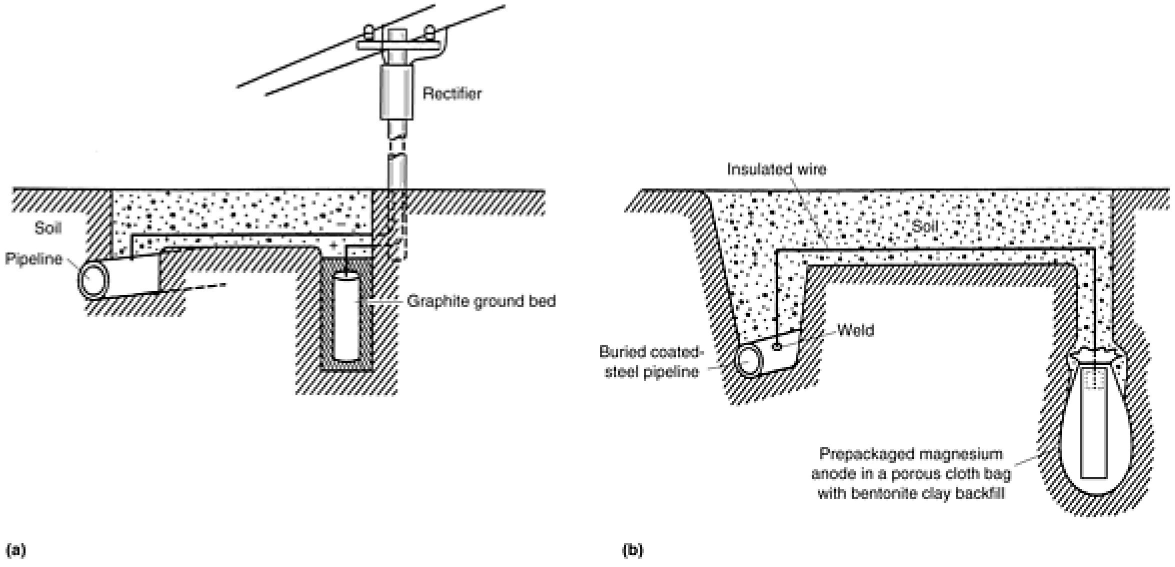

Fig. 14 Two methods of cathodic protection: (a) by impressed current and (b) by a sacrificial anode. Source: Ref 27

It is seen in Fig. 15(a) that the corrosion rate of the unprotected steel is approximately 1 mA/cm^2 (~460 mils/year). If a direct current is applied between the mild steel structure and an inert electrode (Fig. 14a), the corrosion current will drop as the steel is cathodically polarized, and, if an acceptable corrosion rate is 10^{-6} A/cm^2 (or 0.46 mils/year), then a current density of ~10^{-2} A/cm^2 would have to be applied. However, this practice would be an impractical solution to this particular problem, for it would require excessively high currents (e.g., for the protection of 1 m^2 exposed area, >100 A would be required), and there would be a safety problem of dealing with the excessive amounts of hydrogen evolved at the inert anode. A more practical use for this impressed current approach to cathodic protection is for low-carbon steels in aerated, neutral environments (such as seawater). In this situation, the relevant reduction reaction is O_2/OH^- (Eq 5a), whose rate is limited by oxygen diffusion control (compare with Fig. 3b) at the high cathodic overpotentials. Thus, as shown in Fig. 15(b), the applied current necessary to reduce the oxidation current for the Fe/Fe^{2+} reaction to 1 μA/cm^2 is only 100 μA/cm^2 (i.e., markedly less than in acidic environments).

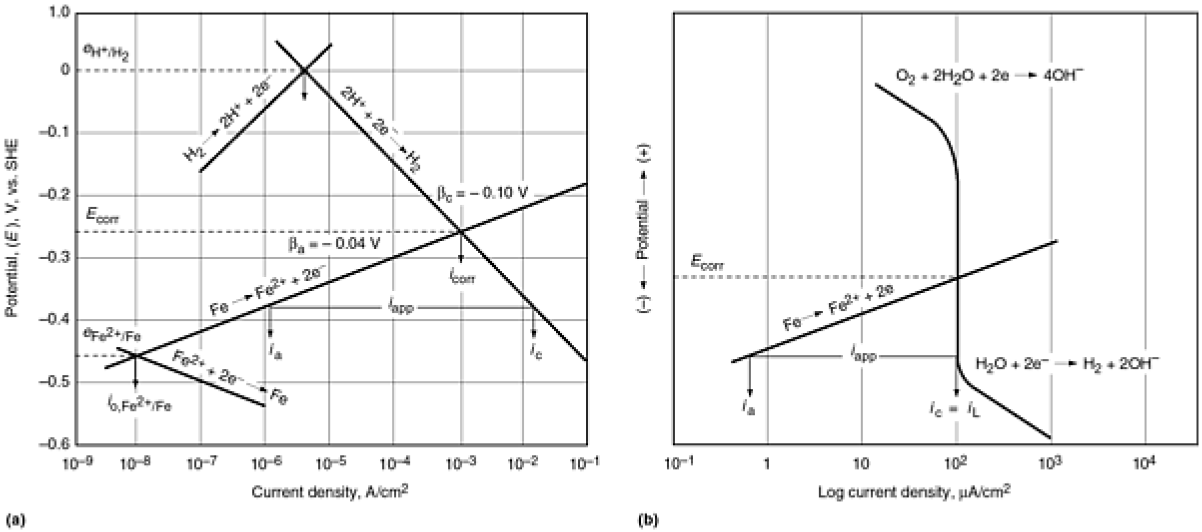

Fig. 15 Cathodic protection with an impressed current density i_{app} for (a) steel in acid solution and (b) steel in neutral aerated water. Source: Ref 5

The principles of the sacrificial-anode approach follow those principles outlined above for sacrificial metallic coatings. In this situation, however, the sacrificial anodes are physically separated from the protected structure (Fig. 14b). The extent of the physical separation of the sacrificial anodes is dictated by the conductivity of the environment (e.g., the soil and its backfill) and the acceptable corrosion rates of the protected structure and the sacrificial anode. For instance, it is seen in the Evans diagram in Fig. 16 that the corrosion rate of the metal structure can be reduced from i_{corr} to a miniscule rate $i_{corr(sc)}$ by coupling it electrically to a sacrificial anode, G. However, the corrosion rate on the sacrificial anode can be significant, given the fact that the cell current is concentrated on the relatively small area of the anode; this high sacrificial dissolution rate will reduce the design life of the protection system. This arrangement can be modified by changing the anode material (e.g., substitute a 55Al-4Zn alloy rather than use pure zinc) to one that is less active. In this way, the corrosion rate of the main metal structure may be slightly increased from $i_{corr(sc)}$, but it is still acceptable and the design life of the system is increased. An alternative approach would be to decrease the conductivity of the backfill (assuming that this can be done) so that the iR potential drop between anode and cathode is increased (Fig. 16), thereby increasing the potential of the metal, decreasing the potential of the sacrificial anode, and leading to compromise corrosion rates of the metal and sacrificial anode.

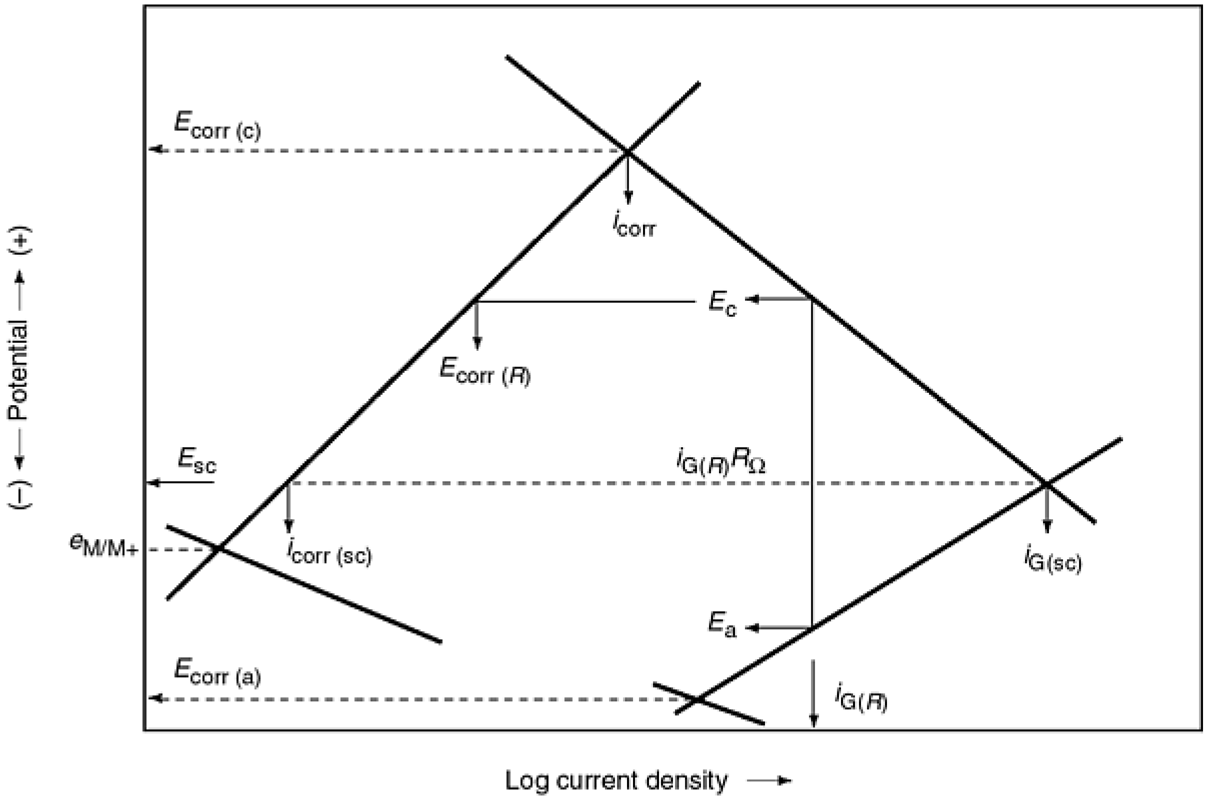

Fig. 16 Schematic polarization diagram for a sacrificial anode, G, coupled to a cathodically protected metal structure, i_{corr}, is reduced to $i_{corr(sc)}$ by the galvanic current $i_{G(sc)}$. Note that the presence of a higher-resistivity environment between anode and structure leads to an *i*R potential drop, which increases the metallic structure corrosion current to $i_{G(R)}$, separates anode and cathode by a potential $i_{G(R)}$ RΩ, and reduces i_{corr} to $i_{corr(R)}$. Source: Ref 5

Anodic protection is applicable only to alloys that exhibit an active/passive transition in their anodic polarization characteristics (refer to Fig. 3c, 9, 10) and is generally confined to stainless steels, nickel and its alloys, and titanium in relatively acidic solutions. The application method is similar to cathodic protection by impressed current, except that the structure is *anodically* polarized so that the metal potential is in the passive regime. The cathodes are, for instance, nickel-plated steel, platinum, brass, silicon cast iron, or copper, depending on the environment (Tables 3, 4). Constant monitoring of the potential of the metal structure is needed, because if the potential falls from the desired passivation potential range into the active range, excessive corrosion can occur (Fig. 17).

Table 3 Cathode materials for anodic protection

Cathode material	Environment
Platinum on brass	Various
Steel	Kraft digester liquid
Illium G	Sulfuric acid (78-105%)
Silicon cast iron	Sulfuric acid (89-105%)
Copper	Hydroxylamine sulfate
Stainless steel	Liquid fertilizers (nitrate solutions)
Nickel-plated steel	Chemical nickel plating solutions
Hastelloy C	Liquid fertilizers (nitrate solutions) Sulfuric acid Kraft digester liquid

Table 4 Reference electrodes for use in anodic protection

Electrode	Solution
Calomel	Sulfuric acid
Silver-silver chloride	Sulfuric acid, Kraft solutions, fertilizer solutions
Mo-MoO$_3$	Sodium carbonate solutions
Bismuth	Ammonium hydroxide solutions
Type 316 stainless steel	Fertilizer solutions, oleum
Hg-HgSO$_4$	Sulfuric acid, hydroxylamine sulfate
Pt-PtO	Sulfuric acid

Localized Attack

Dissimilar-Metal Corrosion. If two metals, say aluminum and copper, are immersed in aerated chloride solutions, they will individually attain corrosion potentials of about -1.0 and -0.25 V (vs. SCE), respectively, as indicated in the galvanic series (Fig. 13). If these metals are electrically connected, then electrons will flow through the connection from the aluminum to the copper, and the aluminum will become anodically polarized and copper will be cathodically polarized with respect to their original (unconnected) corrosion potentials. The extent of this polarization and the resultant corrosion rates on the two metals will be dependent on the relative areas of the two electrodes and the conductivity of the solution. For instance, referring to the schematic Evans polarization diagrams for two metals M and N (Fig. 18), it is seen that their corrosion potentials change from the "unconnected" values E_{corrM} and E_{corrN} toward a common value $E_{corr\text{-}couple}$, which is determined by the criterion that the total reduction current is balanced by the total oxidation current at the various parts of both surfaces. The result is that the corrosion current on the more active metal is increased from I_{corrM} to $I_{corrMcouple}$. The increase depends on the relative areas of the two metals; this important aspect can be illustrated by considering the aluminum/copper couple in aerated chloride solutions (Fig. 19). If it is assumed that the area of the two metals are equal (say 1 cm^2), then in the uncoupled condition the corrosion rate on the aluminum is about 0.7 μA/cm^2 (0.3 mil/year), but when connected to the copper, the corrosion potential will increase from -1.05 V (vs. SCE) to approximately -0.8 V (vs. SCE), and the corrosion rate on the aluminum will increase dramatically to ~70 μA/cm^2 (30 mils/year). However, if the area of the copper is increased by a factor of ten, then the oxygen reduction current on the copper will increase by a factor of ten, and consequently, the current density on the original 1 cm^2 of aluminum will be increased to a catastrophic 700 μA/cm^2 (300 mils/year).

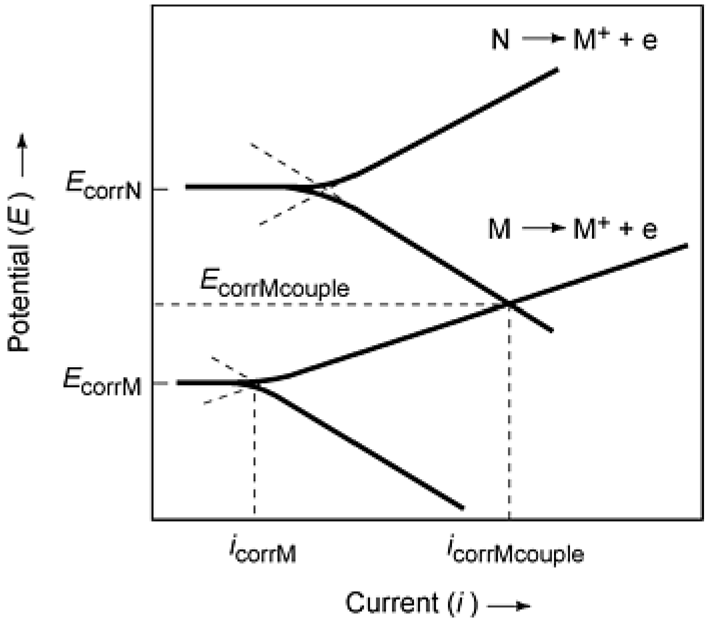

Fig. 18 Schematic potential/current curves for metals M and N, illustrating the fact that the corrosion current on M (i_{corrM}) increased to $i_{corrMcouple}$ when connected to metal N. This current is determined by the criterion that the total oxidation and reduction currents be equal.

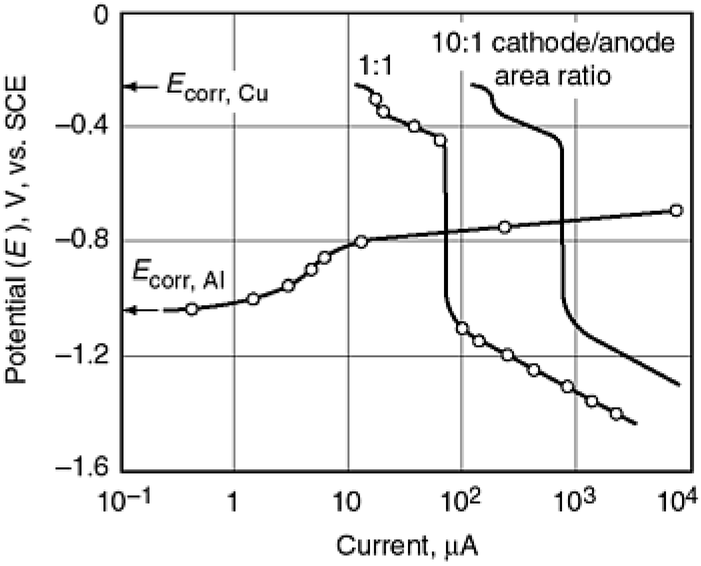

Fig. 19 Prediction of galvanic corrosion rates of aluminum/copper couples and effect of aluminum/copper surface area ratio. Source: Ref 5

The other important factor in this phenomenon is the ionic and electronic resistivity of the overall circuit. For instance, as the ionic resistance increases, the resultant "*i*R" drop in the solution will eventually cause the corrosion potentials to revert to the uncoupled values. However, it is incorrect to assume that all areas of a given metal surface are at the same corrosion potential (which is created by the *local* metal-environment interface) because of local polarization (e.g., areas of the aluminum adjacent to the copper) or chemistry variations (e.g., oxygen consumption in crevices and cracks). Thus, if the metals are physically in contact, the area immediately adjacent to the joint will be polarized, causing the attack at dissimilar-metal joints to be localized near the joint itself.

The obvious design factors in systems involving dissimilar metals are to: (a) select metals with the least difference in "uncoupled" corrosion potentials, or (b) minimize the area of the more noble metal with respect to that of the active metal, or (c) insert an electrically insulating gasket between the two dissimilar metals (Fig. 20).

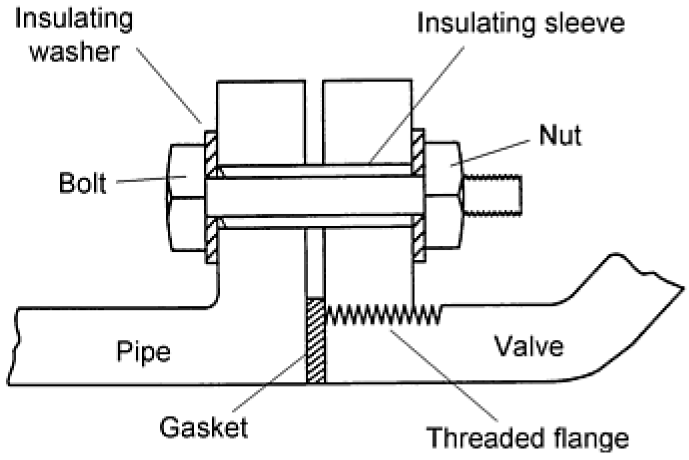

Fig. 20 Flange insulated to eliminate a galvanic couple. Source: Ref 10

Intergranular Attack. Metals discussed so far in this article have been regarded as homogeneous, but in fact, most engineering alloys are multiphased or contain distributions of solid-solution elements that have different chemical activities. Such metallurgical inhomogeneities occur especially at grain boundaries, either due to grain-boundary segregation or intermetallic precipitation, and these can give rise to localized intergranular corrosion.

Intergranular corrosion of austenitic Fe-Cr-Ni stainless steels offers an ideal example of the phenomenon and design methods to counteract it. In this system, chromium carbide can precipitate at the grain boundary by a classical thermally activated nucleation and growth process during heat treatment or welding. This carbide precipitation, called *sensitization,* occurs at about 510 to 790 °C (950 to 1450 °F) and is accompanied by chromium depletion in the adjacent metal matrix such that the chromium content can fall from 18% to less than 10% Cr in a band up to 10 μm from the grain boundary. This depleted zone will have markedly different corrosion properties from the adjacent high-chromium matrix. For instance, it is seen (Fig. 21) that if the chromium content falls much below 12%, then the corrosion rate in acidic solutions rises markedly in a given oxidizing potential range, and preferential corrosion will occur. This behavior will be aggravated by the fact that this narrow depleted zone will have a lower corrosion potential than the larger area of passivated high-chromium alloy connected to it, and hence further corrosion will occur due to galvanic effects, as explained in the previous section, "Dissimilar-Metal Corrosion."

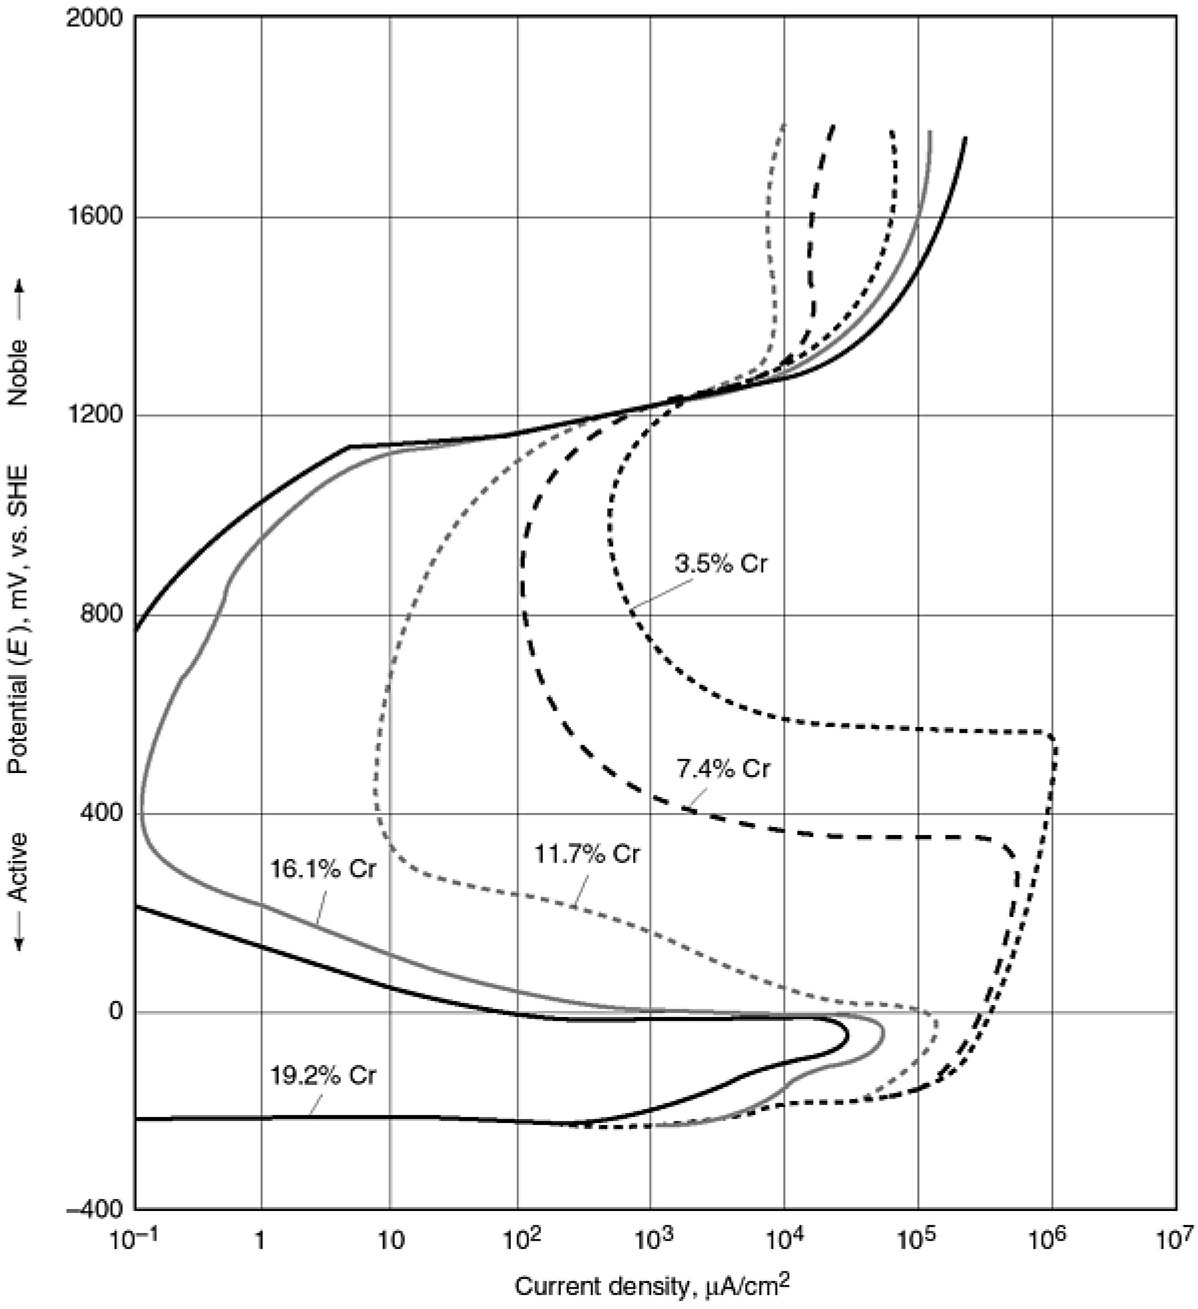

Fig. 21 Effect of chromium content on anodic polarization of Fe-Ni alloys of 8.3 to 9.8% Ni in 2N H_2SO_4 at 90 °C. Source: Ref 106

This type of attack depends on two conjoint conditions, and the problem can be resolved by attention to only one of these conditions. First, grain-boundary chromium-carbide precipitates and their associated chromium-depleted zone are necessary. These conditions can be avoided by attending to such factors as the temperature/time requirements for such "sensitization," by annealing the structure to solutionize the carbide, and by making alloy compositional changes such as low carbon content (e.g., L-grade stainless steels with <0.03% carbon) or the addition of elements such as niobium or titanium, which form more stable carbides than chromium carbide. Second, the intergranular corrosion will be observed only under oxidizing potential conditions; thus, avoidance of oxidizers such as oxygen, Fe^{3+} or Cu^{2+} (e.g., Eq 5a, 5b, 6, 7) may well alleviate the problem.

Similar intergranular attack phenomena are seen in other passive systems, where the localized attack is associated with either active depleted zones (e.g., the copper-depleted zones in Al-Cu or Al-Zn-Mg-Cu alloys or the molybdenum-depleted zones in Ni-Cr-Mo alloys) or with active precipitates (e.g., Mg_2Al_3 in the Al-Mg alloys or $MgZn_2$ in Al-Zn-Mg

alloys). In all instances, however, mitigation can be obtained by attention to the metallurgical conditions that give rise to the precipitation or to the specific environments in which galvanic attack occurs.

Dealloying corrosion is associated with alloys whose constituents are elements having very different electrochemical activities. For instance, zinc-copper, gray cast iron, and aluminum-tin alloys give rise to phenomena classified as "dezincification," "graphitic corrosion," and "dealuminification," respectively. In two-phase structures such as α/β brasses and graphitic iron, the mechanism is partially galvanic (or dissimilar-metal) attack, but it is believed that in some systems, the mechanism is enhanced by combined dissolution of both elemental components and then reprecipitation of the more noble element. The resultant damage is a friable surface with large amounts of porosity. Given these component parts to the mechanism, it is apparent that potential changes can either exacerbate or mitigate the problem.

Pitting, Crevice Corrosion, and Differential Aeration. Pitting and crevice corrosion arise from the creation of a localized aggressive environment that breaks down the normally corrosion-resistant passivated surface of the metal. This localized environment normally contains halide anions (e.g., chlorides) and is generally created because of differential aeration, which creates potential drops between most of the surface and occluded regions (e.g., pits, crevices, and inclusions) that concentrate the halide at discrete locations.

In pitting, this localization may begin at microscopic heterogeneities such as scratches and inclusions (e.g., sulfides). Above a given potential, negatively charged anions (e.g., Cl^-) accumulate on the metal surface and can cause breakdown of the protective oxide. The breakdown mechanism continues to be a topic of research (Ref 28). Catastrophic localized breakdown occurs at a specific corrosion potential, E_{pit}, that is a function of the material, chloride concentration, pH, and temperature (Fig. 22). Once this breakdown occurs, pit propagation can progress rapidly, because:

- The environment within the pit is deaerated (i.e., at low potential), thereby setting up a potential drop between the pit and the higher-potential surface surrounding the pit. This potential drop concentrates the aggressive anion in the pit.
- Electroneutrality considerations dictate that the increase in negatively charged non-OH^- anions be counterbalanced by an increase in cations, and these usually are hydrogen ions (i.e., the pH decreases).
- The combination of the two factors above leads to an increased metal dissolution rate within the pit.
- The high concentration of metal cations produced in the pit leads to the precipitation of, for example, metal hydroxides near the mouth of the pit, which helps ensure that the severe localized environment is contained (Fig. 23).
- The precipitation of noble ions on the metal surface, or within the alloy as second phases, further accelerates the corrosion rate.

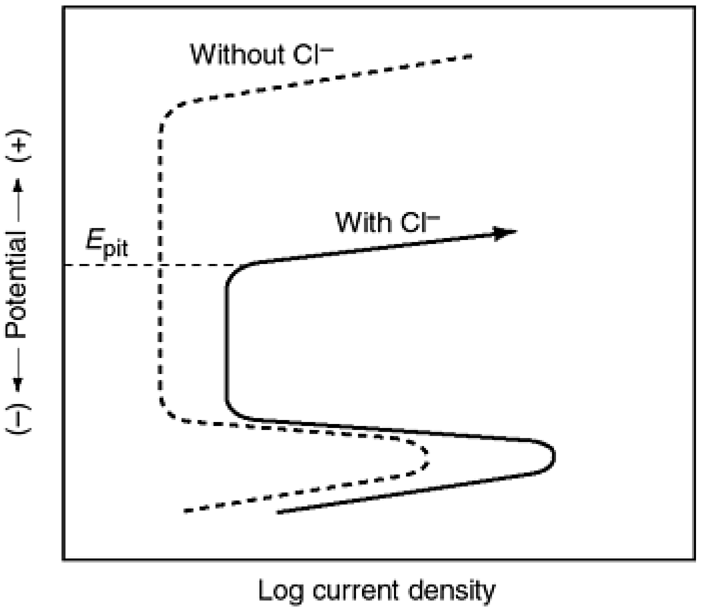

Fig. 22 Schematic representation of critical pitting potential, E_{pit}, due to anodic polarization. Source: Ref 5

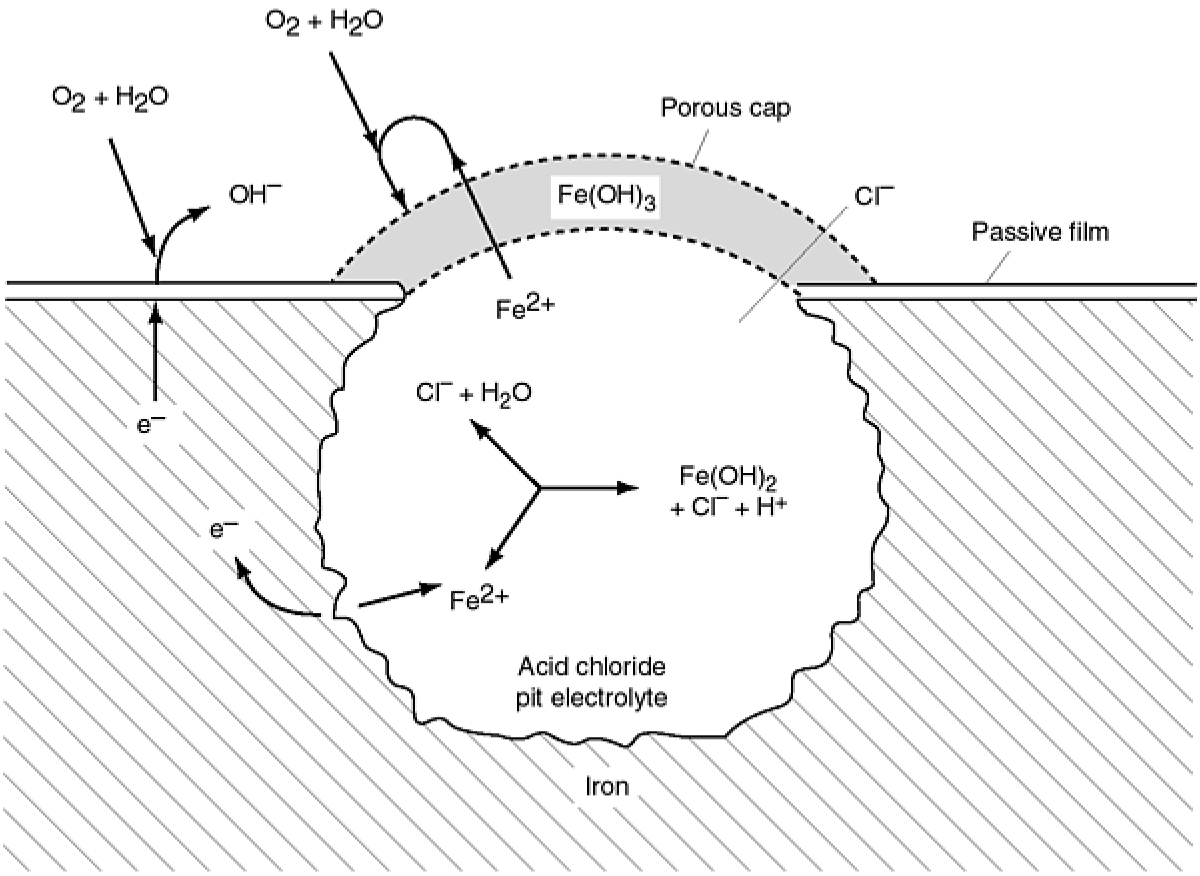

Fig. 23 Schematic representation of processes occurring in an actively growing pit in iron. Source: Ref 5

A very similar sequence of events occurs in crevice corrosion, the main difference being that the initiation event is associated with the creation of a localized aggressive environment in a macroscopic (often a designed-in, geometric) crevice. As with pitting, however, the mechanism of this localization is associated with deaeration (low potential) inside the crevice, coupled with an aerated (high-potential) environment outside.

Environmentally Assisted Cracking

Environmentally assisted cracking describes the initiation and subcritical crack propagation in structural metals due to the combined action of tensile stress, material microstructure, and environment. The conditions of these three parameters may be specific to a given alloy/environment system, and if one of these conditions is not met, the problem does not occur.

The topic is made more difficult, however, by the superposition of various mechanisms (slip dissolution, hydrogen embrittlement) and phenomena (stress corrosion, corrosion fatigue, hydrogen embrittlement). Part of this problem is addressed in the section "Life Prediction and Management" in this article. The rest of this section addresses the understanding of the mechanisms of environmentally assisted cracking and how this can be used qualitatively to control cracking.

Candidate Crack-Propagation Models. The basic premise for all of the proposed crack-propagation mechanisms for ductile alloys in aqueous solutions is that the crack tip must propagate faster than the corrosion rate on the unstrained crack sides. If this were not true, the crack would degrade into a blunt notch (Ref 29, 30). Indeed, the suppression of both stress corrosion and corrosion fatigue in many systems can be explained in terms of blunting of cracks during the early propagation stage. For instance, low-alloy steels will not exhibit stress corrosion in acidic or concentrated chloride solutions unless the general corrosion/blunting effect is counteracted with chromium or nickel alloying additions (Ref 31,

32). Similar blunting explanations can be proposed for the case of corrosion-fatigue crack initiation of aluminum in chlorides in comparison to hydroxides (Ref 33).

Numerous crack propagation mechanisms were proposed in the period 1965-1979 (Ref 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44). With the advent in recent years of more sensitive analytical capabilities, however, many of the earlier cracking hypotheses have been shown to be untenable. The candidate mechanisms for environmentally assisted crack propagation (for both stress corrosion and corrosion fatigue) have been narrowed down to slip dissolution, film-induced cleavage, and hydrogen embrittlement.

Qualitative Prediction Methods for Environmentally Assisted Cracking in Ductile Alloy/Aqueous Environments. Qualitative predictions of cracking have centered around the observation that the rate-determining step in all of the above cracking mechanisms is not necessarily the atom-atom rupture process itself, but is one (or a combination) of mass transport of species to and from the crack tip, passivation reactions, and the dynamic strain processes at the crack tip (Ref 29, 30). Thus, changes in cracking susceptibility for most ductile alloy/aqueous environment systems with, for instance, changes in temperature, electrode potential, stressing mode, or environmental composition, can be explained logically (Ref 29, 30) using a reaction-rate surface (Fig. 24), regardless of the specific atom-atom rupture mechanism at the crack tip. This fact can be reinterpreted in terms of the crack propagation rate/stress intensity (Fig. 25) (Ref 29) relationship for a given alloy/environment system subjected to different loading histories in which the limiting and rate-controlling reactions can be defined (Ref 29).

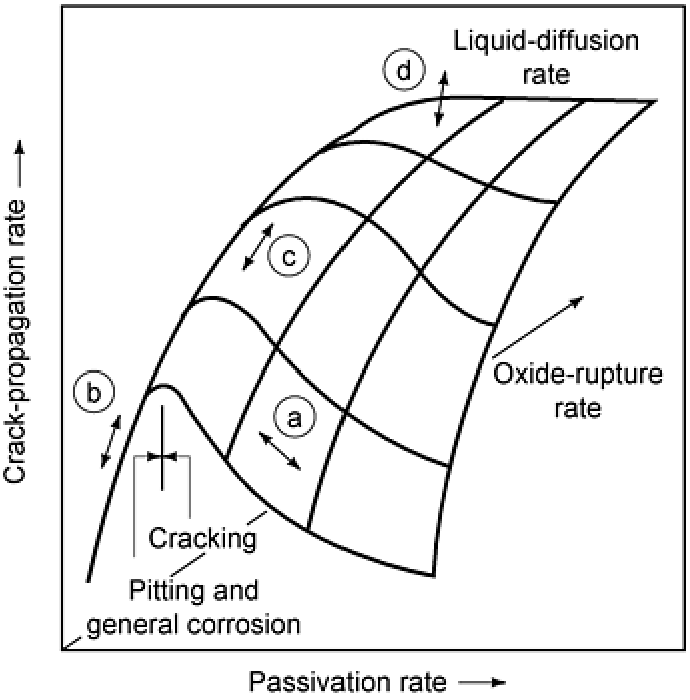

Fig. 24 Schematic reaction-rate surface illustrating the variation in crack-propagation rate with the rate-controlling parameters in the slip-dissolution, film-induced cleavage and hydrogen-embrittlement mechanisms for environmentally assisted cracking in ductile alloy/aqueous environment systems. Source: Ref 29, 30

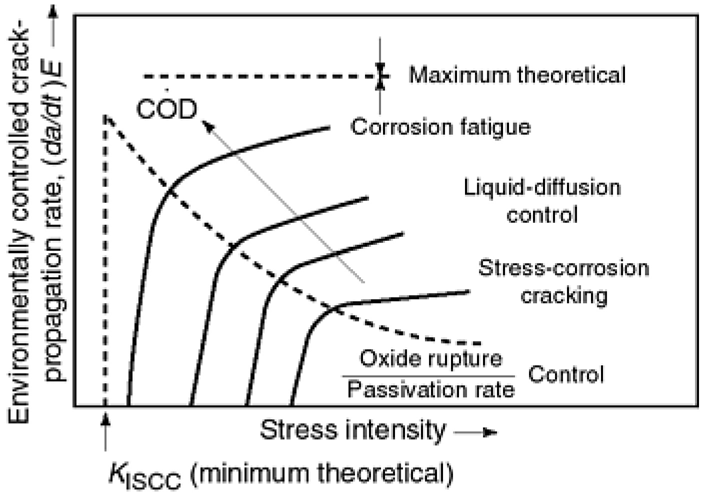

Fig. 25 Suggested variation (Ref 29) in environmentally controlled crack-propagation rate with stress intensity for various crack-tip deformation rates COD. Note the suggested rate-controlling parameters and the fact that these relationships should be bounded by a maximum crack propagation and a minimum theoretical K_{Iscc} or K_{TH}.

The importance of passivation kinetics on crack propagation is well recognized (Ref 29, 45, 46, 47, 48, 49). Very slow passivation rates at the crack tip will promote crack blunting due to excessive dissolution on the crack sides, whereas very fast rates will minimize the amount of crack-tip penetration per oxide-rupture event. Maximum susceptibility, with high-aspect-ratio cracks, will occur at intermediate passivation rates or in regimes of barely stable passivity (e.g., near the passivation potential). The effects of potential, anion (or cation) content, and alloying addition on cracking susceptibility can be quantitatively understood by this simple concept, regardless of whether the advancement mechanism is slip dissolution or hydrogen embrittlement. For instance, cracking susceptibility in poorly passivating systems (e.g., austenitic stainless steel in caustic at high temperature, low-carbon steel in caustic or phosphate) will be increased by actions that promote passivation. Thus in these systems, cracking susceptibility will be greatest in potential ranges adjacent to active/passive transitions on a polarization curve (Fig. 26). In contrast, systems that exhibit strongly passivating behavior (e.g., aluminum alloys, austenitic stainless steels in neutral solutions) will crack most severely under potential conditions where incipient passivity breakdown occurs due to the presence of aggressive anions (e.g., chloride) (Fig. 26b).

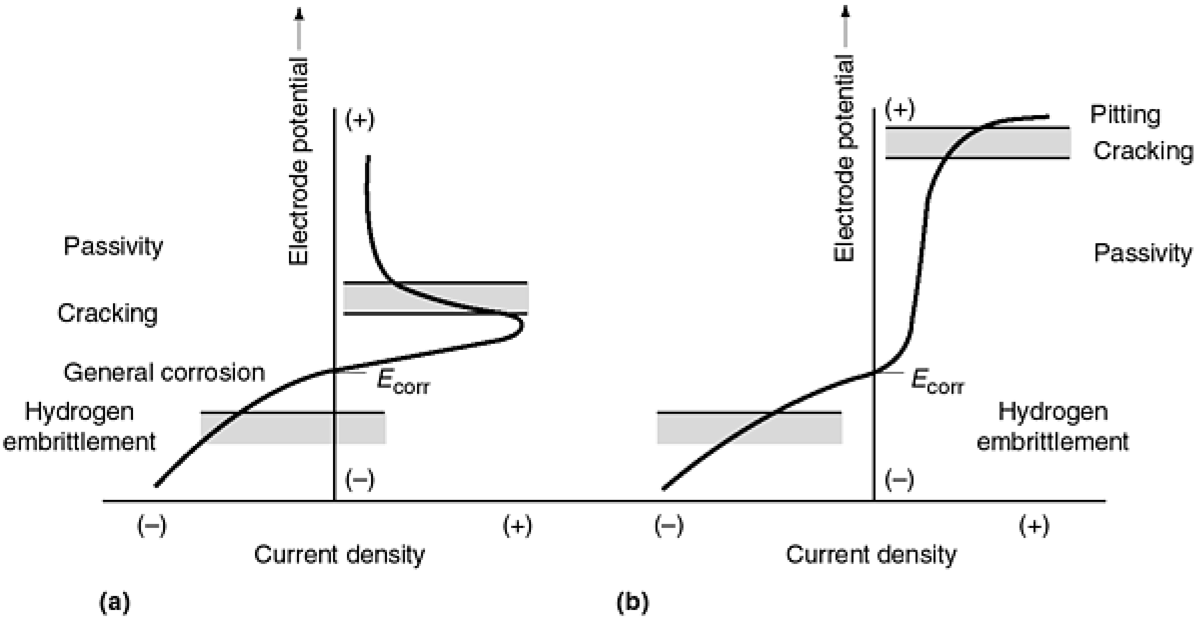

Fig. 26 Schematic electrode-potential/current-density relationship for (a) "poorly" passivating and (b) "strongly" passivating systems, indicating where severe cracking susceptibility in ductile alloy/aqueous

environment systems is commonly encountered

The fundamental importance of passivation on the crack-propagation process in ductile alloy/aqueous environment systems also indicates an analytical method of determining the potential ranges where cracking susceptibility may be severe. An example is the direct measurement of passivation rate (Ref 50), by comparing the bare surface and fully passivated dissolution rates to determine whether a high-aspect-ratio crack is possible, or by performing potentiodynamic scans at various rates. Such rapid prediction capabilities are of use in preliminary failure analyses or risk assessments, but this usefulness should be tempered by the realization that these techniques will indicate only the possibility of severe susceptibility.

As indicated in Fig. 24 and 25, the rate-determining step can change as the system parameters (e.g., corrosion potential, stressing frequency, temperature) lead to an increase in crack-propagation rate. Ultimately the rate-determining step will often be liquid diffusion, either of solvating water molecules, anions, or solvated cations to and from the crack tip. Under these conditions, the propagation rate will become independent of stress intensity (i.e., the stage II region in Fig. 25) and will exhibit a temperature dependence associated with an activation enthalpy of ~4 kcals/(g mole) associated with liquid diffusion. It is important from a practical viewpoint to realize that this is a limiting condition, and that the activation enthalpy can change continuously between 4 and ~30 kcals/(g mole) (symptomatic of passivation control) with corresponding changes in, for instance, loading rate (Ref 29), and temperature (Ref 29). Thus, mechanistic analyses based on a specific value of activation enthalpy must be treated with caution, unless it is determined that a limiting value is being measured.

Design for Corrosion Resistance

F. Peter Ford and Peter L. Andresen, General Electric Corporate Research and Development Center; Peter Elliott, Corrosion and Materials Consultancy, Inc.

Engineering Design Principles

The earlier sections of this article provide a background about the principles of corrosion. This section focuses on engineering aspects of design that can, without due care and attention, precipitate unexpected premature failure. More extensive texts relating specifically to design are available (Ref 51, 52, 53, 54), as are guides from various material suppliers and promoters (Ref 55, 56, 57). However, it is the fine details of engineering design, often compounded by human errors or poor communication (Ref 22, 58, 59, 60, 61, 62, 63, 64), that account for many unexpected failures, at times significant. On occasion a poor design can cause premature failure of the most advanced corrosion-resistant materials.

Design Considerations

Designing for corrosion control can only be effective if it is part of the overall design philosophy. However, a designer is seldom a corrosion engineer, so it is necessary to convey corrosion knowledge to the designer. Unlike conventional engineering, the basic difficulty is that corrosion is not a tangible property; it is more a *behavioral* pattern. Thus, to realize safe, reliable designs, it is essential that there be a rigid control on materials and fabrication and an extensive effort to eliminate human errors or misunderstandings that result from poor communication.

The results of a survey of chemical-process plants (Ref 65) showed that design faults ranked highest (58%) in the reasons for failure. Of almost equal ranking was the incorrect application of protective treatments (55%), followed by categories that demonstrate a lack of knowledge about the operating conditions (52%), lack of process control (35%), and an unawareness that there was actually a corrosion risk (25%).

In an ideal world, designers would call for some corrosion assessment *prior* to preparing the detailed engineering design. Typically, schemes would permit some form of evaluation with respect to both function and the necessary action, for example from the proposal-to-production planning stages (Fig. 27) (Ref 65). In the practical "real" world, however, communication of "agreed" reasons for failures may not always reach the designer. Indeed, communication to contractors, who are closest to the application, is even poorer (Ref 65, 66). Studies have shown that, while management is always informed of the reasons for failure in the chemical-processing industry, site personnel are informed only 77% of the time, designers 55%, material suppliers 37%, and contractors only 11% of the time.

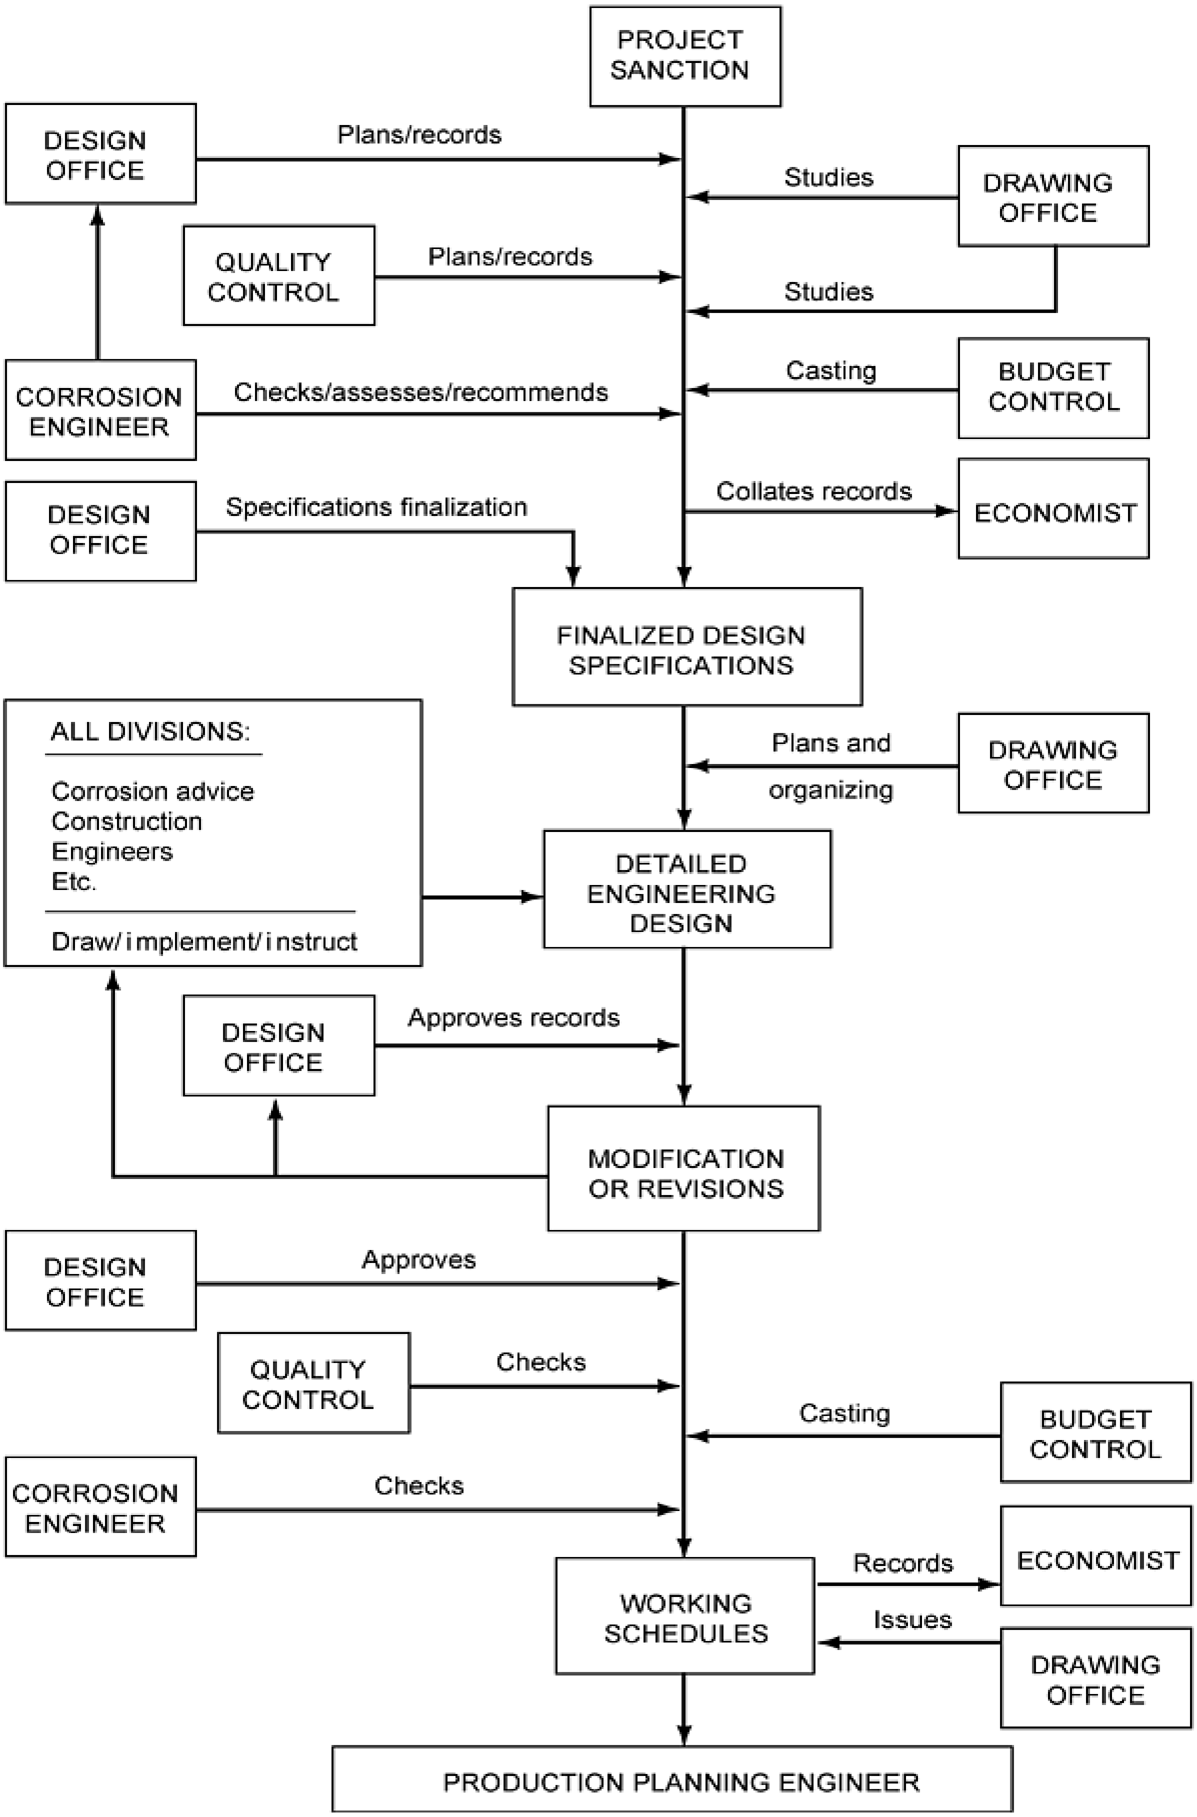

Fig. 27 Action steps during design. Source: Ref 64

"Draftsmen's Delusions." A further complication in designing against corrosion relates to the general interpretation of design drawings in what has been referred to as "draftsmen's delusions." For example, the draftsman might be considering a certain piece of equipment without knowledge of the fact that there may be unusual shapes, moving parts, or environmental issues. A lack of attention to design detail causes many premature failures by corrosion-related processes.

All too often, the designer will have in mind one thing, which in reality becomes totally different. For example, a simple cross-over line between two reactor vessels might, in practice, become an extended line with several turns, merely to position a shut-off valve at a more convenient and accessible position closer to ground level. There are countless examples of this situation in "real-world" failure analysis, where the actual designs were not those originally intended; examples will be provided below.

Quality assurance and control usually ensure that the requested material is what it should be, given rigorous inspection. However, material controls at fabrication are sometimes less than perfect. In one case, an inspector noticed a blemish on the outside of a steel pressure vessel. Upon closer scrutiny (from the vessel interior) the problem was found to be a steel bolt that had been inadvertently rolled into the steel plate during fabrication.

While considering materials, it is important to avoid nonspecific descriptions or terms in reference to design drawings and specifications. There are many instances where generic terms, such as "stainless steel," "bronze," "Hastelloy," or "Inconel," are too vague and the ultimate choice is far from what was expected and required. Wherever possible, and notably in high-risk areas, materials should be selected and tested according to code requirements (Ref 67, 68). Substitutes, if requested, should be properly evaluated before use.

Reliability Engineering

The designer should play a significant role in reliability management. The communication chain, or the "reliability loop" from the designer, to the manufacturer, then to the user and back to the designer, is a key factor (Ref 66, 69). When a risk is well documented, it should be possible to overdesign or at least isolate the area to minimize risk to users. Where a risk of failure is high, the emphasis should be toward a "fail-safe" or "no-fail/replace" procedure. Failures vary considerably: the design function can be partially or totally affected; the onset of failure can be gradual or sudden. The combination of sudden and total failure represents the worst catastrophic situation (e.g., explosions, fires, and total structural collapse), many of which can be attributed to "a small design detail."

Corrosion Awareness

This article is intended to improve corrosion awareness, but clearly this is only a starting point. To be effective, the user must also be willing to take action and the designer should insist on appropriate codes and/or recommended working practices. Whether the necessary action will be taken is affected by financial, technical, safety, social, and/or political issues (Ref 69).

To prevent corrosion/degradation, the designer can:

- Avoid obvious design weaknesses (see examples below).
- Use more reliable materials, even if this entails greater cost.
- Introduce additional precautions (inhibitors, cathodic protection, coatings).
- Establish efficient maintenance/repair teams having detailed procedures and including qualified surveyors, inspectors, and supervisors.
- Ensure that standby products are available, fully labeled, and properly stored (using dessicants and noncorrosive packaging)

As noted above, the planned approach for reliable engineering design should include corrosion control and/or preventive measures, for which standards and specifications are available. Actual (real-world) approaches vary from plant to plant (or component to component) and include the:

- "Avoid failure" approach

- "Keep-it-working" approach
- "Let-it-fail-then-repair" approach

Aspects germane to these approaches are summarized in Table 5 (Ref 66, 69).

Table 5 Design aspects for reliability

Approach	Factors to be taken into account (typical)
"Avoid failure" approach	
Control product duty	Fail safe. Visible instrumentation.
Keep product simple	Fewer functions. Fewer joints.
Predict reliability	Maintain in fixed limits. Overdesign (thicker), etc.
Study variable interfaces	Contact faces, bearings. Lubrication (wear, friction). Seals. Consult experts and test work.
Instill care for familiar items or designs	Complacency. Negligence.
Study innovation	Consult experts and test work. Records of operation. Records of failure mode/frequency.
Redundant items	Stand-by units in good repair. Storage. Handling. Vibration, impact, wear, etc.
Recognize human limits	Misreading of instructions. Sequence of controls (hypnosis?). Adequate housekeeping. User attitudes.
Test product design	Proving the design. Variables. Safety limits. Pilot plant and real-life testing.
Control malfunctions	Human. Automatic. Mixture. Important for software/hardware.
"Keep it working" approach	
Maintainability	Access.
Short-term items	Replace routinely before failure. Regular inspection. Monitoring.
Spares	Identity correctly coded. Location known. Easy access replacement. Avoid identical mating systems.
Built-in adjustments	Corrects for progressive deterioration. Manual/automatic.
"Let it fail then repair" approach	
Defects	Subtle or catastrophic.
Spares	Need quantified reliability (difficult for corrosion).
Minimize off period	Keep repair time low. Speedy fault diagnosis. Speedy removal of failed part(s). Speedy replacement. Speedy check of assembly. Experts, inspectors.

Source: Ref 66

New plants and process equipment are commonly designed to prevent or reduce problems that occurred previously. Updated and improved procedures are of little use, however, if no action is made until after the equipment fails (Ref 70). Situations have occurred where cathodic protection was ineffective because the anode material was not connected to the structure it was protecting; a monitoring signal (a bell) was ignored because of noise; online monitoring data were estimated (guessed at) so that the inspector could avoid travel in blizzard conditions; and a sentinel hole (weep hole) leaked for weeks without any investigation as to cause until the vessel exploded.

Why Failures Occur

In the context of design, there are several factors that relate to material/component failure:

- *Overload* suggests a weakness in plant control instrumentation or operation.
- *Abnormal conditions* can result from a lack of process control or variations in raw materials (alloy type or chemical inhibitors, etc.).
- *Poor fabrication* may relate to inadequate instructions or inspection (e.g., excessive cold work, overmachining, flame cutting, or excessive torque loading).
- *Poor handling.* Scratches or machine marks can result from poor detailing or poor instruction. Not to be excluded are identity marks (incised codes) and inspection stamps.
- *Assembly,* if incorrect (e.g., welds and fasteners) can seriously influence stress, flow, and compatibility.
- *Storage and transportation* can significantly influence material performance, especially for items shipped to/from tropical, humid climates where heavy rains, violent seas, storms, and cargo sweat may each contribute to material degradation unless adequate precautions are taken (Ref 71). Proper design

and effective corrosion control management normally should accommodate these aspects of material handling.

- *Accessibility.* Some structures or components may not be accessible for remedial work, even if a corrosion risk is recognized. Buried structures can be affected where soil and bacterial corrosion might apply (Ref 72).

Design and Materials Selection

Corrosion control measures are best initiated at the design stage (Fig. 27). Materials are usually selected to perform a basic function or to provide a functional requirement (see the article "Materials Selection" in Ref 22). Therefore, in many instances the material choice is dictated not by corrosion, but by characteristics such as strength, reflectivity, wear resistance, and dimensional stability. In some situations a corrosion-resistant alloy may not be satisfactory.

High-Temperature Service. The subject of designing for high-temperature service is outside the scope of this article (see the article "Design for High-Temperature Applications" in this Volume and Ref 58, 73, and 74); however, high temperatures always accelerate corrosion processes, and certain gases or liquids, which are considered innocuous under ambient conditions, become aggressive to materials when hot. A tenfold change in corrosion rate is not uncommon for a temperature change of 30 °C under aqueous conditions. The same tenfold change (or considerably worse) can occur with a 20 °C change under high-temperature conditions. If temperatures are too high, the material might oxidize (i.e., scale). Thick scales and metal loss result from overheating (loss of water cooling, absence of insulation, etc.). Heat-transfer contributions will increase as the scale/deposit thicknesses increase.

Candidate high-temperature materials need to be strong and resistant to oxidation or to other corrosion processes that might involve complex multioxidant environments having highly volatile phases and molten salts. It is important for designers and others to recognize that several corrosion elements might simultaneously be involved in an application (e.g., oxygen, halogen, and sulfur) (Table 6). Material selection for high-temperature service needs to be reviewed for each individual part and application. Alloy steels and more sophisticated alloys based on nickel and cobalt are most commonly used, in which key elements for high-temperature corrosion resistance include chromium, aluminum, silicon, and rare-earth additions for scale retention.

Table 6 Types of corrosion and corrodents encountered in high-temperature processes or components

Process components	Temperature, °C	Types of corrosion or corrodent
Chemical/petrochemical		
Ethylene steam cracking furnace tubes	to 1000	Carburization, oxidation
Steam reforming tubes	to 1000	Oxidation, carburization
Vinyl chloride crackers	to 650	Halide gas
Hydrocracking heaters, reactors	to 550	H_2S and H_2
Petroleum coke calcining recuperators	816	Oxidation, sulfidation
Cat cracking regenerators	to 800	Oxidation
Flare stack tips	950-1090	Oxidation, thermal fatigue, sulfidation, chlorination, dewpoint
Carbon disulfide furnace tubes	850	Sulfidation, carburization, deposits
Melamine production (urea)-reactors	450-500	Nitriding
Other processes		
Titanium production reactor vessels	900	Oxidation, chlorination
Nitric acid--catalyst grid	930	Oxidation, nitriding, sulfidation
Nuclear reprocessing reactors	750-800	Oxidation (steam), fluorination (HF)
Oil-fired boiler superheaters	850-900	Fuel ash corrosion
Gas turbine blades corrosion	to 950	Sulfates, chlorides, oxidation, ash
Waste incinerators--superheaters	480	Chlorination, sulfidation, oxidation, molten salts
Fiberglass manufacturing recuperators	1090	Oxidation, sulfidation, molten salts

Source: Ref 58

Different behavior can arise at similar temperatures, depending on the source of heat, such as electrical heating elements; fuel combustion, flue gases and deposits; flame impingement; friction and wear. When hot gases cool, condensation can cause acid dewpoint conditions, thereby changing the material choice to a corrosion-resistant alloy.

Design Factors That Influence Corrosion. The basic factors that most influence design for corrosion resistance are summarized in Table 7 (Ref 58). Each factor plays a unique yet not always unrelated role with other factors. For example, localized corrosion damage adjacent to the spindle support of a stainless steel paddle stirrer (Fig. 28) resulted not only from crevice corrosion (oxygen differential cell) but also because of galvanic corrosion, caused by a small steel retaining screw (anodic) that had been used inadvertently for assembly. Ultimately, the stirrer support loosened, which allowed further deterioration by fretting.

Table 7 Corrosion factors that can influence design considerations

Environment	**Natural** **Chemical** **Storage/transit**
Stress	Residual stress from fabrication Operating stress--static, variable, alternating
Shape	Joints, flanges Crevices, deposits Liquid containment and entrapment
Compatibility	Metals with metals Metals with other materials Quality control
Movement	Flowing fluids Parts moving in fluids Two-phase fluids
Temperature	Oxidation, scales Heat-transfer effects Molten deposits Condensation and dewpoint
Control	Surface cleaning and preparation Coatings Cathodic protection Inhibitors Inspection Planned maintenance

Source: Ref 57

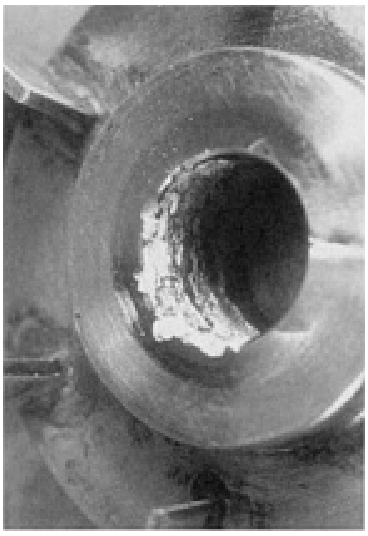

Fig. 28 Crevice corrosion of a stainless-steel paddle stirrer, exacerbated by galvanic corrosion by a steel retaining pin

Design Details. The following sections demonstrate aspects of design detail that can accelerate corrosion.

Location. Exposure to winds and airborne particulates can lead to deterioration of structures.Designs that leave structures exposed to the elements should be carefully reviewed, because atmospheric corrosion is significantly affected by temperature, relative humidity, rainfall, and pollutants. Also important are the season and location of on-site fabrication, assembly, and painting.Codes of practice must be adapted to the location and the season.

Shape. Geometrical form is basic to design.The objective is to minimize or avoid situations that worsen corrosion. These situations can range from stagnation (e.g., retained fluids and/or solids; contaminated water used for hydrotesting) to sustained fluid flow (e.g., erosion/cavitation in components moving in or contacted by fluids, as well as splashing or droplet impingement).

Common examples of stagnation include nondraining structures, dead ends, badly located components, and poor assembly or maintenance practices (Fig. 29). General problems include localized corrosion associated with differential aeration (oxygen concentration cells), crevice corrosion, and deposit corrosion.

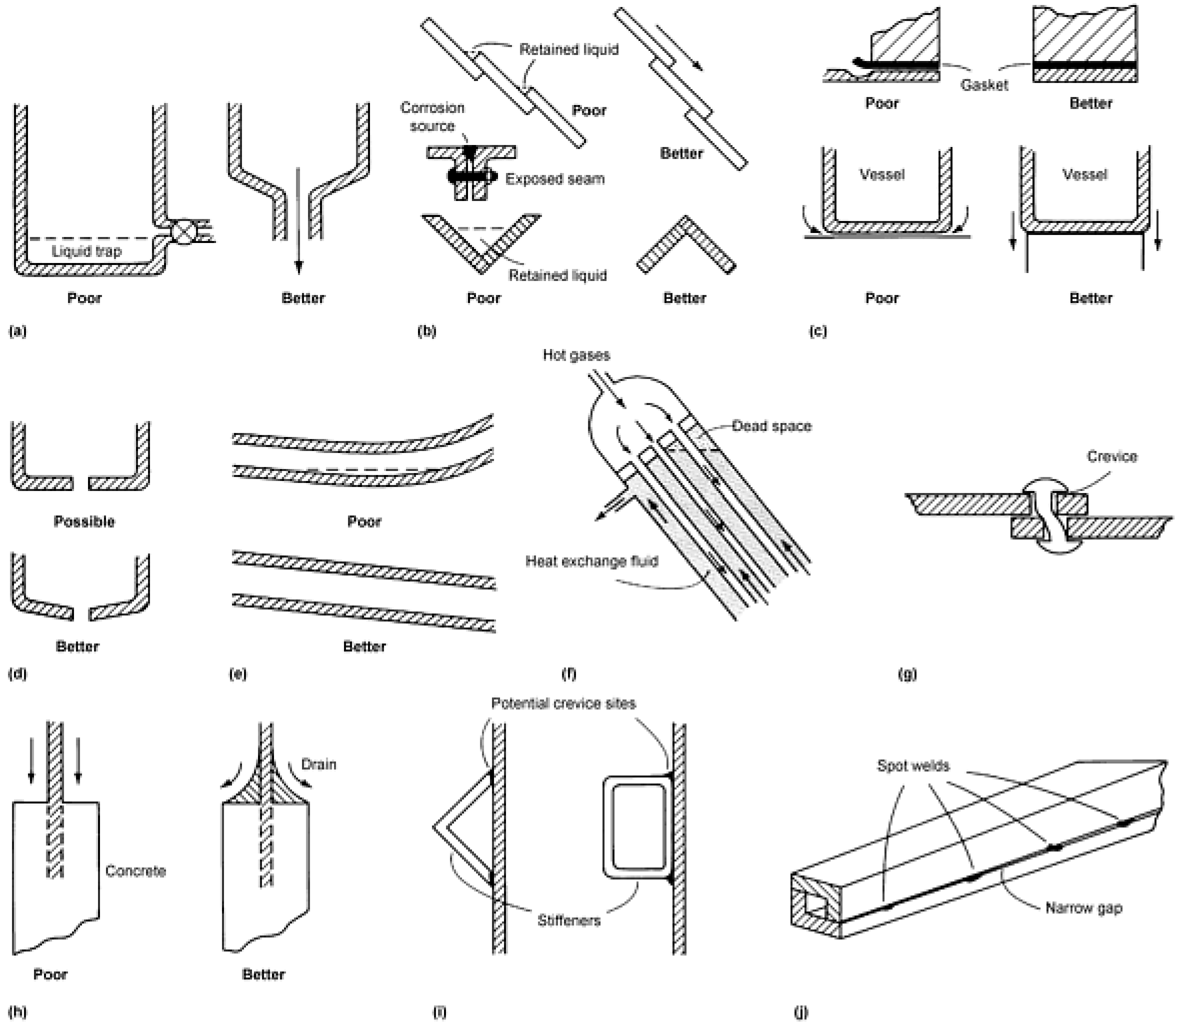

Fig. 29 Examples of how design and assembly can affect localized corrosion by creating crevices and traps where corrosive liquids can accumulate. (a) Storage containers or vessels should allow complete drainage; otherwise, corrosive species can concentrate in vessel bottom, and debris may accumulate if the vessel is open to the atmosphere. (b) Structural members should be designed to avoid retention of liquids; L-shaped sections should be used with open side down, and exposed seams should be avoided. (c) Incorrect trimming or poor design of seals and gaskets can create crevice sites. (d) Drain valves should be designed with sloping bottoms to avoid pitting of the base of the valve. (e) Nonhorizontal tubing can leave pools of liquid at shutdown. (f) to (j) Examples of poor assembly that can lead to premature corrosion problems. (f) Nonvertical heat exchanger assembly permits dead space that is prone to overheating if very hot gases are involved. (g) Nonaligned assembly distorts the fastener, creating a crevice that can result in a loose fit and contribute to vibration, fretting and wear. (h) Structural supports should allow good drainage; use of a slope at the bottom of the member allows liquid to run off, rather than impinge directly on the concrete support. (i) Continuous weld for

horizontal stiffeners prevents traps and crevices from forming. (j) Square sections formed from two L-shape members need to be continuously welded to seal out the external environment.

Movement. Fluid movement need not be excessive to damage a material. Much depends on the nature of the fluid and the hardness of the material.A geometric shape may create a sustained delivery of fluid or may locally disturb a laminar stream and lead to turbulence. Replaceable baffle plates or deflectors are beneficial where circumstance permit their use; they eliminate the problem of impingement damage to the structurally significant component.

Careful fabrication and inspection should eliminate or reduce poor profiles (e.g., welds, rivets, bolts), rubbing surfaces (e.g., wear, fretting), and galvanic effects due to the assembly of incompatible components. Figure 30 shows typical situations in which geometric details influence flow.

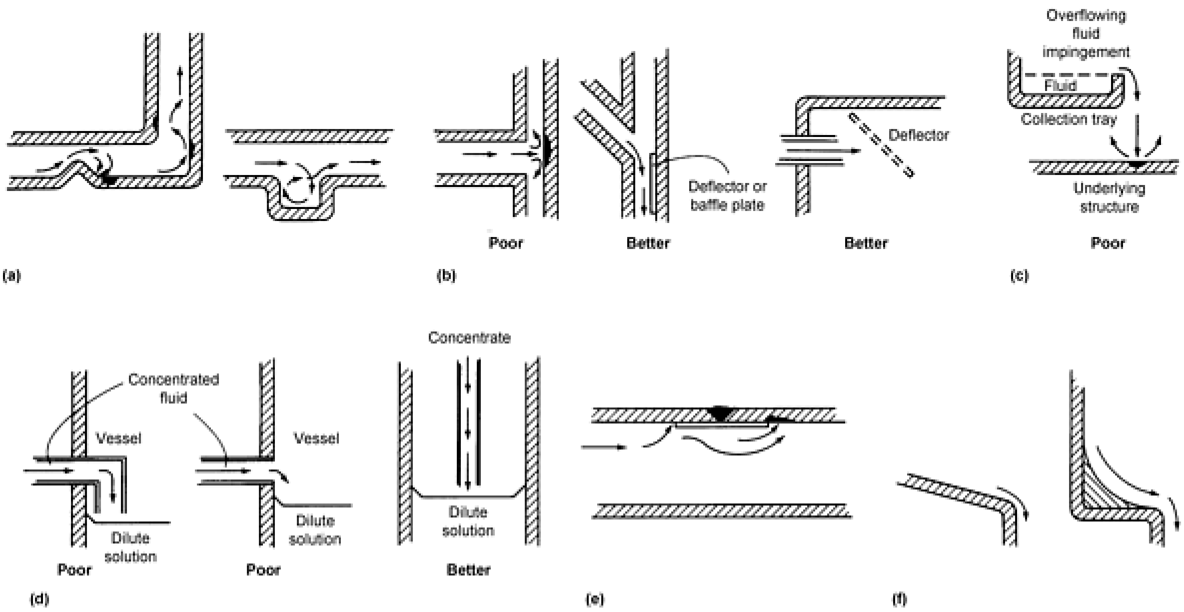

Fig. 30 Effect of design features on flow. (a) Disturbances to flow can create turbulence and cause impingement damage. (b) Direct impingement should be avoided; deflectors or baffle plates can be beneficial. (c) Impingement from fluid overflowing from a collection tray can be avoided by relocating the structure, increasing the depth of the tray, or using a deflector. (d) Splashing of concentrated fluid on container walls should be avoided. (e) Weld backing plates or rings can create local turbulence and crevices. (f) Slope or modified profiles should be provided to permit flow and minimize fluid retention.

Compatibility. In plant environments, it is often necessary to use different materials in close proximity.Sometimes, components that were designed in isolation can end up in direct contact in the plant (Fig. 31). In such instances, the ideals of a total design concept become especially apparent, but usually in hindsight. Direct contact of dissimilar metals introduces the possibility of galvanic corrosion, and small anodic (corroding) areas should be avoided wherever this contact is apparent.

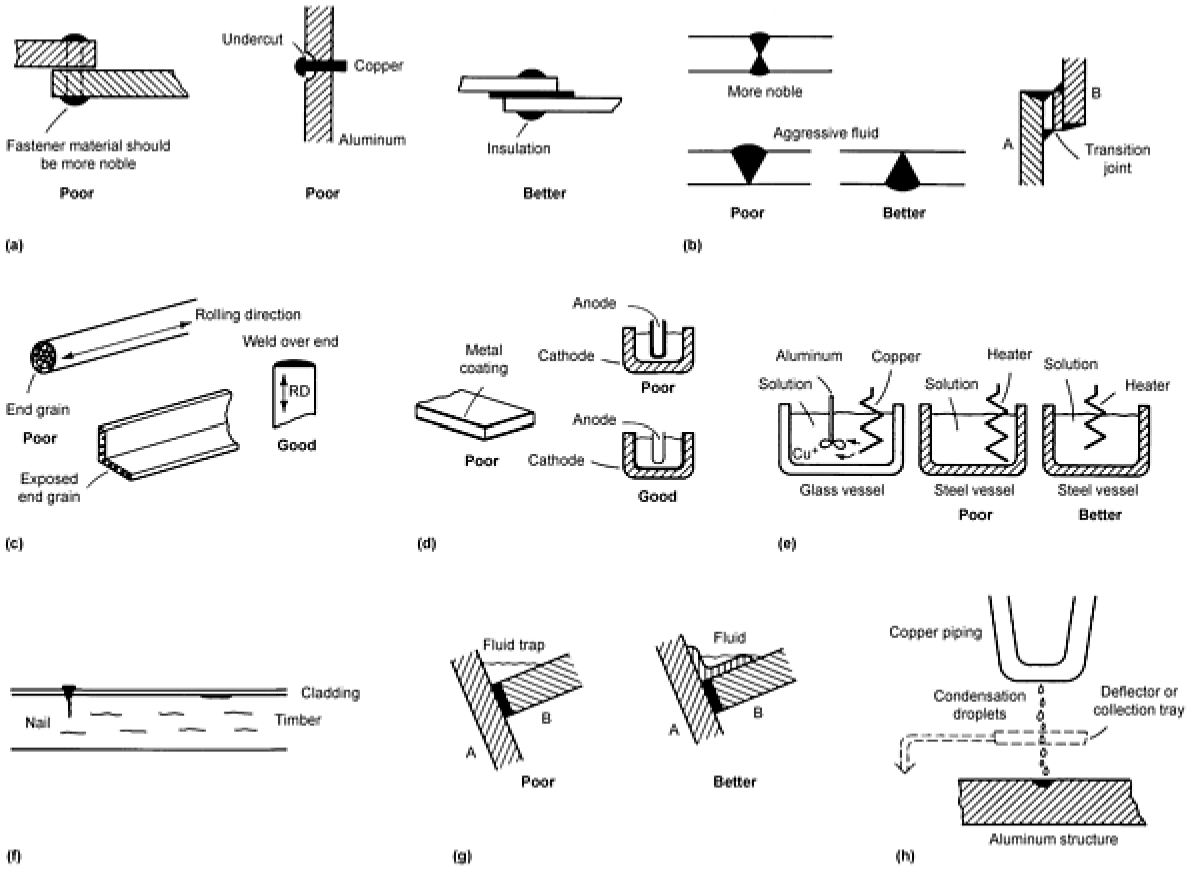

Fig. 31 Design details that can affect galvanic corrosion. (a) Fasteners should be more noble than the components being fastened; undercuts should be avoided, and insulating washers should be used. (b) Weld filler metals should be more noble than base metals. Transition joints can be used when a galvanic couple is anticipated at the design stage, and weld beads should be properly oriented to minimize galvanic effects. (c) Local damage can result from cuts across heavily worked areas. End grains should not be left exposed. (d) Galvanic corrosion is possible if a coated component is cut. When necessary, the cathodic component of a couple should be coated. (e) Ion transfer through a fluid can result in galvanic attack of less noble metals. In the example shown at left, copper ions from the copper heater coil could deposit on the aluminum stirrer. A nonmetallic stirrer would be better. At right, the distance from a metal container to a heater coil should be increased to minimize ion transfer. (f) Wood treated with copper preservatives can be corrosive to certain nails, especially those with nobility different from that of copper. Aluminum cladding can also be at risk. (g) Contact of two metals through a fluid trap can be avoided by using a collection tray or a deflector.

Galvanic corrosion resulting from metallurgical sources is well documented. Problems such as weld decay and sensitization can generally be avoided by material selection or suitable fabrication techniques. Less obvious instances of localized attack occur because of end-grain attack and stray-current effects, which can render designs ineffective.

End-grain attack, or preferential attack of grains exposed by cross-cutting through a metal plate or rod (Fig. 31c), occurs in many corrosive fluids. An example is the cut edges and punched-out "holes" in a stainless steel reactor tray (Fig. 32).

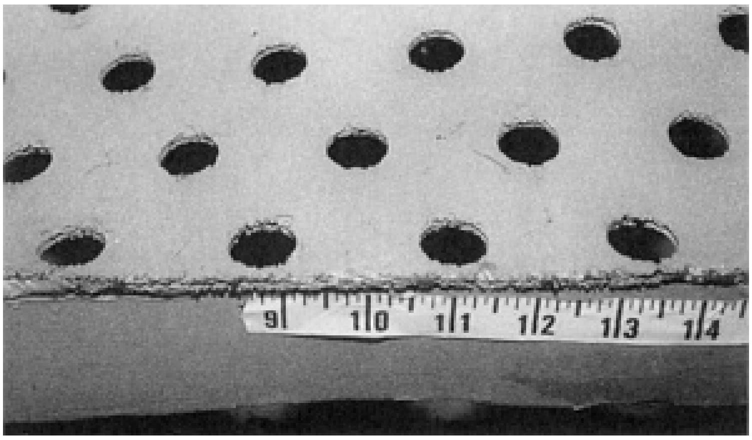

Fig. 32 End-grain corrosion along cut edges and punched holes in a reactor tray made from type 316 stainless steel

Stray-current effects are common on underground iron or steel pipelines that are located close to electrical supply lines, or where stray currents can cause active corrosion at preferred sites. For example, stray-current attack caused a titanium flange spacer to become anodic "during service" due to inappropriate grounding of welding equipment on an adjacent part of the plant structure.

Designers, when aware of compatibility effects, need to exercise their ingenuity to minimize the conditions that most favor increased corrosion currents. Table 8 provides some suggestions.

Table 8 Sources of increased corrosion currents and related design considerations

Source	Design considerations
Metallurgical sources (both within the metal and for relative contact between dissimilar metals)	Difference in potential of dissimilar materials; distance apart; relative areas of anode and cathode; geometry (fluid retention); mechanical factors (e.g., cold work, plastic deformation, sensitization)
Environmental sources	Conductivity and resistivity of fluid; changes in temperature; velocity and direction of fluid flow; aeration; ambient environment (seasonal changes, etc.)
Miscellaneous sources	Stray currents; conductive paths; composites (e.g., concrete rebars)

The most common design details relating to galvanic corrosion include jointed assemblies (Fig. 29, 31). Where dissimilar metals are to be used, some consideration should be given to compatible materials known to have similar potentials (Fig. 13). Care should be exercised because the galvanic series is limited and refers to specific environments, usually seawater.

Where noncompatible materials are to be joined, it is advisable to use a more noble metal in a joint (Fig. 31b). Effective insulation can be useful if it does not lead to crevice corrosion. Some difficulties arise in the use of adhesives, which may not be sealants.

The relative surface areas of anodic and cathodic surfaces should not be underestimated, because corrosion at a small anodic zone can be several hundred times greater than that for the same bimetallic components of similar area. As noted already, synergistic effects must also be recognized, such as failure resulting from a combination of galvanic and crevice attack. This example shows the unfortunate choice of a carbon steel bolt to tighten the spindle in a stainless steel paddle stirrer (Fig. 33). The result was crevice corrosion at the stirrer support (Fig. 28), which was exacerbated by the galvanic action caused by the carbon steel/stainless steel metal-to-metal contact.

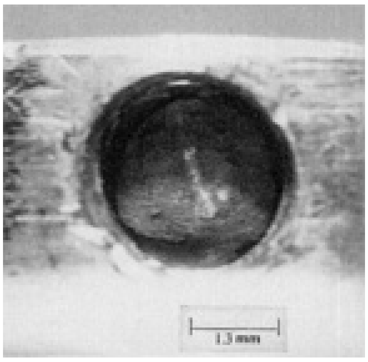

Fig. 33 The incorrect choice of a carbon-steel retaining bolt for a stainless-steel spindle resulted in localized galvanic corrosion of the paddle-stirrer assembly (see Fig. 28)

Less obvious examples of galvanic corrosion occur when ion transfer results in the deposition of active and noncompatible deposits on a metal surface. For example, an aluminum stirrer plate used in water was extensively pitted because the water bath was heated by a copper heater coil (Fig. 31e). The pits resulted from deposition of copper ions from the heater element. More rapid, but similar, damage occurred when a dental aspirator (Teflon-coated aluminum) was attacked by mercury from a tooth filling. These two metals rank as a "high risk" combination for galvanic corrosion (see Fig. 13). The aluminum section was rapidly pitted once the Teflon had first been worn away by sharp fragments of tooth enamel.

Anodic components can on occasion be overdesigned (made thicker) to allow for the anticipated corrosion loss. In other instances, easy replacement is a cost-effective option (Table 5).

Where metallic coatings are used, there may be a risk of galvanic corrosion, especially along the cut edges. Rounded profiles and effective sealants or coatings are beneficial. Transition joints can be introduced when different metals are to be in close proximity. These and other situations are illustrated in Fig. 31. Another possibility is coating of the cathodic material for corrosion control. Ineffective painting of an anode in an assembly can significantly reduce the desired service lifetime, because local defects (anodes) effectively multiply the risk of localized corrosion.

Insulation represents another area for potential corrosion attack, although most problems arise because of poor installation. Insulation types and properties vary considerably, and expert advice from suppliers is recommended. The most common corrosion problems include crevice corrosion (where insulation and/or adhesives are tightly held against a metal surface, for example when straps or ties are too tight) and pitting corrosion (where moisture condenses on the metal, usually because the insulation barrier was too thin or was improperly installed). Moisture-absorbing tendencies vary from one insulation to another (Ref 75).

Wet-dry cycling has been known to lead to concentration effects (e.g., chloride ions from calcium-silicate insulation). There have been reported instances of chloride stress-corrosion cracking (SCC) in certain stainless steel pipes and vessels, or pitting of these and other materials, such as aluminum, when contacted by insulation. The early instances of SCC failure were mainly attributable to high chloride levels (500-1500 ppm) associated with asbestos-type materials. The chloride levels have been significantly reduced in recent years to a level that is not expected to cause SCC. Standards are now available, as are tests to evaluate insulation materials (Ref 76). A parallel German standard calls for zero nitrite content and <0.2% ammonia levels in elastomeric insulation that is used for copper and copper-alloy piping to reduce the risk of SCC (Ref 77).

Figure 34 shows some typical examples in which design and installation procedures could have been improved. Other problems occur when insulation is torn or joints are misaligned or incorrectly sealed with duct tape or similar bandaging, none of which is recommended by insulation suppliers.

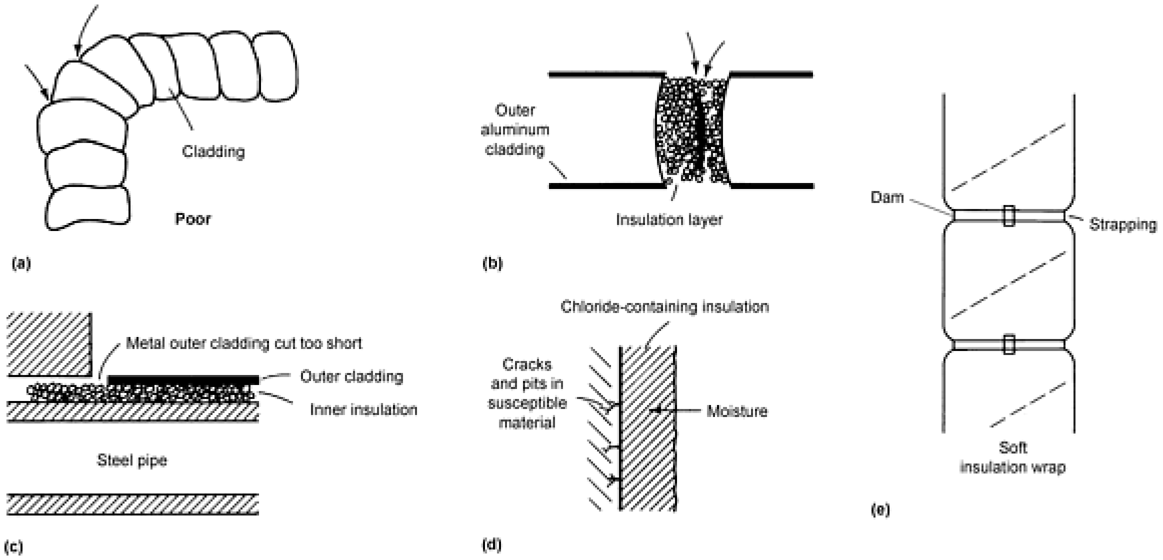

Fig. 34 Corrosion problems associated with improper use of insulation and lagging. (a) Incorrect overlap in lobster-back cladding does not allow fluid runoff. (b) Poor installation left a gap in the insulation that allows easy access to the elements. (c) Outer metal cladding was cut too short, leaving a gap with the inner insulation exposed. (d) Insufficient insulation can allow water to enter; chloride in some insulation can result in pitting or stress-corrosion cracking of susceptible materials. (e) Overtightened strapping can damage the insulation layer and cause fluid "dams" on vertical runs

Stress. From a general design philosophy, environments that promote metal dissolution can be considered more damaging if stresses are also involved. In such circumstances, materials can fail catastrophically and unexpectedly. Safety and health may also be significantly affected.

A classic example of chloride SCC occurred in a type 304 (UNS S30400) stainless steel vessel (Fig. 35). The stress-corrosion cracks extended radially over the area where a new flanged outlet was welded into the vessel. Residual stresses (from flame cutting) and the fluids inside the vessel (acidic with chlorides) were sufficient to cause this failure in a matter of weeks.

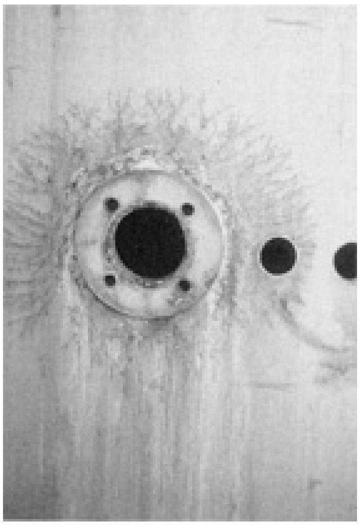

Fig. 35 Chloride SCC in a type 304 stainless-steel vessel after a new flange connection was welded into place

Figure 36 shows examples of using design detail to minimize stress. Perfection is rarely attained in general practice, and some compromise on materials limitation, both chemical and mechanical, is necessary. Mechanical loads can contribute to corrosion, and corrosion (as a corrosive environment) can initiate or trigger mechanical failure. Designs that introduce local stress concentrations directly or as a consequence of fabrication should be carefully considered.

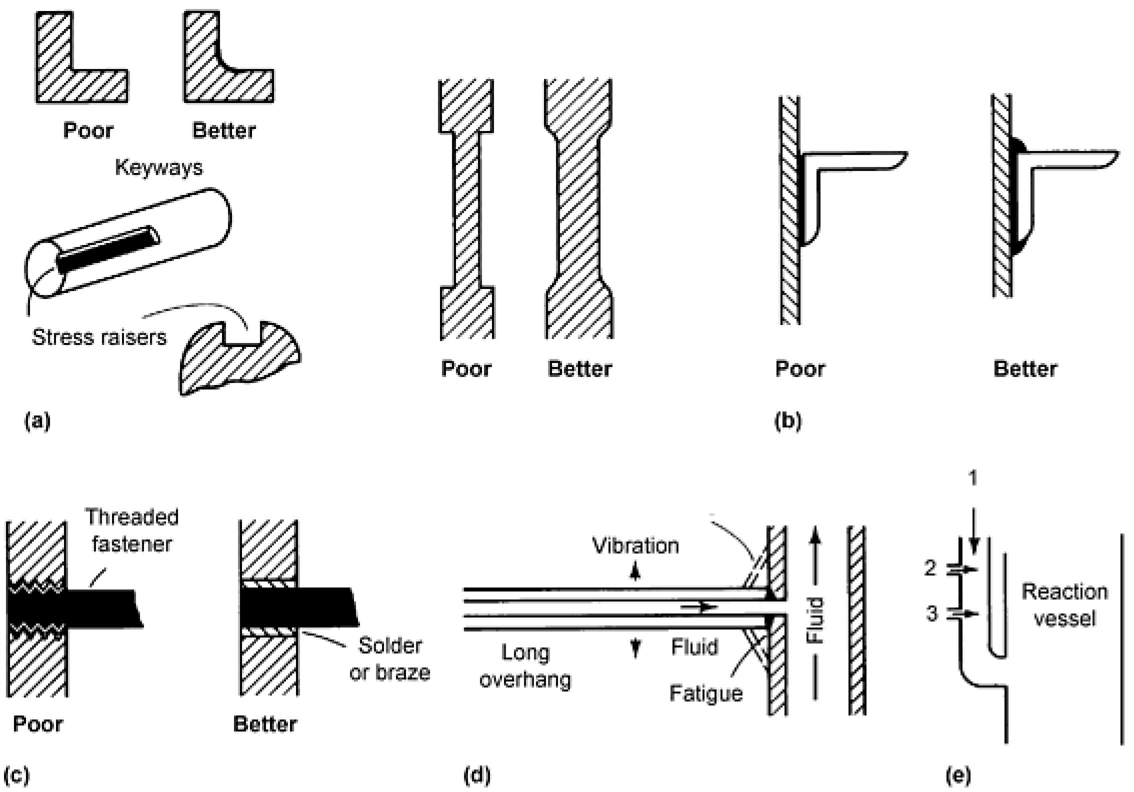

Fig. 36 Design details that can minimize local stress concentrations. (a) Corners should be given a generous radius. (b) Welds should be continuous to minimize sharp contours. (c) Sharp profiles can be avoided by using alternative fastening systems. (d) Too long an overhang without a support can lead to fatigue at the junction. Flexible hose may help alleviate this situation. (e) Side-supply pipework may be too rigid to sustain thermal shock from a recurring sequence that involves (1) air under pressure, (2) steam, and (3) cold water.

Of particular importance in design are stress levels for the selected material: the influence of tensile, compressive, or shear stressing; alternating stresses; vibration or shock loading; service temperatures (thermal stressing); fatigue; and wear (fretting, friction). Profiles and shapes contribute to stress-related corrosion, especially if material selection dictates the use of materials that are susceptible to failure by SCC or corrosion fatigue (Ref 10, 22, 30, 78).

Materials selection is especially important wherever critical components are used. Also important is the need for correct procedures at all stages of operation, including fabrication, transport, storage, startup, shutdown, and normal operation.

Surfaces. Corrosion is a surface phenomenon, and the effects of poorly prepared surfaces, rough textures, and complex shapes and profiles can be expected to be deleterious (Ref 79). Figure 37 shows some examples in which design details could have considerably reduced the onset of corrosive damage resulting from ineffective cleaning or painting.

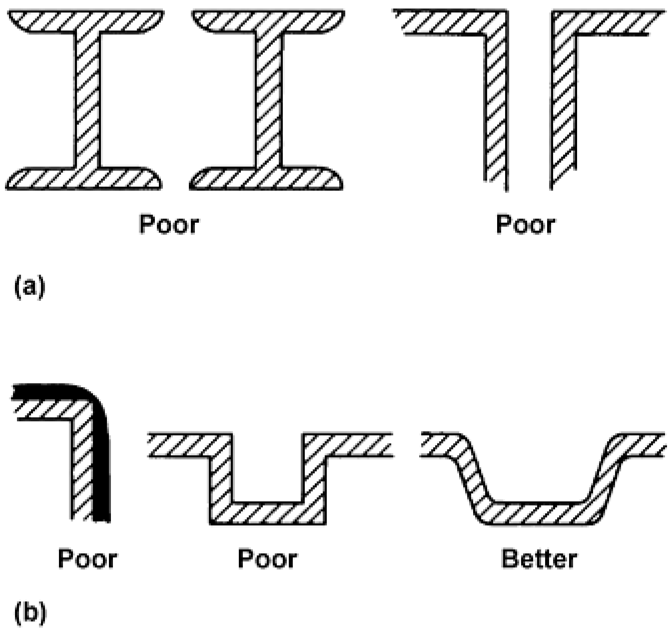

Fig. 37 Effects of design on effectiveness of cleaning or painting. (a) Poor access in some structures makes surface preparation and painting difficult; access to the types of areas shown should be maintained at a minimum of 45 mm ($1\frac{3}{4}$ in.), or one-third of the height of the structure. (b) Sharp corners and profiles should be avoided if the structure is to be painted or coated.

Designs should provide for surfaces that are free from deposits; access to remove retained soluble salts before painting; free-draining assemblies; proper handling of components to minimize distortion, scratches, and dents; and properly located components relative to adjacent equipment (to avoid carryover and spillages).Other recommended procedures for coating constructional materials are shown in Fig. 38 (Ref 18).

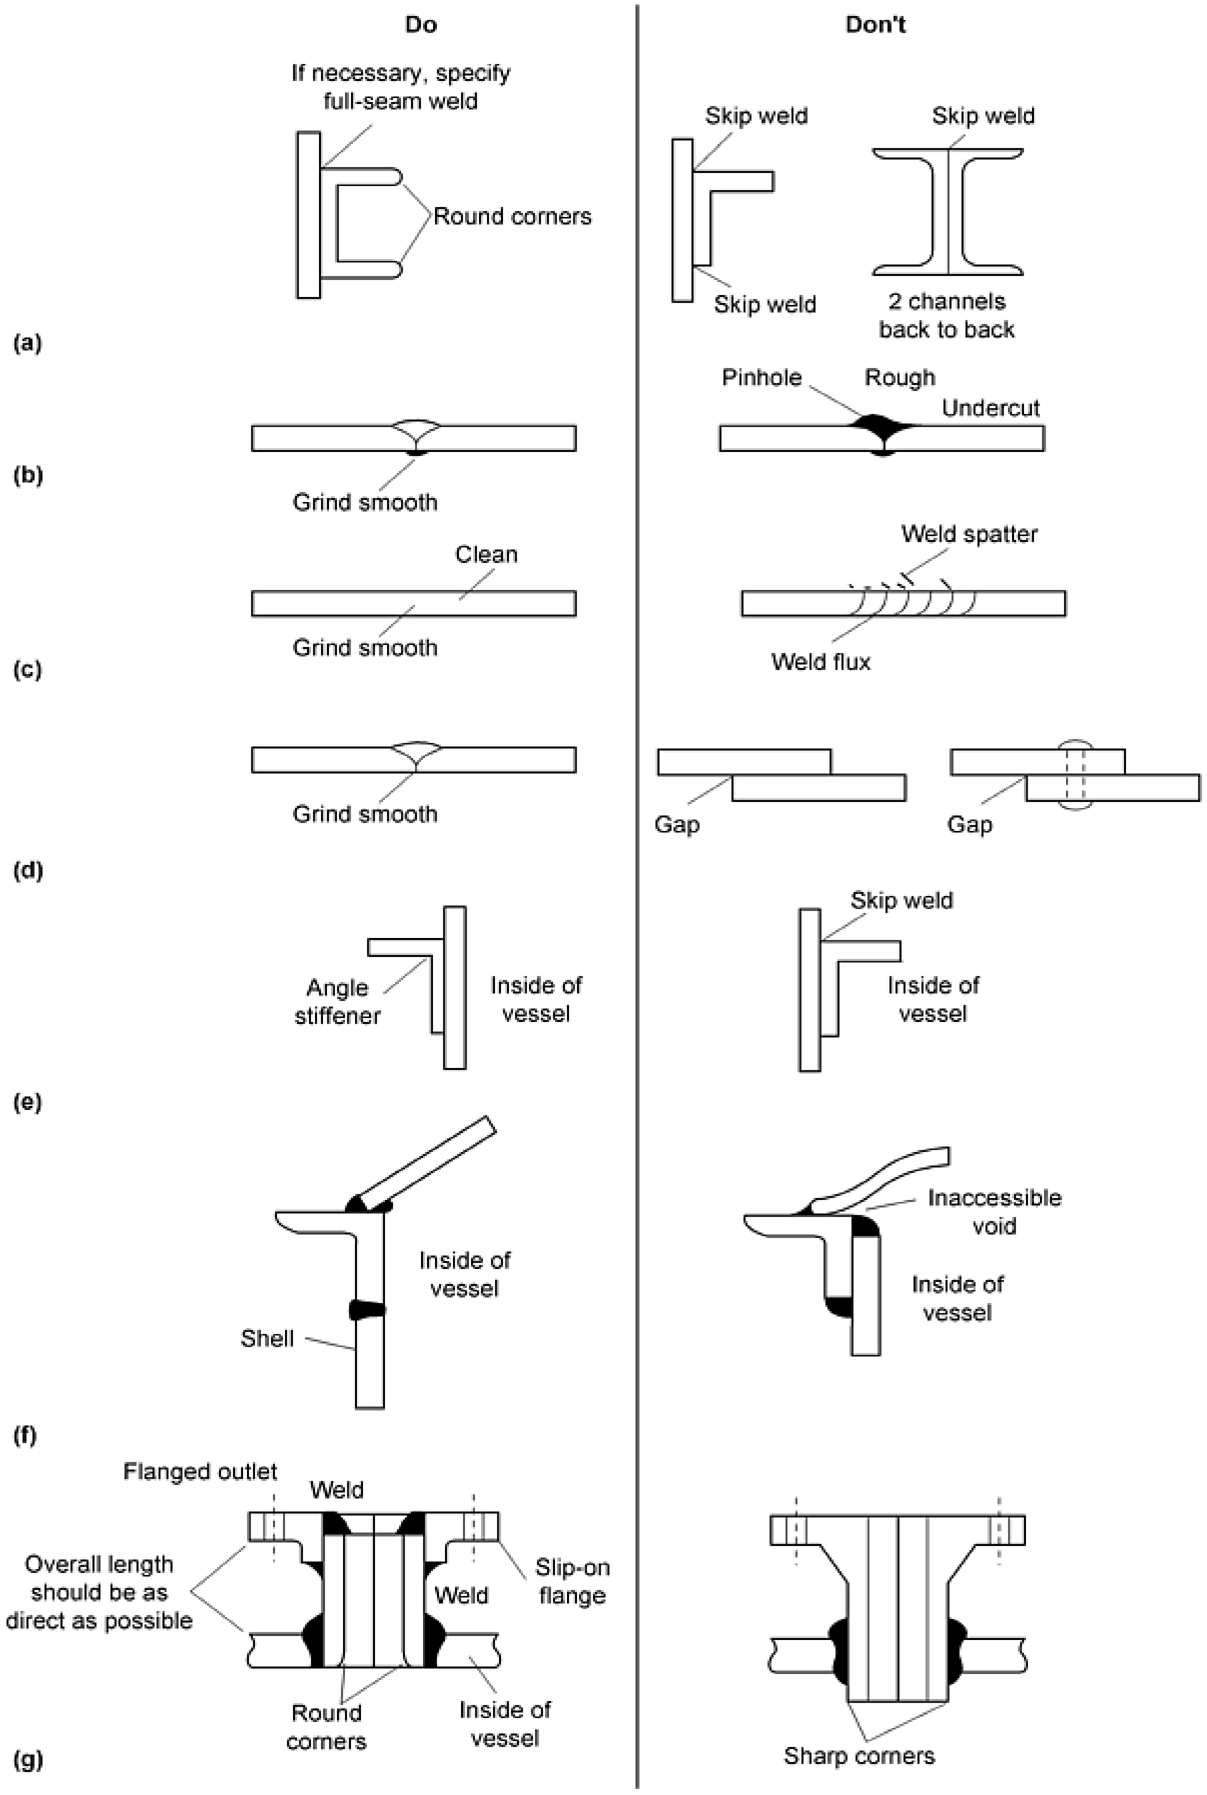

Fig. 38 Suggestions for steel construction to be coated. (a) Avoid pockets or crevices that do not drain or cannot be cleaned or coated properly. (b) Joints should be continuous and solidly welded. (c) Remove weld spatter. (d) Use butt welds rather than lap welds or rivet joints. (e) Keep stiffeners to outside of tank or vessel.

(f) Eliminate crevice (void) at roof-to-shell interface in nonpressure vessel. (g) Outlets should be flanged or pad type, not threaded. Where pressure limits allow, slip-on flanges are preferred, because the inside surface of the attaching weld is readily available for radiusing and grinding. Source: Ref 80

Neglect and poor (or no) maintenance caused localized pitting on the underside of a type 304 stainless steel vessel lid that was exposed to high humidity, steam, and chloride vapors. Access in this example was possible, but not used. Common engineering structural steelwork requires regular preventive maintenance, and restricted access makes this impossible. Figure 37 shows situations in which surface cleaning and/or painting is difficult or impossible. Condensation in critical areas can also contribute to corrosion.Typical structures susceptible to this phenomenon include automobile exhaust systems and chimneys or exhausts from high-temperature plants, such as boilers, kilns, furnaces, or incinerators.

Painting and surface coating techniques have advanced in recent years and have provided sophisticated products that require careful mixing and application. Maintenance procedures frequently require field application where some control (use of trained inspectors) is essential, as in offshore oil and gas rigs. Inspection codes and procedures are available and total design should incorporate these wherever possible. In critical areas, design for online monitoring and inspection will also be important. The human factor in maintenance procedures is often questionable. Adequate training and motivation are of primary importance in ensuring that design details are appreciated and implemented.

Design for Corrosion Resistance

F. Peter Ford and Peter L. Andresen, General Electric Corporate Research and Development Center; Peter Elliott, Corrosion and Materials Consultancy, Inc.

Life Prediction and Management

As pointed out in previous sections, corrosion degradation is largely understood mechanistically, and logical mitigation actions and design decisions can be formulated with a reasonable scientific basis. However, in recent years there has been a further requirement in some industries that the lifetime of various components be predicted and that the technical (and economic) benefits of life extension actions be quantitatively defined. Such further design requirements for life management are especially seen, for instance, in the aerospace and power industries.

To meet these particular design criteria, it is necessary to derive accurate and verifiable life prediction methods. An example is given below of such a derivation for the example of environmental degradation in light-water nuclear reactors (LWRs). The specific corrosion phenomena in these structures have been widely publicized and discussed, especially in a series of conferences (Ref 81, 82, 83, 84, 85, 86, 87, 88, 89, 90) organized by the National Association of Corrosion Engineers (NACE, now known as NACE International), the American Institute of Mining, Metallurgical, and Petroleum Engineers (AIME), and the American Nuclear Society (ANS), and in books (Ref 91, 92). Moreover, this particular topic of corrosion in nuclear reactors has been addressed in the *ASM Handbook* (Ref 93). These incidences have covered all forms of corrosion, including erosion corrosion, galvanic attack, general corrosion, intergranular corrosion, SCC, and corrosion-fatigue cracking in, primarily, carbon/low-alloy steels, austenitic stainless steels, nickel-base alloys, and zirconium-base alloys. To one extent or another, these phenomena have affected the integrity of most of the components in reactors, including irradiated core structures, piping, tubing, pressure vessel, service water systems, and heat exchangers. Moreover, the publications have addressed the whole spectrum, from the mechanistic aspects of degradation in a particular alloy/environment system to the adequacy of the existing design and life prediction methods.

The objective of this section is to focus on one form of degradation, environmentally assisted cracking, not only because it is one of the severest forms of life-limiting phenomena, but also because it represents an area where "fundamental" approaches to resolving the design/prediction problems are most advanced.

There have been well-documented instances of environmentally assisted cracking (e.g., stress-corrosion and strain-assisted cracking and corrosion fatigue) in high-temperature water of austenitic stainless steels, nickel-base alloys, low-alloy and carbon steels, and their weld metals in various subcomponents of LWRs. These events have had a considerable economic impact (Ref 81) and are occurring at a time when competitive and deregulation pressures are forcing nuclear utilities (at least in the United States) to reduce costs (Ref 82). Thus, there is an incentive to develop validated life prediction methods to (a) evaluate the extent of a problem (i.e., is an incident an isolated occurrence or is it the precursor to a more widespread generic problem?) and (b) quantitatively define the benefit of a specific mitigation action and evaluate its cost-effectiveness.

Unfortunately, the scatter in data from which such design or life prediction codes can be formulated is extreme. This scatter applies to data obtained from both field experience (Ref 94) and "well-controlled" laboratory experiments. This latter observation is illustrated in Fig. 39 by crack-propagation rate/stress-intensity relationships for stainless steels (Ref 96). Similar data scatter has been noted for nickel-base alloys (Ref 97) and low-alloy steels (Ref 97) in 288 °C high-purity water. In other instances, a large database does not exist, so it is impossible to define a usable life prediction algorithm. An example of this is irradiation-assisted stress-corrosion cracking of stainless steels in reactor cores.

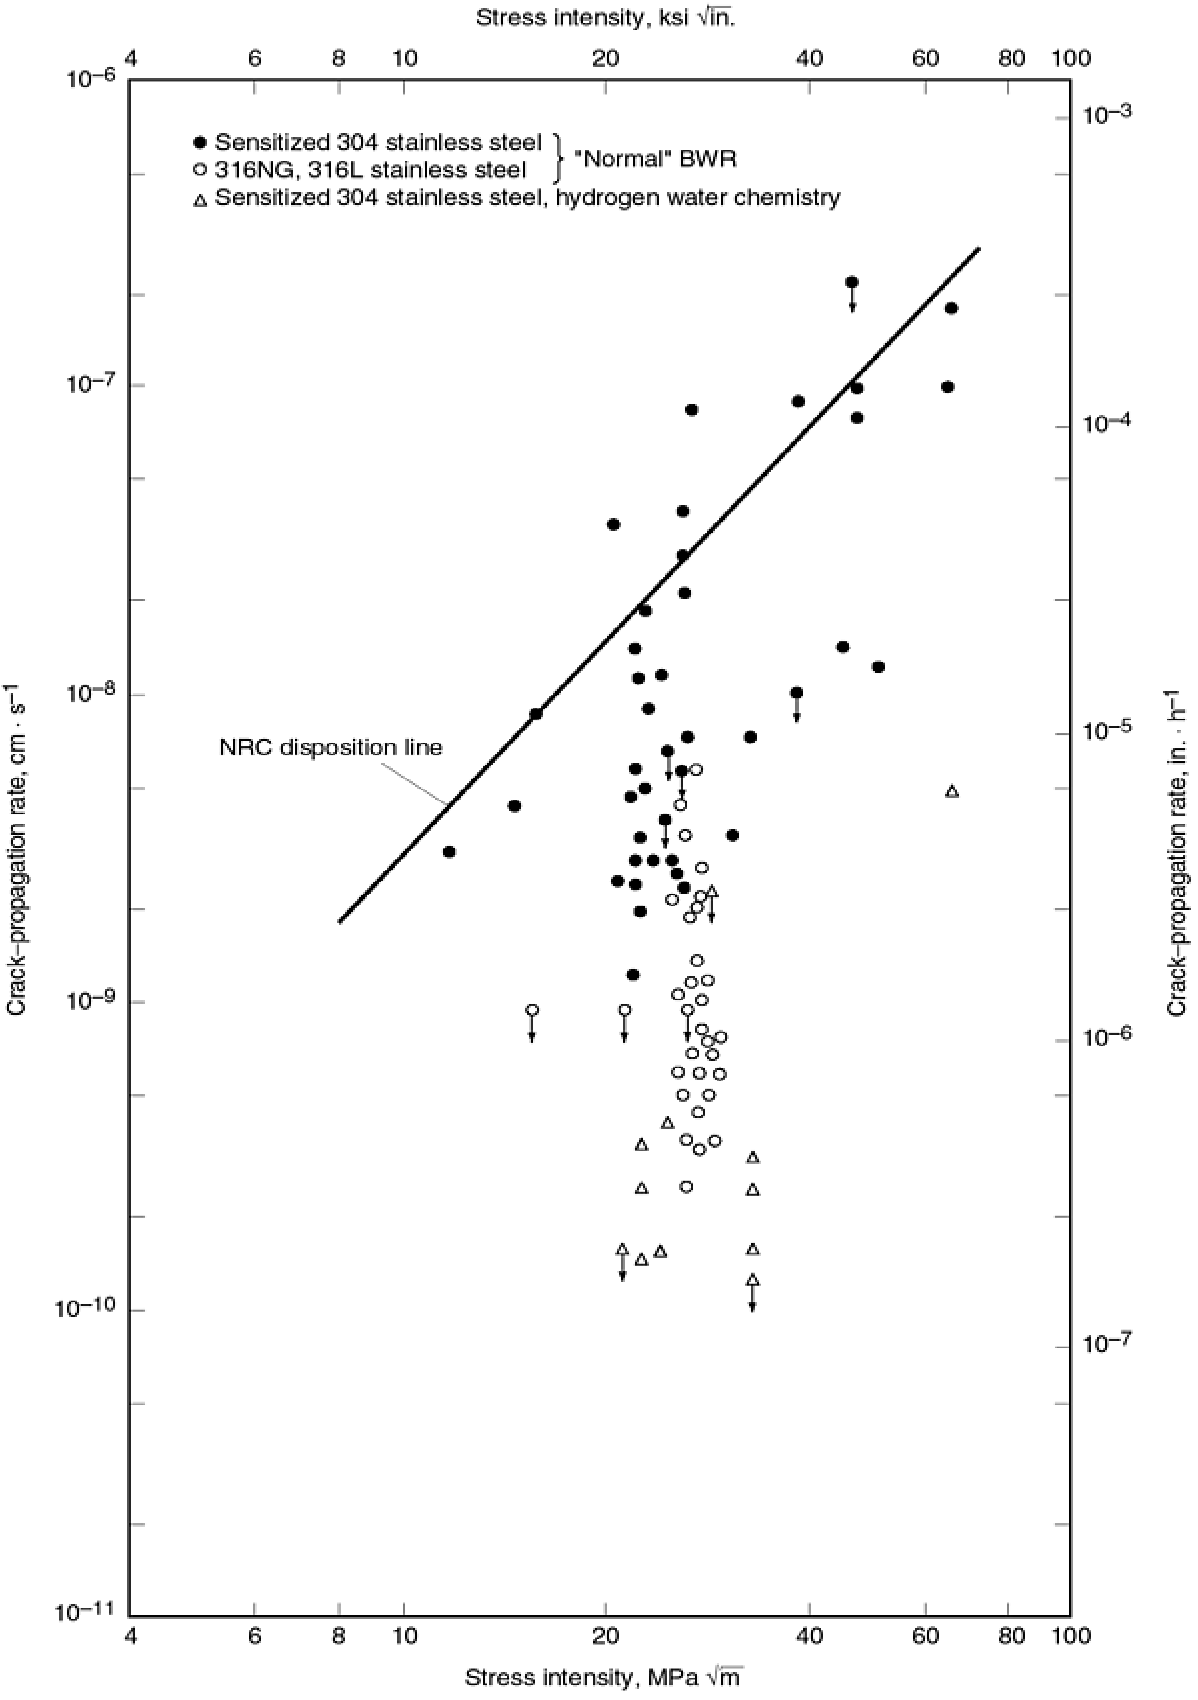

Fig. 39 Crack-propagation rate vs. stress-intensity data for stainless steel in 288 °C water. Also shown is the Nuclear Regulatory Commission disposition line. Source: Ref 95

Consequently, the current life prediction codes for environmentally assisted cracking of structural materials in 274 to 345 °C water, representative of the coolant, used in boiling-water reactors (BWRs) and pressurized-water reactors (PWRs),

usually represent upper bounds of the database available at a given time. Moreover, a single crack-propagation-rate/stress-intensity relationship (e.g., ASME Section XI for life prediction/evaluation) or cyclic-stress/cycles-to-crack-initiation relationship (e.g., ASME Section III for fatigue design) is usually quoted with no account of the different cracking susceptibilities that are associated with the wide range of material/environment conditions in LWR systems. This conservative "upper bound" scenario can put unreasonable constraints on the continued operation of specific plants that have been operating under system conditions far better than those on which the design or life evaluation code was originally based.

Various statistical (extreme-value, pattern-recognition) or neural-network approaches can be applied to the available cracking database to develop an algorithm for component life, or crack depth, as a function of all the reactor operating parameters. This "classical" approach is limited, however, because there are comparatively few datasets for crack propagation, for example, that have been obtained under adequate control of system conditions (e.g., water purity, loading) and using sensitive enough techniques that continuously monitor propagation rates that are relevant to design lives of the order of 40 to 60 years for LWRs.

This situation is offset by the increase in mechanistic understanding of environmentally assisted cracking, which has accelerated in the last 20 years due to the availability of experimental and analytical procedures that allow quantification and validation of various cracking hypotheses. Because the precise shape of the crack depth/operational time relationship must be a function of the specific material, environmental, and stressing conditions, it follows that if there is a range in the actual system operating conditions, then there will be a predictable range in the observed cracking susceptibility, with the distribution of the range in cracking mirroring the distribution of system conditions that affect the propagation process. This predictable range in observed cracking susceptibility provides a bridge between deterministic and statistical/probabilistic life prediction methods (Ref 96, 99).

Historically, environmentally assisted cracking has been divided into the "initiation" and "propagation" periods. To a large extent, this division is arbitrary, because in most investigations, "initiation" is defined as the time at which a crack is detected, or when the load has relaxed a specific amount (in a strain-controlled situation). Such a definition of initiation, however, can correspond to a crack depth of significant metallurgical dimensions (e.g., >2 mm). Thus, for the purpose of lifetime modeling, it is proposed (Fig. 40) that, phenomenologically, initiation is associated with microscopic crack formation at localized corrosion or mechanical-defect sites and is generally related to pitting, intergranular attack, scratches, weld defects, or design notches. It is further proposed that the probability is high of such microscopic initiation sites existing or developing relatively early in the life of the component. Then the problem of life prediction devolves to understanding the growth of small cracks from these geometrically separated initiation sites, and the coalescence of these small cracks to form a major crack, which may then accelerate or arrest, depending on the specific material, environment, and stress conditions.

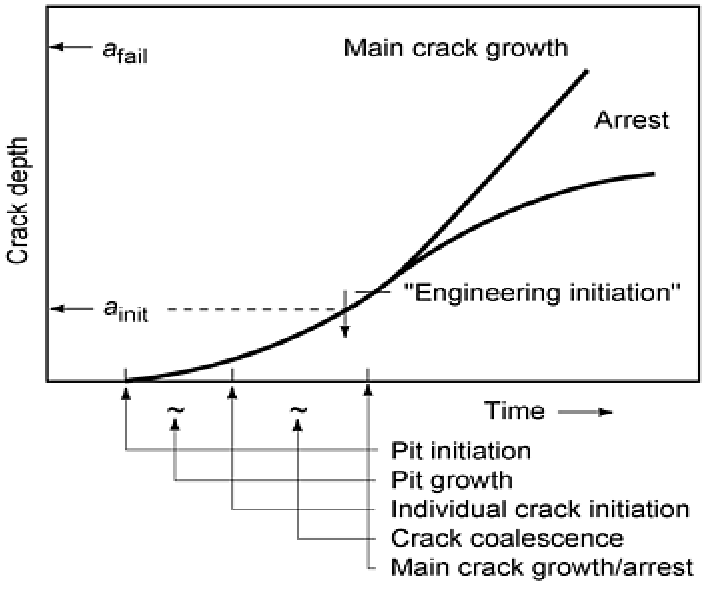

Fig. 40 Proposed sequence of crack initiation, coalescence, and growth for steels undergoing subcritical cracking in aqueous environments

Attention has been focused primarily on the propagation rates for "deep" cracks (e.g., approximately one grain diameter and greater), recognizing that the resultant life prediction can be conservative because the microscopic crack initiation and crack coalescence periods are not being accounted for.

Numerous mechanisms have been advanced for crack propagation in ductile alloy/aqueous environment systems. The usual procedure in developing a quantitative predictive model for crack propagation is to advance a hypothesis for the cracking mechanism and then independently quantify the relevant parameters in that mechanism. The resultant prediction algorithms are then validated by comparison with observed crack-propagation data. Once validated, these algorithms are used for design-life-extension decisions. This process is described very briefly below for stainless steels in 288 °C water (the boiling-water reactor coolant), where the hypothesis is made that the cracking mechanism is slip dissolution (Ref 96, 100, 101).

Quantification of the Slip-Oxidation Mechanism for Stainless Steels in 288 °C High-Purity Water. Various theories have been proposed to relate crack propagation in various ductile alloys, including stainless steels, to oxidation rates and the stress/strain conditions at the crack tip. These theories were supported by an early correlation between the average oxidation current density on a straining surface and the crack-propagation rate for several systems (Ref 101, 102). Experimentally validated elements of these earlier proposals have been combined such that crack propagation in many systems can be correlated with the oxidation that occurs when the protective film at the crack tip is ruptured (Ref 103, 104).

Consider the change in oxidation charge density with time following the rupture of a protective film at the crack tip. Initially, the oxidation rate and, hence, crack-advance rate are rapid and are typically controlled by activation or liquid diffusion kinetics as the bare metal dissolves. In most LWR cracking systems, a protective oxide rapidly reforms at the bared surface and the total oxidation rate (and crack-tip advance) will slow with time. Thus, crack advance can be maintained only if the film rupture process is repetitive. Therefore, for a given crack-tip environment and material condition, the crack-propagation rate will be controlled by the change in oxidation-charge density with time and the frequency of film rupture at the strained crack tip. This latter parameter is determined by the fracture strain of the film, ε_f, and the strain rate at the crack tip, $\dot{\varepsilon}_{ct}$. By invoking Faraday's law, the average environmentally controlled crack-propagation rate, $\overline{V}_t$, can be related to the oxidation-charge density (metal oxidation current integrated over time) passed between film-rupture events, Q_f, and the strain rate at the crack tip, $\dot{\varepsilon}_{ct}$:

$$\overline{V}_t = \frac{M}{z\rho F}\frac{Q_f}{\varepsilon_f}\dot{\varepsilon}_{ct} \quad \textbf{(Eq 23)}$$

where M and ρ are the atomic weight and density of the crack-tip metal, respectively.

Because the oxidation-charge density on a bare surface varies with time at a rate that is dependent on the material and environment compositions, Eq 23 can be reformulated in terms of a power-law relationship:

$$\overline{V}_t = A\,(\dot{\varepsilon}_{ct})^n \quad \textbf{(Eq 24)}$$

where A and n are constants that depend on the material and environment compositions at the crack tip, and are related to the oxidation reaction rates, or current densities, in the specific crack-tip material/environment system (Ref 102).

Under constant load or displacement conditions, the crack-tip strain rate can be related to the creep processes at a moving crack tip, and under monotonically increasing or cyclically changing bulk strain conditions, $\dot{\varepsilon}_{ct}$ can be related to an applied strain rate, $\dot{\varepsilon}_{app}$ (Ref 96, 102). Thus, the slip-oxidation mechanism can be applied not only to stress corrosion but also to strain-induced cracking (Ref 105) and corrosion fatigue. Under cyclic loading conditions, however, the crack is also moving forward by irreversible cyclic plastic deformation (e.g., fatigue-striation formation). Because this mechanical crack advance occurs independently of the crack advance by oxidation processes, these two crack-advance mechanisms (fatigue-striation formation and corrosion oxidation) are considered additive.

Thus, the starting point in the development of a quantitative prediction method for environmentally assisted cracking is Eq 24. However, to develop a *useful* methodology, it is necessary to redefine this fundamental equation in terms of measurable engineering or operational parameters. This redefinition involves: (a) defining the crack-tip alloy/environment composition (e.g., in terms of bulk alloy composition, anionic concentration or solution conductivity, dissolved-oxygen

content or corrosion potential); (b) measuring the reaction rates for the crack-tip alloy/environment system that corresponds to the "engineering" system; and (c) defining the crack-tip strain rate in terms of continuum parameters such as stress, stress intensity, and loading frequency. Extensive work has been conducted in these areas, which has been reviewed elsewhere (Ref 10).

As a result of these examinations of the crack-tip metallurgical, chemical, and stressing conditions, practical crack-propagation-rate algorithms of the following form have been developed for stainless steels in 288 °C BWR water:

$$V_t = 7.8 \times 10^{-3}\, n^{3.6}\, (\dot{\varepsilon}_{ct})^n \quad \textbf{(Eq 25)}$$

$$n = f(\kappa, \text{EPR}, \phi_c) \quad \textbf{(Eq 26)}$$

$$\dot{\varepsilon}_{ct} = 6 \times 10^{-14}\, K^4 \text{ for constant load} \quad \textbf{(Eq 27)}$$

$$\dot{\varepsilon}_{ct} = 5\dot{\varepsilon}_{app} \text{ for monotonically increasing strain} \quad \textbf{(Eq 28)}$$

$$\dot{\varepsilon}_{ct} = 100\dot{\upsilon} A_R\, \Delta K^4 \text{ for cyclic loading} \quad \textbf{(Eq 29)}$$

where κ is the conductivity of coolant (μS · cm^{-1}), ϕ_c is the corrosion potential of the steel (mV$_{SHE}$), EPR is the measurement of grain-boundary chromium depletion due to heat treatment annealing or welding, K is the stress intensity (ksi$\sqrt{\text{in.}}$), $\dot{\varepsilon}_{app}$ is the applied strain rate (s^{-1}), $\dot{\upsilon}$ is the cyclic-loading frequency (s^{-1}), ΔK is the stress-intensity amplitude under cyclic loading, and A_R is a parameter that is a function of the mean stress under cyclic loading.

Validation of Life-Prediction Algorithms and Their Application. The overall comparison between the observed and theoretical crack-propagation rates in type 304/316 stainless steels in 288 °C water is shown in Fig. 41. The laboratory database upon which this comparison was made was obtained under a wide range of stressing (static, monotonically increasing, and cyclic load), material (solution annealed vs. various degrees of sensitization) and water composition (<10 ppb O_2 to >8 ppm O_2, <0.1 to 10 μS · cm^{-1}). It is seen that there is a reasonable agreement between observation and prediction.

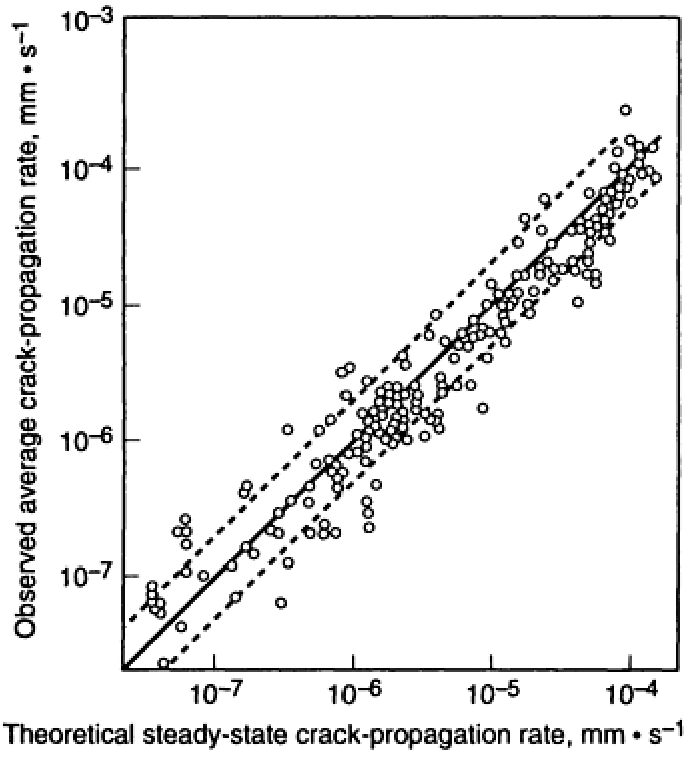

Fig. 41 Comparisons between observed and theoretical crack-propagation rates for type 304/316 stainless steels in 288 °C water. This database represents a wide combination of stressing material and environmental

conditions. Source: Ref 96

Changes in corrosion potential within the range expected in BWRs can have a significant effect on the cracking susceptibility of type 304/316 stainless steels, especially under constant-load conditions. This predicted and observed effect is illustrated in Fig. 42 for furnace-sensitized type 304 stainless steel under constant stress intensity (25 ksi$\sqrt{\text{in.}}$) in water with the conductivity in the range 0.1 to 0.3 μS · cm^{-1}. It is seen that over the corrosion potential range -550 mV$_{SHE}$ to +250 mV$_{SHE}$ (spanning "hydrogen-water" conditions to those under "normal" core conditions) the crack-propagation rate can change three orders of magnitude. From an operational design viewpoint, therefore, it is seen that considerable benefit may be predicted by developing actions that lower the corrosion potential of the stainless steel structures, thereby highlighting remedial actions that lower the effective concentration of oxidants (oxygen, hydrogen peroxide) in the coolant. Solution conductivity is also predicted to have an effect on the cracking susceptibility, as indicated by the three theoretical relationships shown in Fig. 42, thereby highlighting the quantitative value of maintaining water-purity control.

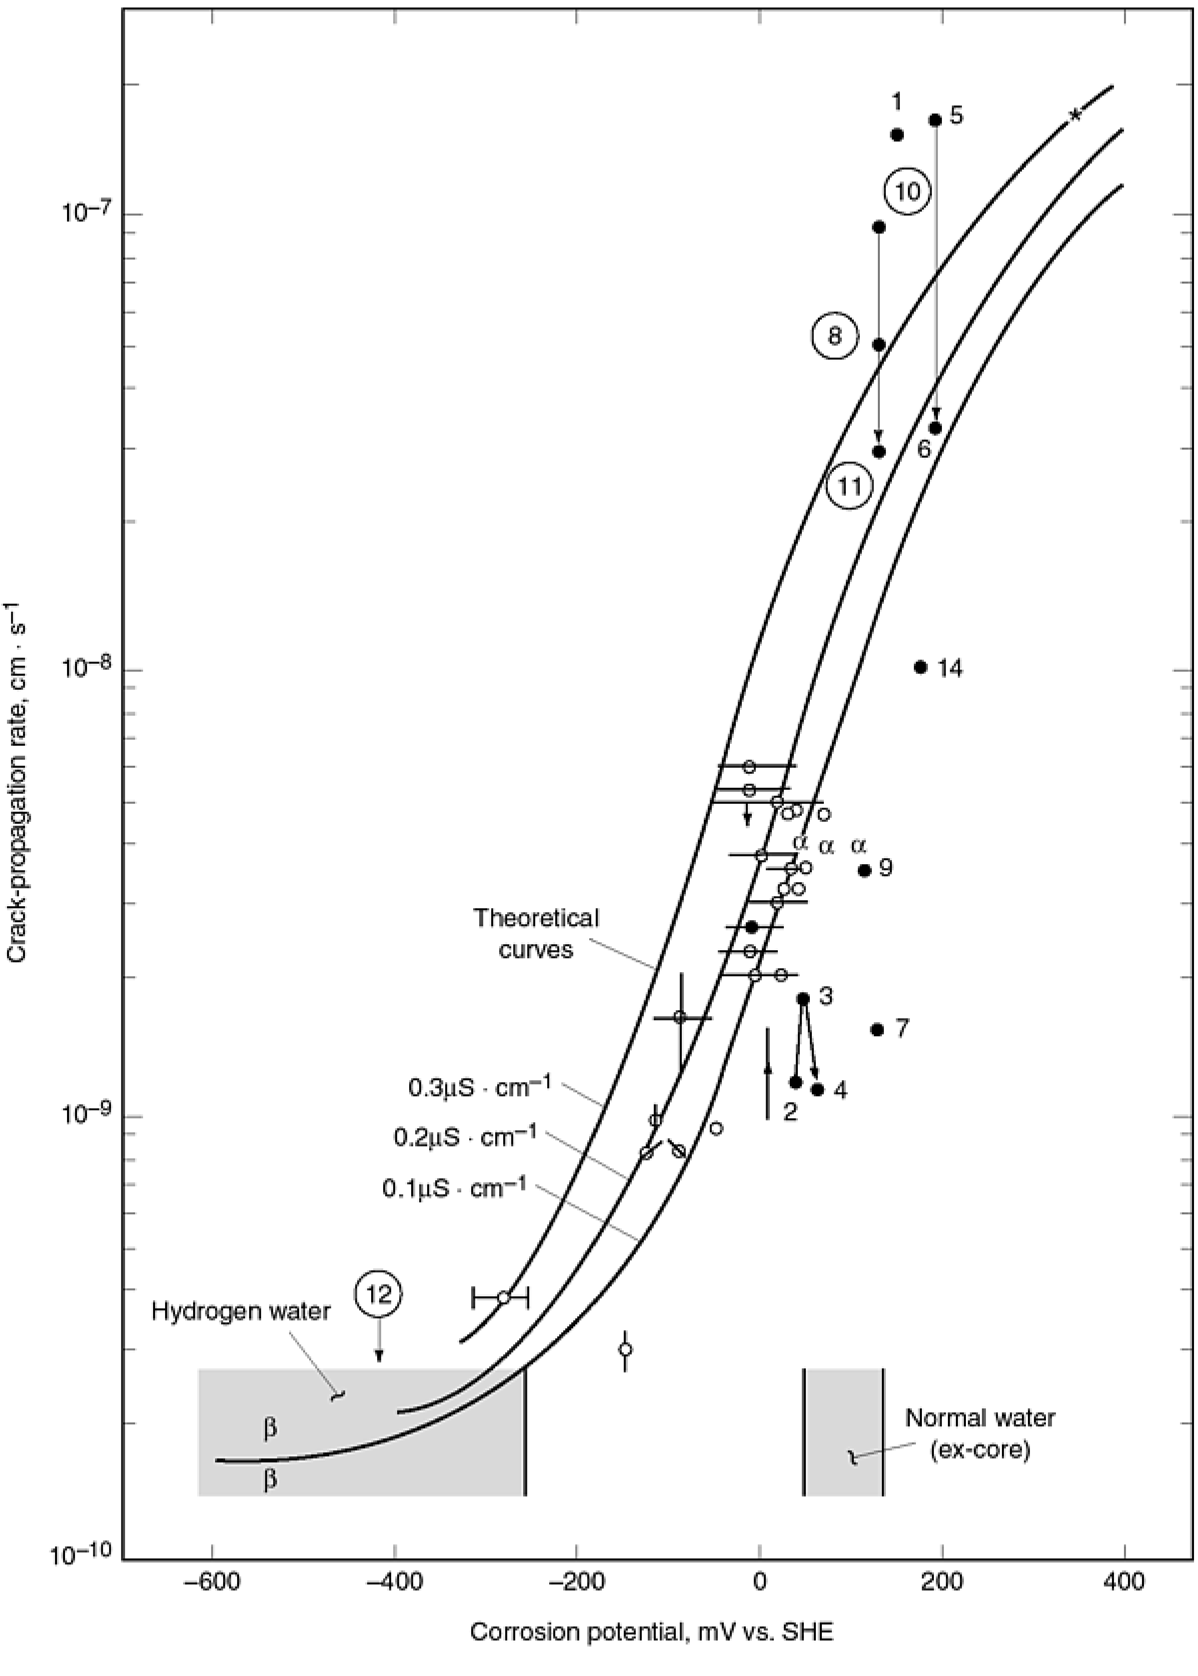

Fig. 42 Observed and predicted sensitivity of stress-corrosion-cracking sensitivity to corrosion potential for sensitized type 304 stainless steel in 288 °C water. The data points are measurements made in the laboratory or in reactors. The curves are the predicted relationships for the indicated conductivities. The numbered data points were obtained at the Harwell variable-energy cyclotron. The circled numbers were with the proton irradiation turned on, and the uncircled numbers were with the irradiation off. Similarly the data point * was obtained under fast neutron irradiation in a boiling-water-reactor core.

So far, the comparisons between observation and theory have centered on material/environment systems variables that affect *n* in Eq 25 and 26. The effect of stressing/straining conditions on the cracking susceptibility occur primarily through their effect on the crack-tip strain rate in Eq 27, 28, and 29. It follows that because the crack tip does not recognize *how* the strain rate is maintained, the cracking susceptibility for a given material/environment condition should adhere to the same crack-propagation rate/crack-tip strain-rate relationship, regardless of the stressing/straining mode. The truth to this statement is illustrated in Fig. 43, which shows the theoretical and observed crack-propagation rate strain-rate relationship for a severely sensitized type 304 stainless steel in 8 ppm O_2, 0.5 $\mu S \cdot cm^{-1}$ water. Movement along the strain-rate axis has been achieved by increasing stress intensity under constant-load conditions, increasing applied strain rate under monotonically increasing strain conditions, or cyclic loading under a variety of stress-intensity amplitude, mean stress, and loading frequency conditions. The single theoretical relationship line in Fig. 43 adequately predicts the cracking under this wide range of loading modes, indicating that the prediction method applies to stress-corrosion cracking (SCC), strain-induced cracking (SIC), and corrosion fatigue (CF).

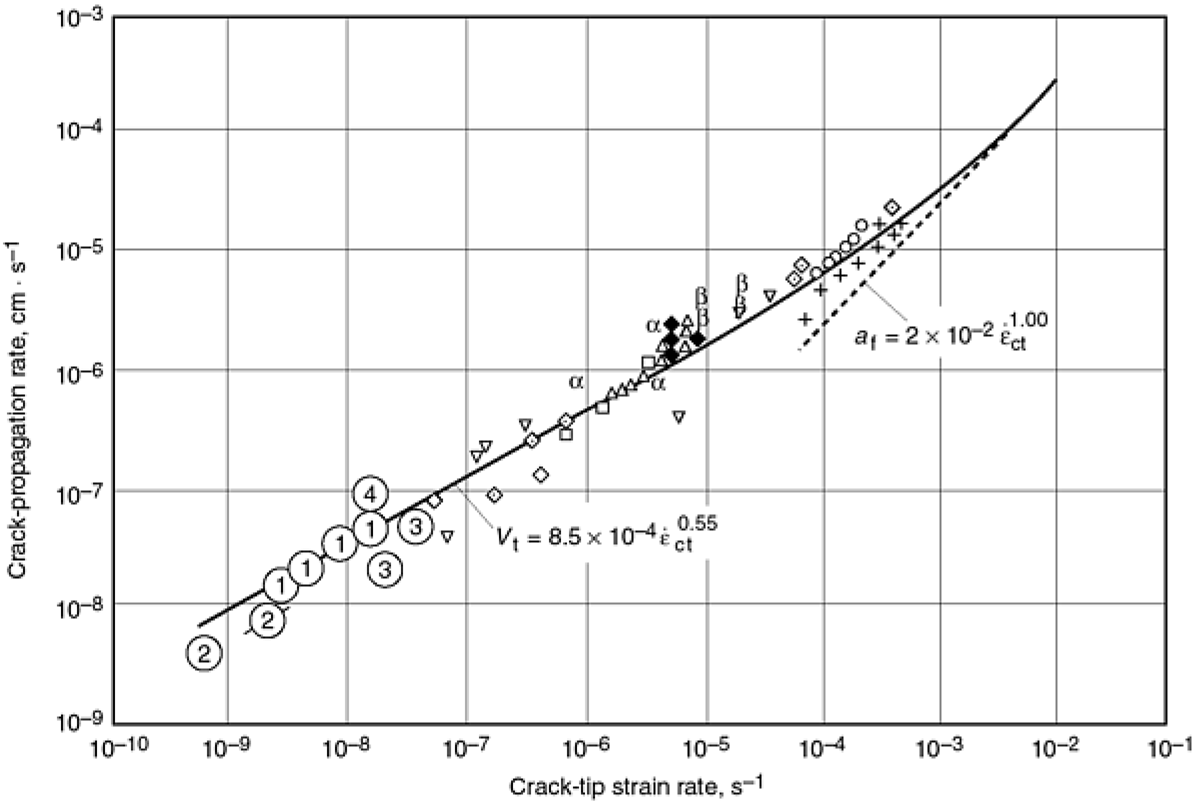

Fig. 43 Predicted and observed crack-propagation rate/crack-tip strain-rate relationships for sensitized type 304 stainless steel in 8 ppm oxygenated, 0.5 $\mu S \cdot cm^{-1}$ purity water at 288 °C

The old lore that these types of cracking (SCC, SIC, CF) are separate phenomena with, by implication, different mitigation or design modification needs is probably incorrect. For instance, it follows from Eq 25 that the sensitivity of the cracking susceptibility to the crack-tip strain rate will be a function of the material/environment conditions that affect *n* (Eq 26). Thus, the slope of the crack-propagation-rate/strain-rate relationship will be relatively shallow for severe environmental and material conditions (e.g., high dissolved oxygen, impure water, and high degrees of grain-boundary sensitization), and the relationship will be steep for less severe material/environmental conditions. This predicted and observed (Fig. 44) change in propagation-rate/strain-rate dependency with system conditions is significant when evaluating the validity of accelerated tests that are often used for development of design codes. For instance, increasing the crack-tip strain rate, and hence cracking susceptibility, by using the "slow-strain-rate test" is a valid test acceleration procedure (because it is accelerating one of the rate-determining steps in the cracking mechanism), but the factor of improvement between a reference condition and a proposed mitigation condition will be less in this test than at the lower stressing or strain-rate conditions expected in the operating plant. The relationship (i.e., Fig. 44) also gives an explanation for the lore that the cracking susceptibility is more dependent on the specific environmental conditions under constant-load stress-corrosion conditions than under corrosion-fatigue conditions.

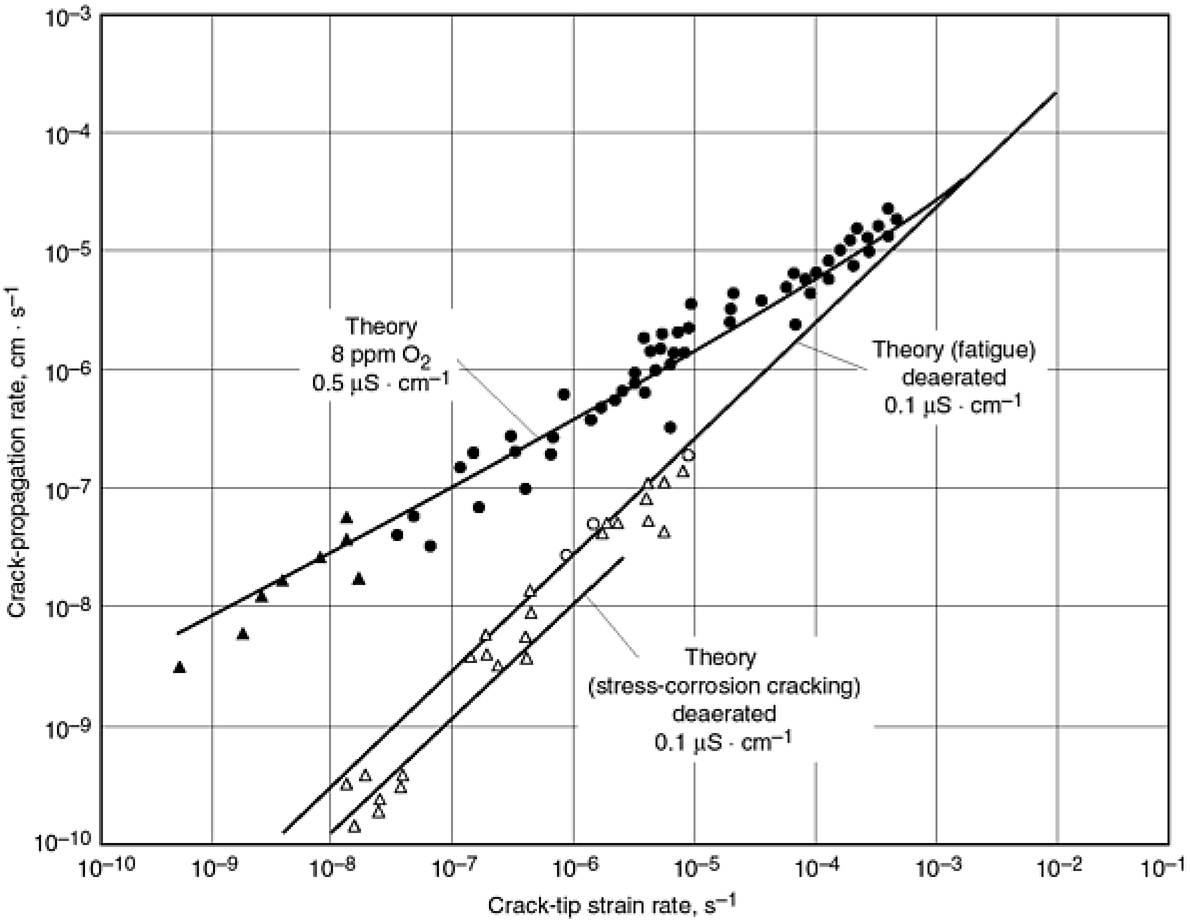

Fig. 44 Predicted and observed crack-propagation rate/crack-tip strain-rate relationships for stainless steels in a variety of material/environment systems

In summary, therefore, it is apparent that the crack-prediction algorithms are able to quantitatively explain the changes in crack-propagation rates for type 304/316 stainless steel in water at 288 °C for a wide combination of water composition (corrosion, potential, conductivity), material sensitization, and stressing (constant load/displacement, cyclic load) conditions. It follows, however, that because the cracking response is so sensitive to changes in combinations of system conditions, it is necessary to combine the predictive method with system-defining sensors and models (Fig. 45). Provided this combining is done, it is then possible to make predictions of the extent of cracking in specific plant components (Fig. 46) and the increase in life associated with specific system changes (Fig. 47).

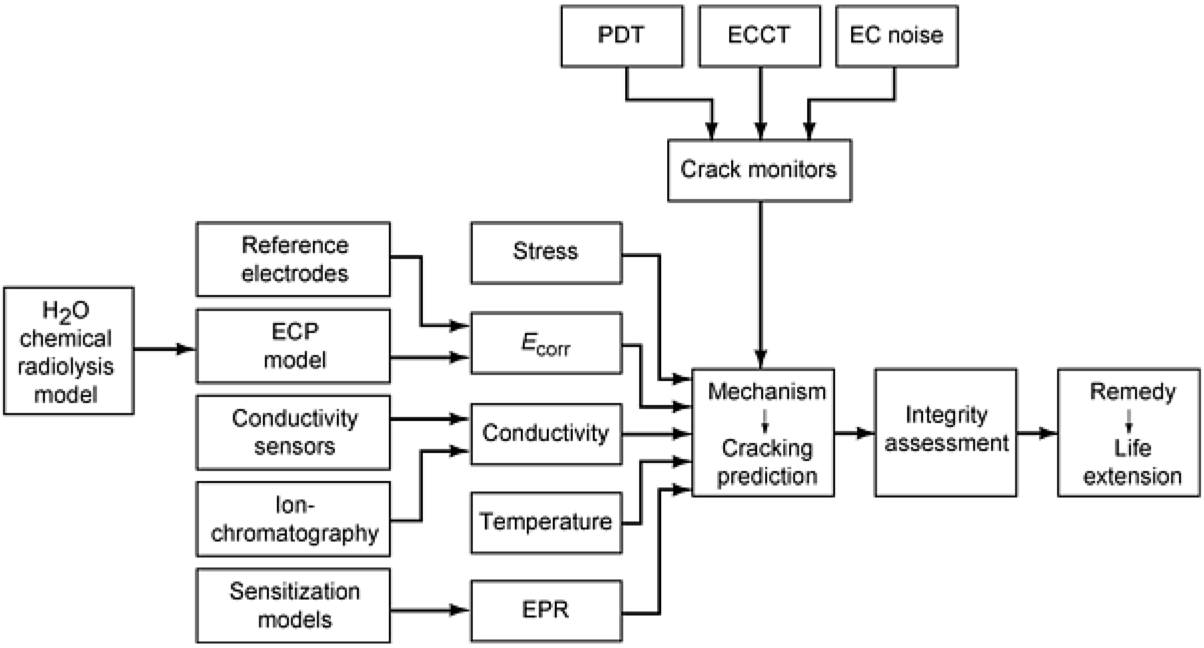

Fig. 45 The integration of system monitors, sensors, and environmental/material models as inputs to a crack-propagation-rate model

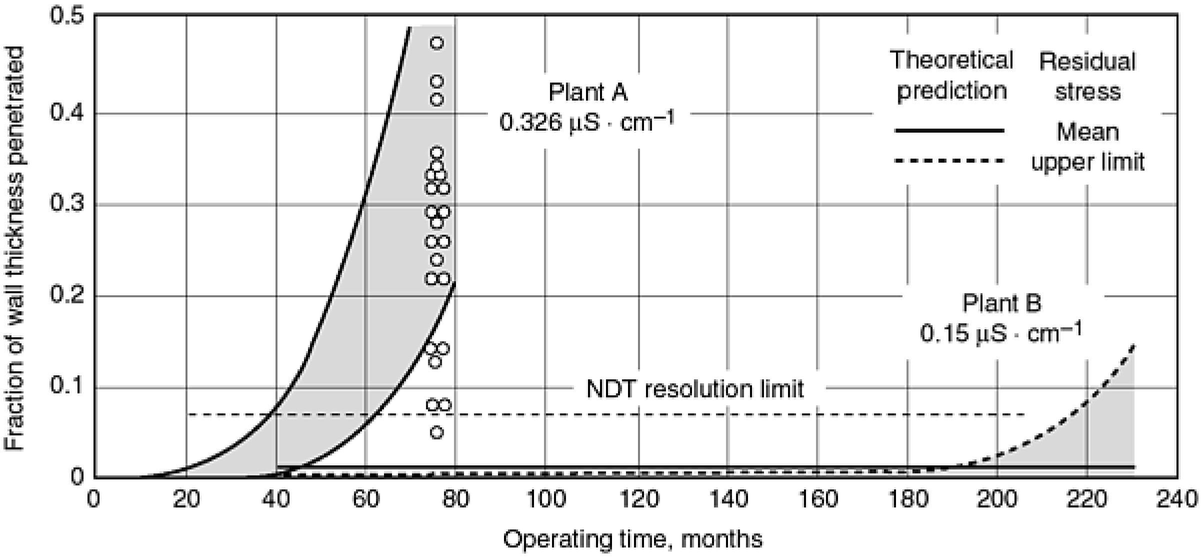

Fig. 46 Theoretical and observed intergranular stress corrosion crackdepth vs. operational-time relationships for 28 in. diameter schedule 80 type 304 stainless steel piping for two boiling-water reactors operating at different mean coolant conductivities. Note the bracketing of the maximum crack depth in the lower-purity plant by the predicted curve, which is based on the maximum residual-stress profile and the predicted absence of observable cracking in the higher-purity plant (in 240 operating months).

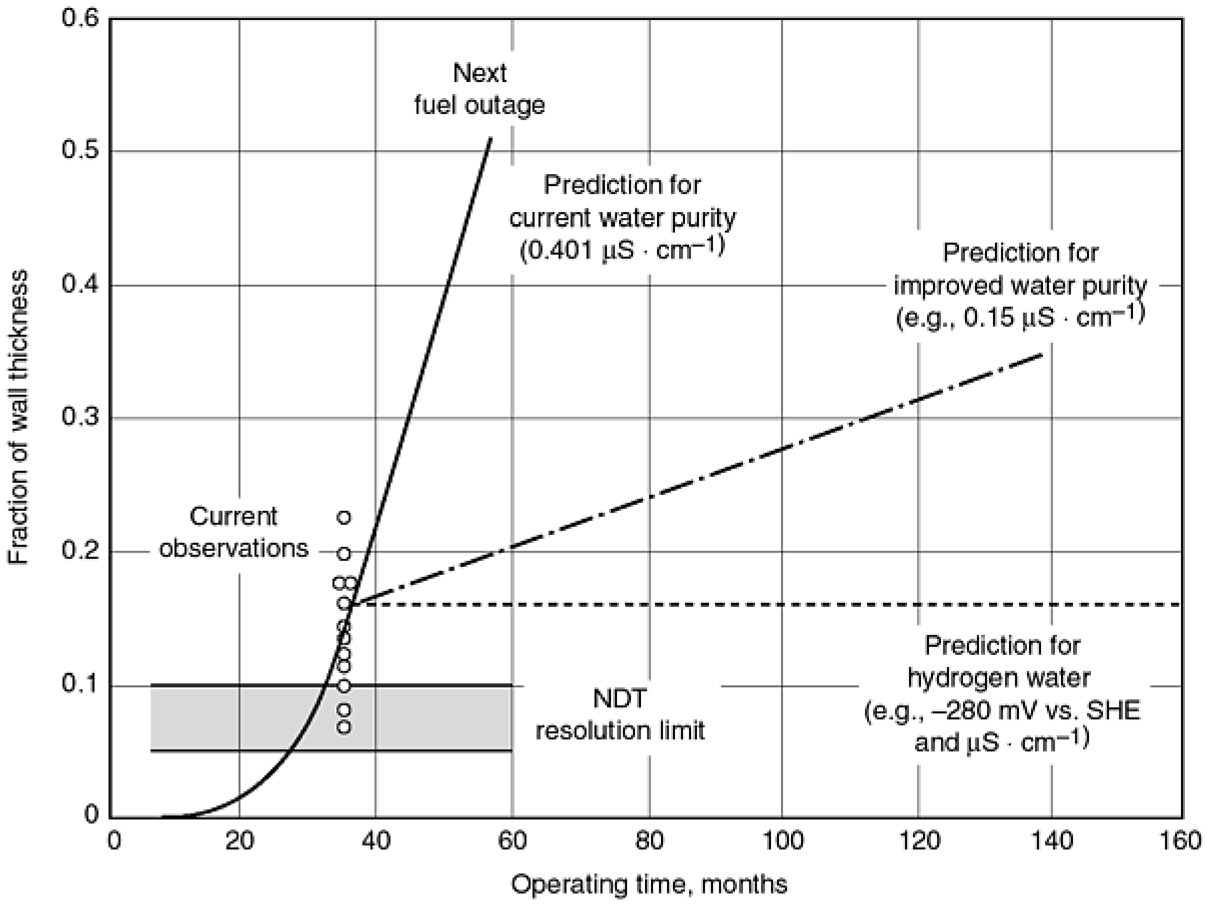

Fig. 47 Predicted crack depth vs. time response for defected 28 in. diameter schedule 80 recirculation piping in a given boiling-water reactor to defined changes in water purity. Also shown is the crack-depth limit that can be resolved by nondestructive testing (NDT).

Design for High-Temperature Applications

David A. Woodford, Materials Performance Analysis, Inc.

Introduction

APART FROM nineteenth-century steam boilers, machines and equipment for high-temperature operation have been developed principally in the present century. Energy conversion systems based on steam turbines, gas turbines, high-performance automobile engines, and jet engines provide the technological foundation for modern society. All of these machines have in common the use of metallic materials at temperatures where time-dependent deformation and fracture processes must be considered in their design. The single valued time-invariant strain associated with elastic or plastic design analysis in low-temperature applications is not applicable, nor is there in most situations a unique value of fracture toughness that may be used as a limiting condition for part failure. In addition to the phenomenological complexities of time-dependent behavior, there is now convincing evidence that the synergism associated with gaseous environmental interactions may have a major effect, in particular on high-temperature fracture.

This article reviews the basic mechanisms of elevated-temperature behavior and associated design considerations with emphasis on metals. Subsequently, the engineering analysis will be confined to presenting data in the form that a designer might use, with emphasis on design principles rather than detailed design analysis. Thus, multiaxial stresses, part analysis, and creep-fatigue interaction are not formally treated. However, remaining life assessment and the effect of nonsteady stresses are covered. A broader treatment of most of these aspects can be found in other articles that appear in the *ASM Specialty Handbook: Heat-Resistant Materials* and in *Mechanical Testing,* Volume 8 of the *ASM Handbook.* Emphasis here is placed on developing an appreciation of the uses (and abuses) of creep and rupture testing, data presentation, data analysis, limitations of long-time tests, and alternative approaches to high-temperature design. The objective is to provide a solid foundation for design principles from a materials performance perspective.

Acknowledgements

Of all the people who have influenced his thinking over the years, the author would like to give special thanks to the late Robert Goldhoff, who directed him into this field of study and research; Louis Coffin, who has provided direct and indirect influence over the years; Edward Hart, a rigorous thinker and writer; Roger Bricknell, an intellectual partner; Michael Henry, a creative materials engineer; the late Chester Sims, a force in superalloys; Joanne Beckman, his first Ph.D. student; Donald Van Steele, an outstanding experimentalist; and David Stiles, a supporter of new ideas.

Historical Development of Creep Deformation Analysis

The phenomenon of time-dependent deformation was referred to as slow stretch by Philips (Ref 1) and as viscous flow by Andrade (Ref 2) at the beginning of this century and subsequently became known as creep. There were several seminal ideas in the Andrade work that have had a lasting impact on scientific studies and engineering dogma. The initial work was primarily on lead wires at room temperature (a high temperature relative to the melting point for lead) with some additional experiments on a 78.5% Sn 21.5% Pb alloy and copper. Andrade noted that after applying a fixed load the rate of extension initially decreased then became constant for a time, but finally increased and continued increasing until failure. He recognized that as the wire stretched, the load per unit area increased. Subsequently, he devised a scheme to compensate for this and maintain a constant stress on the wire. As a result of this, the extent of viscous flow, that is, extension linearly dependent on time, increased as shown in Fig. 1. Andrade also recognized that the length of wire being

experimented on at any time is increasing and thus used the concept of true strain. He derived a formula to describe the observed deformation:

$$1 = l_o(1 + \beta t^{1/3})e^{kt} \qquad \textbf{(Eq 1)}$$

where l and l_o are the current and initial specimen lengths, t is the time, and β and k are constants. The initial transient strain (later to be called primary creep) was referred to as beta creep and followed a time to the one-third law, the viscous region (later to be called steady-state creep) was proportional to time, and the accelerating strain region leading to fracture, which was not specifically treated by Andrade, later became known as tertiary creep. Much later, in a comprehensive study of creep in copper and aluminum, Wyatt (Ref 3) concluded that there are two types of transient creep in metals:

- At higher temperatures, beta creep predominates as in Andrade's experiments.
- At lower temperatures, the strain is proportional to log(time), and the flow is referred to as alpha creep.

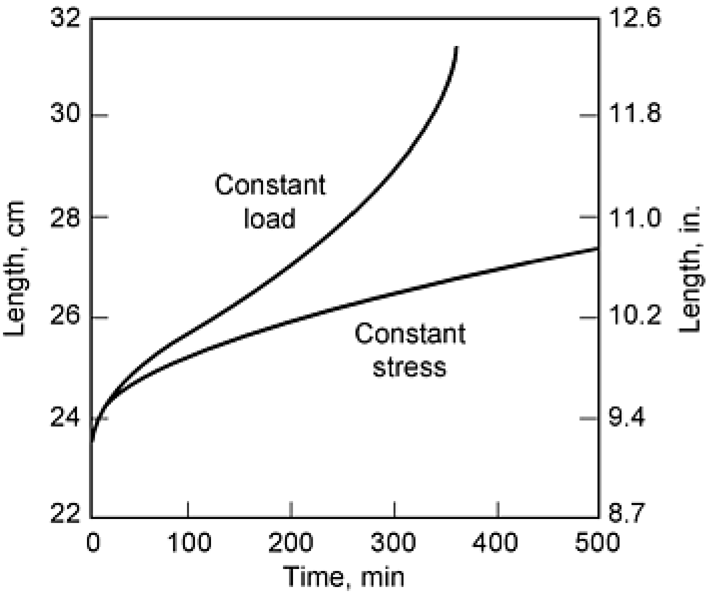

Fig. 1 Creep tests on lead wire. In both tests, initial lengths and initial loads were the same. Source: Ref 2

From this early work, subsequent studies diverged into two investigative paths. The first sought understanding of creep deformation micromechanisms in pure metals and solid-solution alloys in relatively short-term tests, accepted the concept of steady-state creep (although testing was more often conducted at constant load rather than constant stress), and often assumed implicitly that viscous flow was history independent. This means that not only is there a steady creep rate associated with a given applied stress, but that this rate is obtained despite previous deformation at different stresses and temperatures. Although this might be a reasonable approximation for pure metals, it is manifestly wrong for most engineering alloys.

The second investigative path concentrated on generating long-time creep data on engineering materials. The testing was invariably at constant load, and data extracted included times for specific creep strains, minimum creep rates (although the term steady state was often used despite the fact that constant rates cannot be expected when the stress is changing), and time to failure (often referred to as rupture life). This latter measurement was of special significance because it became a basis for design against part failure, and later as a basis for estimating remaining life of operating components.

There thus emerged a framework for design against both creep deformation and fracture using a single testing procedure. It formed a basis for what might be called an uncracked body analysis and comprises the major part of this article. Analysis of cracked bodies involving fracture mechanics concepts as applied to creeping structures is not covered

although some reference is made as appropriate. In particular, the importance of fatigue loading is emphasized in the article "Creep-Fatigue Interaction" in the *ASM Specialty Handbook: Heat-Resistant Materials.*

Until the last quarter century, virtually all creep and creep fracture studies were on metallic materials. However, as early as 1903, Philips (Ref 1) recognized that the phenomenon was not unique to the metallic bond and that materials with covalent and ionic bonds showed similar effects. In fact, creep of polymers is now of considerable importance in plastic automobile components and gas lines, and creep of ceramics is of interest in aerospace applications.

Design for High-Temperature Applications

David A. Woodford, Materials Performance Analysis, Inc.

Basic Concepts of Elevated-Temperature Design

Time-dependent deformation and fracture of structural materials at elevated temperatures are among the most challenging engineering problems faced by materials engineers. In order to develop an improved design methodology for machines and equipment operating at high temperatures, several key concepts and their synergism must be understood. As is described in this section, these include:

- Plastic instability at elevated temperatures
- Deformation mechanisms and strain components associated with creep processes
- Stress and temperature dependence
- Fracture at elevated temperatures
- Environmental effects

Design Phenomenology

The issues of interest from a design basis are the nature of primary creep, the validity of the concept of viscous steady-state creep, and the dependence of deformation on both temperature and stress. The simplest and most pervasive idea in creep of metals is an approach to an equilibrium microstructural and mechanical state. Thus a hardening associated with dislocation generation and interaction is countered by a dynamic microstructural recovery or softening. This process proceeds during primary creep and culminates in a steady-state situation. The idea was first presented by Bailey (Ref 4) and subsequently in the following mathematical form by Orowan (Ref 5):

$$d\sigma = \frac{\partial \sigma}{\partial \varepsilon} d\varepsilon + \frac{\partial \sigma}{\partial t} dt \qquad \textbf{(Eq 2)}$$

where $d\sigma$ represents the change in flow stress, $\partial\sigma/\partial\varepsilon$ represents the hardening that results from an increment of plastic strain $d\varepsilon$, and $\partial\sigma/\partial t$ represents the softening due to recovery in a time increment dt.

At constant stress (and temperature), the steady-state creep rate is given by:

$$\dot{\varepsilon} = -\frac{\partial\sigma/\partial t}{\partial\sigma/\partial\varepsilon} \quad \textbf{(Eq 3)}$$

The numerator is frequently given the symbol *r* as the recovery rate associated with thermal softening, and the denominator is referred to as the strain-hardening coefficient, *h.* Although there is evidence that both hardening and softening processes occur during creep, and despite the fact that numerous studies have attempted to quantify Eq 2, it is in fact incorrect. As pointed out by McCartney (Ref 6), Eq 2 implies that an equation of state exists of the form:

$$\sigma = \sigma(\varepsilon, t) \quad \textbf{(Eq 4)}$$

Equation 2 is the differential form of Eq 4, which assumes that the variables ε and *t* are independent. Since measured strain is in fact a function of elapsed time *t,* it follows that the partial derivatives have no meaning. Lloyd and McElroy (Ref 7) also concluded that the concept required a history-dependent term and the idea had serious deficiencies. They further concluded that the related concept of the applied stress being the sum of an internal stress opposing dislocation motion and an effective stress as the driving force for motion was inconsistent with real behavior. Their alternative theory draws on the observation of anelastic phenomena, which is considered in a subsequent section.

The concept of steady-state creep has been addressed rigorously in very few publications (Ref 8). From these limited studies, however, it can be stated that a constant creep rate cannot occur during the changing stress conditions of the common constant load test (or, if the creep rate appears constant, it cannot be steady state). Further, it can be said that most engineering alloys undergo purely time-dependent changes at temperature associated with an approach to thermodynamic equilibrium, such as precipitate coarsening. With the additional complication of strain-induced changes, it is unlikely that a steady state could be established. It is especially improbable that such a state could be history independent. Any search for a true steady state should, therefore, be limited to pure metals or solid-solution alloys and would require constant stress testing and true-strain plotting.

Plastic Instability

A major issue in the tensile creep test is the role of plastic instability in leading to tertiary creep. Understanding of the nature of plastic instability for time-dependent flow has depended on the theory of Hart (Ref 9). He showed that the condition for stable deformation is:

$$\gamma + m \geq 1 \quad \textbf{(Eq 5)}$$

where *m*, which equals $[(\partial \ln \sigma)/(\partial \ln \dot{\varepsilon})]_{\varepsilon}$, is the strain-rate sensitivity, and γ, which equals $[(\partial \ln \sigma)/(\partial \varepsilon)]_{\dot{\varepsilon}}$, is a measure of the strain-hardening rate. For steady-state flow, γ is equal to 0. For constant stress tests, Burke and Nix (Ref 10) concluded that flow must be unstable when steady state is reached according to Hart's criterion but that macroscopic necking is insignificant and that the flow remains essentially homogeneous. They concluded that a true steady state does exist. Hart himself questioned the conclusions based on their analysis but did not rule out the possibility of a steady state for pure metals (Ref 8). In a very careful experimental analysis, Wray and Richmond (Ref 11) concluded that the concept of a family of steady states is valid. They advocated tests in which two of the basic parameters (stress, strain rate, and temperature) are held constant. However, they reported the intrusion of nonuniform deformation before the steady state was reached. They also pointed out the complexities associated with uncontrolled and often unmeasured loading paths, which produce different structures at the beginning of the constant stress or constant strain rate portions of the test. For constant stress tests in pure metals, although the concept of steady state (viscous flow in Andrade's terminology) is appealing, it appears not yet to have been rigorously demonstrated.

In constant load tests, steady-state behavior would of course result in an increasing creep rate after the minimum, as the true stress increases. As such, the test is inappropriate to evaluate the concept. However, it is by far the most common type of creep test and can be analyzed for instability (Ref 12). The condition for instability may be stated:

$$\ddot{A} \geq 0 \quad \textbf{(Eq 6)}$$

where $\ddot{A}$ is the second derivative of specimen cross-sectional area with respect to time. This in turn leads to a point of instability expressed in terms of gage length:

$$\frac{\ddot{A}}{\dot{A}} = \frac{\ddot{L}}{\dot{L}} - \frac{2\dot{L}}{L} = 0 \qquad \textbf{(Eq 7)}$$

This criterion is shown in Fig. 2 for constant load tests on nickel. The instability criterion is fulfilled at a strain very close to that of the minimum creep rate. However, the value of this criterion remains low up to 20 to 25% strain, at which separate measurements of specimen profiles indicate that macroscopic necking occurs. In this respect, the results are similar to constant stress results (Ref 10) in that although deformation is potentially unstable at the end of the primary stage, it is not grossly so.

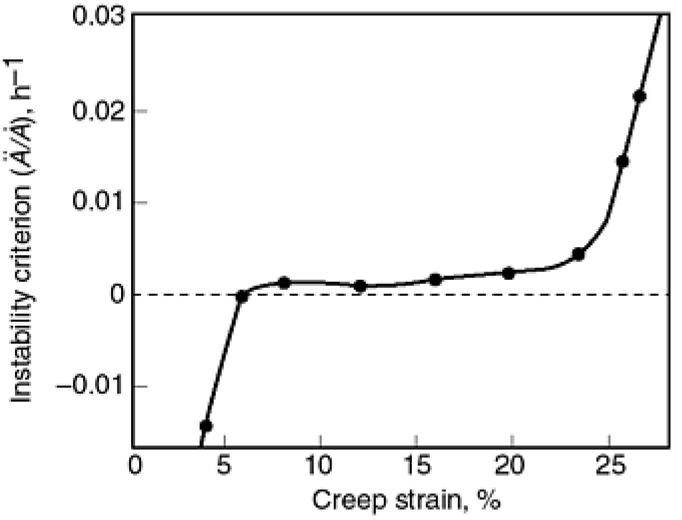

Fig. 2 Change in the parameter $\ddot{A}/\dot{A}$ with creep strain in nickel at 525 °C (980 °F) and 138 MPa (20 ksi). Source: Ref 12

Creep Processes

Creep behavior can be characterized either in terms of deformation mechanisms or in terms of strain constituents.

Deformation Mechanisms. Creep of metals is primarily a result of the motion of dislocations, but is distinct from time-independent behavior in that flow continues as obstacles, which may be dislocation tangles or precipitate particles, are progressively overcome. The rate-controlling step involves diffusion to allow climb of edge dislocations or cross slip of screw dislocations around obstacles. In steady-state theory, there is a balance between the hardening associated with this dislocation motion and interaction, and a dynamic recovery associated with the development of a dislocation substructure. Theory for such a process predicts a power-law dependence of creep rate on applied stress. For example, climb-controlled dislocation creep gives an exponent n = 4 in the following equation (Ref 13):

$$\dot{\varepsilon} = C\sigma^n \qquad \textbf{(Eq 8)}$$

where C is a constant. Nothing in this or similar theories allows for history effects, and although the power function connection may be applicable, the value of n is not only invariably higher, but strongly history dependent in structural alloys (see the following section).

At very high homologous temperatures (T/T_m) and low stresses, creep may occur in both metals and ceramics by mass transport involving stress-directed flow of atoms from regions under compression to regions under tension. In this case,

theory indicates that there is a stress dependence of unity and that the process is controlled either by bulk diffusion (Ref 14, 15) or by grain-boundary diffusion (Ref 16). These various processes of creep (dislocation controlled as well as diffusion controlled) may be represented on a deformation mechanism map to highlight regimes of stress and temperature where each mechanism, based on current theories, may be operating (Ref 17). However, such maps are only as good as the theories on which they are based and give no guidance on deformation path dependence.

Another important deformation process in metallic and ionic polycrystals at high temperature and low stresses is grain-boundary sliding (Ref 18). The resistance to sliding is determined by the mobility of grain-boundary dislocations and by the presence of hard particles at the boundary. This sliding leads to stress concentrations at grain junctions, which are important in nucleating cracks. In ductile materials, these stress concentrations may be relieved by creep and stress relaxation in the matrix or by grain-boundary migration (Ref 19).

Strain Components. There are several different sources of strain at high temperature in response to an applied stress. The elastic strain is directly proportional to stress, and a modulus that is temperature dependent can be determined. For metallic materials and ceramics, although there is a strain-rate dependence of elastic modulus, it is small and often ignored. For polymers, by contrast, the elastic modulus is ill defined because of viscoelasticity.

Plastic strain for all materials may be treated as three separate constituents:

- Time-independent nonrecoverable, which may be thought of as an instantaneous deformation
- Time-dependent nonrecoverable, which may involve any or all of the micromechanisms described above
- Time-dependent recoverable

The first of these is unlikely to be significant in practical applications except in the region of stress concentrations since loading is normally well below the macroscopic yield stress. The second is the major source of creep in normal laboratory testing. The third constituent is not widely studied or analyzed, but may become very important at low stresses and under nonsteady conditions, that is, high-temperature service. It leads to what has been termed creep recovery and anelasticity.

At high temperatures, the application of a stress leads to creep deformation resulting from the motion of dislocations, mass transport by diffusion, or grain-boundary sliding. These processes in turn lead to a distribution of internal stresses that may relax on removal of the stress. This relaxation leads to a time-dependent contraction in addition to the elastic contraction and results in the phenomenon of creep recovery illustrated in Fig. 3. In polymers this phenomenon, which may account for nearly all the nonelastic strain, is termed viscoelastic recovery and is associated with the viscous sliding and unkinking of long molecular chains (Ref 21). In metals it is associated with the unbowing of pinned dislocations (Ref 7), rearrangement of dislocation networks (Ref 22), and local grain-boundary motion (Ref 23). In ceramics it appears to be primarily a grain-boundary phenomenon (Ref 24).

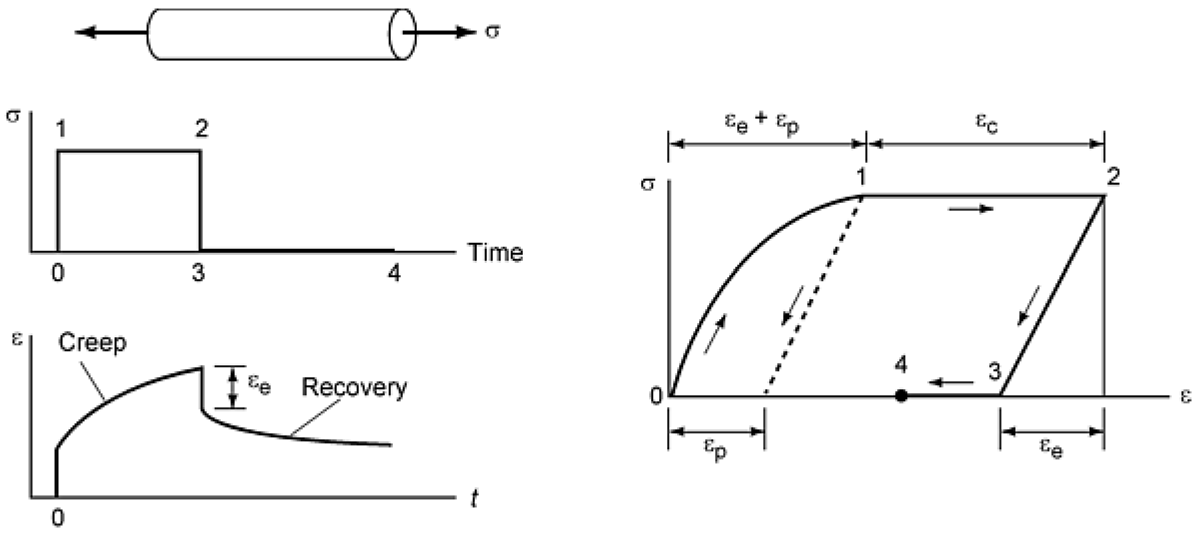

Fig. 3 Stress-time step applied to a material exhibiting strain response that includes time-independent elastic, time-independent plastic, time-dependent creep, and time-dependent anelastic (creep-recovery) components. Source: Ref 20

Whereas the importance of creep recovery is well recognized in polymer design, it has often been ignored in design of metallic and ceramic materials. A few extensive studies have been reported on metals (Ref 25, 26, 27) that have led to several broad conclusions:

- Creep-recovery strain increases linearly with stress for a fixed time at a given temperature, but is dependent on prestrain.
- The rate of creep recovery increases with increasing temperature.
- When the stress is low enough, essentially all transient creep is linear with stress and recoverable.
- Mathematically, the recovery may be described by a spectrum of spring dashpot combinations with a wide range of relaxation times.

Assuming that the measured recovery strain after unloading had made an equivalent contribution to forward creep (Ref 28), it was possible in these studies to separate the anelastic and plastic creep components as shown in Fig. 4. Because the anelastic component is linear with stress and the plastic component is a power function of stress (for the same time), at very low stresses the strain is entirely anelastic. This observation led to the definition of a plastic creep limit that was time dependent. For times up to 100 h in a low-alloy steel tested at 425 °C (800 °F), Lubahn (Ref 26) found this limit to be 140 MPa (20 ksi) (Ref 5); all creep below this stress was fully recoverable. In tests on a similar alloy at 538 °C (1000 °F), Goldhoff (Ref 27) found that the creep limit ranged from 150 MPa (22 ksi) for 1 h to zero at 5000 h. By plotting the ratio of anelastic to plastic strain for a fixed time (1000 h) as a function of stress (Fig. 5), Goldhoff (Ref 27) showed how the former became dominant at low stresses. Figure 5 also shows that a heat treatment that produces low ductility leads to higher ratios, suggesting a link between anelastic deformation and intergranular fracture, which was consistent with microstructural observations of fracture in this alloy.

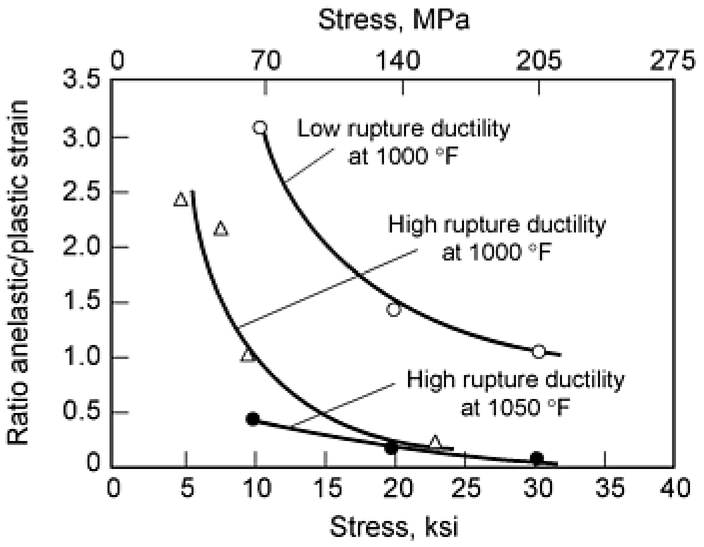

Fig. 5 Effect of ductility on recoverable creep strain for Cr-Mo-V steel after 1000 h creep exposure. Source: Ref 27

There have been even fewer systematic studies of creep recovery in ceramics, but silicon carbide fibers have been shown to recover fully their creep strain between 1000 and 1400 °C (1830 and 2550 °F) (Ref 24). Additionally, provided an appropriate period was allowed for recovery after each stress cycle, tension-tension fatigue resulted in zero cumulative creep strain. This indicates the potential importance of anelastic phenomena in damage accumulation for nonsteady conditions. Very recent work on large specimens of silicon nitride have shown recovery of most of the accumulated strain after unloading from stress-relaxation tests (Fig. 6).

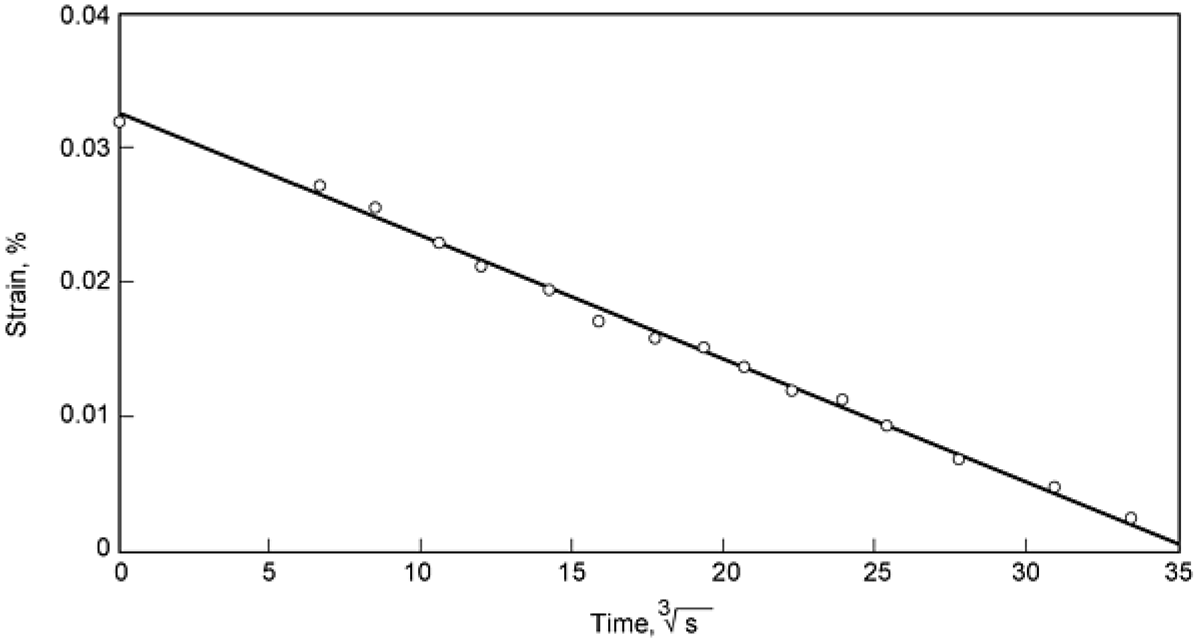

Fig. 6 Recovery of creep strain in silicon nitride at 1200 °C (2190 °F) after unloading from a stress-relaxation test started at 300 MPa (43.5 ksi), showing a time to the one-third dependence

There are strong indications that anelastic phenomena should be included in design considerations. Anelastic contraction as well as extension can occur depending on whether the stress is decreased or increased, whereas plastic shortening never occurs. Although several authors have pointed out that, because of the linear stress dependence the analysis should be

much simpler than for plastic creep analysis (Ref 7, 27), accurate measurements at the low stresses of interest for service applications are difficult. The possible link with fracture processes is also of great interest, but neither consideration has influenced design practice.

Stress and Temperature Dependence

The minimum creep rate in both constant load and constant stress tests is normally represented by a power function of stress (Eq 8), and the temperature by an Arrhenius expression including an activation energy term (*Q*) derived from chemical reaction rate theory (Ref 29):

$$\dot{\varepsilon} = S\sigma^{n} e^{-Q/RT} \qquad \textbf{(Eq 9)}$$

where *S*, which is a constant, depends on structure. Although an exponential or hyperbolic sine stress function may provide a better fit in some cases, the power function has generally prevailed and has become strongly linked with mechanistic treatments. In pure metals, early studies indicated a stress exponent on the order of four and an activation energy close to that for self-diffusion (Ref 13, 29, 30). For engineering alloys, the stress exponents are generally higher and may not be constant (Ref 31), and the value of the activation energy may be much higher than that for the alloy matrix self-diffusion and may be sensitive to test temperature.

Because the basic formulation of Eq 9 is used to correlate much engineering data and is used in creep analysis of components, it is useful to examine critically some of the limitations in this analysis as they apply to engineering alloys. It was first shown by Lubahn (Ref 32) that, because of the rapidly decreasing creep rate in the primary stage, a strain-time plot of a portion of this stage always appears to show approximately constant rates at the longest times. This has led to many errors in the literature with false minimum creep rates. Some of these errors may lead to apparent *n* values close to one and consequent speculations about Newtonian viscous creep (Ref 33). Figure 7 shows results for minimum creep rates in a Cr-Mo-V steel in tests lasting up to 50,000 h. Also included are plots where time restrictions on the measurements were imposed to illustrate this potential for error. Nevertheless, the true minimum data points indicate *n* values ranging from 3.3 to 12.

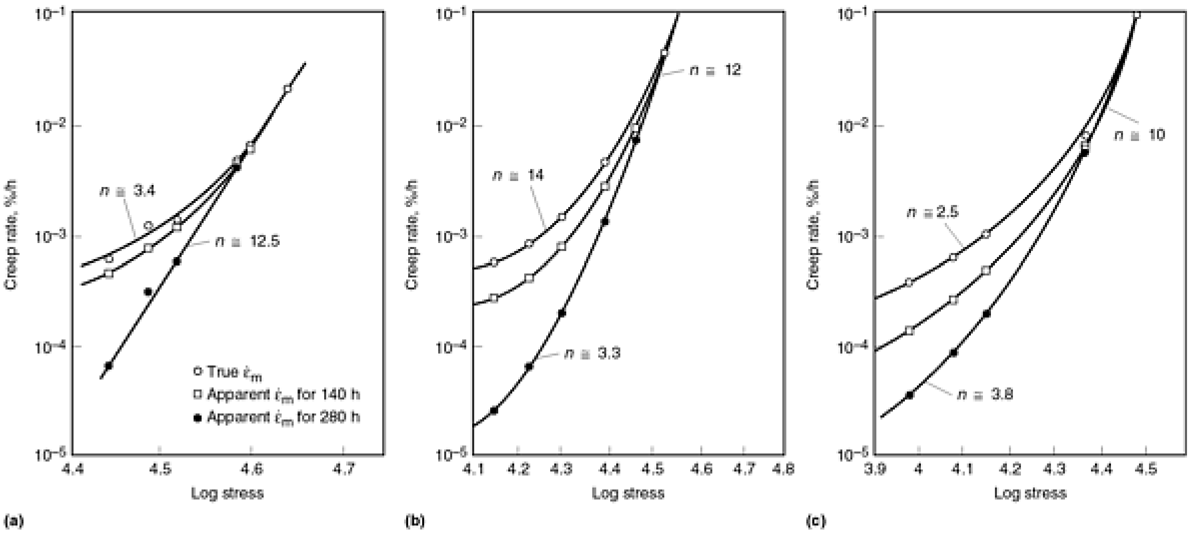

Fig. 7 Effect of test time restrictions on the apparent stress sensitivity of creep rate for a chromium-molybdenum steel at temperatures of (a) 510 °C (950 °F), (b) 565 °C (1050 °F), and (c) 593 °C (1100 °F). Source: Ref 33

As pointed out by Woodford (Ref 33), the curvature indicates that Eq 9 with *S* as a constant does not apply over the stress range, and it is meaningless to consider both *n* and *S* changing. In fact, the slope at any point has no clear physical significance because the structural state at the minimum creep rate is different for each test because of the different deformation history. To approximate a constant structure determination, creep rates have been measured under decreasing stress either by discrete stress drops (Ref 34) or during stress relaxation (Ref 35). The stress exponents measured from

these data are much higher than those obtained from the minimum creep-rate data, but have clear physical significance because they relate to an approximately constant structure. An alternative approach for measuring stress dependence at close to constant structure is to monitor the creep rate and corresponding stress increase in constant load tests at strains beyond those corresponding to the minimum creep rates (Ref 33, 36). In this method $n = d \log \dot{\varepsilon}/d \log \sigma_o (1 + \varepsilon)$ where σ_o is the initial stress and ε the nominal strain. Results for the steel data are shown in Fig. 8 giving *n* values for individual tests between 30 and 100, which are much higher than values estimated from the slopes of the lines drawn through the minimum creep rates. It has been shown that, as in the stress-decrement measurements, the values of *n* may be related to a particular structural state. The reciprocal of these values gives a measure of strain-rate sensitivity and correlates well with elongation at fracture (Ref 33, 36, 37).

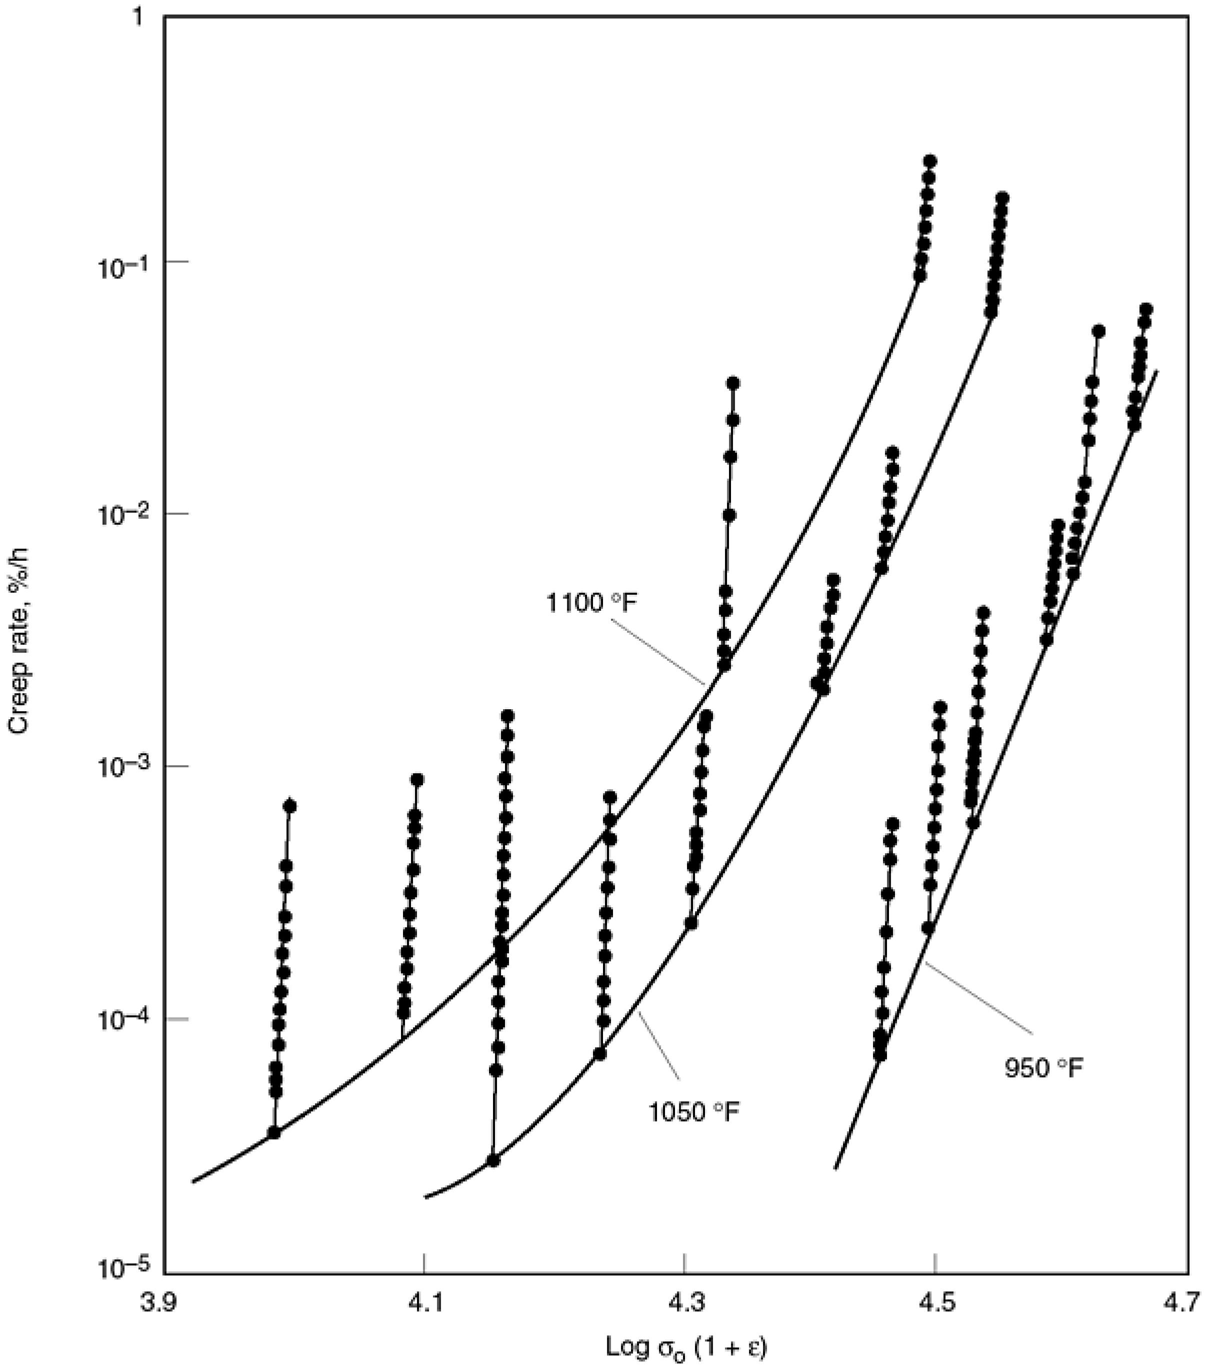

Fig. 8 Creep rate for a chromium-molybdenum steel as a function of the true stress showing that the stress sensitivity measured in a single test is different from that measured in separate tests. Source: Ref 33

Although the representation of creep data in the engineering literature has been strongly influenced by the simple correlations reported for short-time tests for pure metals, it is clear that any physical significance is lost for most structural materials. The stress dependence of creep determined from the slope of a line drawn through minimum creep-rate data is expected to be quite different from that determined for a stress change on an individual specimen. The importance of deformation history is again apparent. Likewise, an exponential temperature dependence of minimum creep rates should be viewed as an empirical correlation. Temperature change experiments on a single specimen usually do not give the same activation energy, and because the structural state changes with temperature, a temperature change sequence effect on the apparent activation energy is also to be expected.

Fracture at Elevated Temperatures

As indicated previously, the constant load creep rupture test is the basis for design data for both creep strength (minimum creep rate or time to a specific creep strain) and failure (time to rupture). The various ways in which such data are presented, correlated, and extrapolated are addressed in subsequent sections. However, it is useful to note here that the well-known Monkman-Grant relationship (Ref 38) shown in Fig. 9 indicates that the time to rupture is reciprocally related to the minimum creep rate. This relationship is commonly observed in ductile materials and has been used to predict one property from the other. However, the true significance of the correlation is that the rupture life is principally a measure of creep strength rather than fracture resistance. This leads to a number of inconsistencies in design procedures that are discussed later in this article.

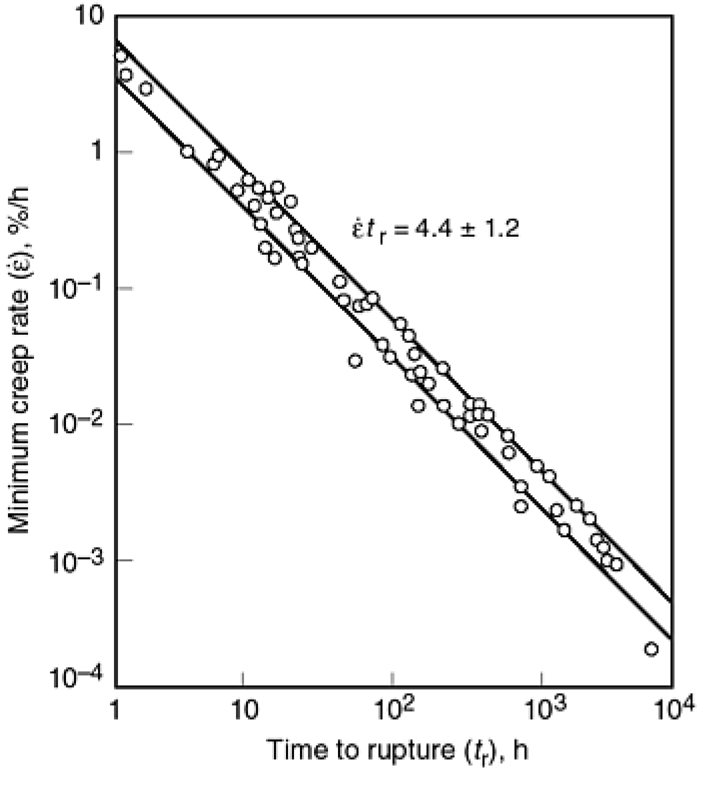

Fig. 9 Monkman-Grant relationship between minimum creep rate and time to rupture for a $2\frac{1}{4}$Cr-1Mo steel. Source: Ref 39

At this point, it is appropriate to consider the processes leading to fracture. Plastic instability in ductile materials has already been reviewed. This process may lead directly to fracture in pure metals and contribute significantly to fracture in engineering materials at moderately high stresses. However, of much greater concern are the processes leading to intergranular fracture with reduced ductility at low stresses and high temperatures. Here again, many of the basic studies have been conducted on pure metals and solid-solution alloys.

Crack Nucleation and Morphology. Two types of cracking have been identified: wedge-shaped cracks emanating from grain-boundary triple points and the formation of cavities or voids on grain-boundary facets often oriented

perpendicular to the applied tensile stress (Ref 40). An example of creep cracks in nickel that appears to show both forms is given in Fig. 10. A fractographic study of creep cavities in tungsten concluded that the different crack morphologies actually reflected differences in growth rate. At low growth rates, surface diffusion allowed the cavities to reduce their surface tension by assuming nearly equiaxed polyhedral shapes. At higher growth rates, irregular two-dimensional cracks developed that on sectioning appeared as wedge cracks (Ref 42).

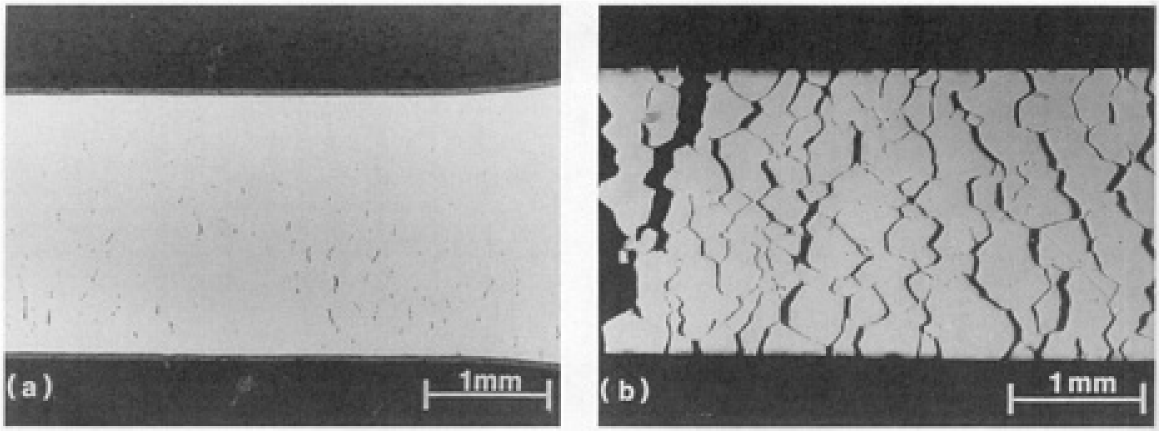

Fig. 10 Unetched microstructure of nickel samples after air testing at 15.8 MPa (2.3 ksi) and 800 °C (1470 °F). (a) Low-carbon Ni270 unloaded after 500 h slight cavitation. (b) Standard Ni270 after failure in 23 h. Source: Ref 41

Although much work continues to model the nucleation and growth of these cracks and cavities (Ref 43), there are uncertainties in the mechanism of nucleation and in the identification of a failure criterion. For example, McLean has shown that a stress concentration up to 1000 is needed to nucleate a hole unless it is stabilized by internal pressure (Ref 44). As a consequence, the nucleation stage has been treated with less enthusiasm than has the modeling of growth. This issue may well be resolved on the basis of environmental interaction (see the section "Environmental Effects" in this article). Another major problem is the effect of temperature and stress on the extent of cracking at failure. Most theories assume that failure occurs at some critical cavity distribution or crack size. However, it has been shown that the extent of cavitation at failure or at any given fraction of the failure life is very sensitive to the test conditions (Ref 45, 46). Thus cavitation damage at failure at a high stress may be comparable to damage in the very early stage of a test at low stress. For stress-change experiments, there is therefore a loading sequence effect on rupture life, which is discussed later in this article, for engineering alloys.

Embrittlement Phenomena. As pointed out previously, rupture life is primarily a measure of creep strength; fracture resistance would be identified better with a separate measure that reflects the concern with embrittlement phenomena that may lead to component failure. Most engineering alloys lose ductility during high-temperature service. This has been shown to be a function of temperature and strain rate (Ref 47) so that there is a critical regime for maximum embrittlement. At a fixed strain rate, for example, ductility first decreases with increasing temperature. This is believed to be caused by grain boundaries playing an increasing role in the deformation process leading to the nucleation of intergranular cracks. At still higher temperatures, processes of recovery and relaxation at local stress concentrations lead to an improvement in ductility. Figure 11 is an example of a ductility contour map for a low-alloy steel based on measurements of reduction of area (RA) of long-term rupture tests (Ref 48). Maximum embrittlement occurred in a critical range of temperature and stress (or strain rate). This type of embrittlement generally coincides with a sensitivity to notches, which emphasizes its practical significance. For example, Fig. 12 shows that the ratio of notch strength to smooth strength for various test times passes through minima corresponding to ductility minima (Ref 49) based on reduction in area at failure in the notch. This tendency to develop so-called notch weakening at temperature is of great concern in selecting alloys and monitoring their service performance.

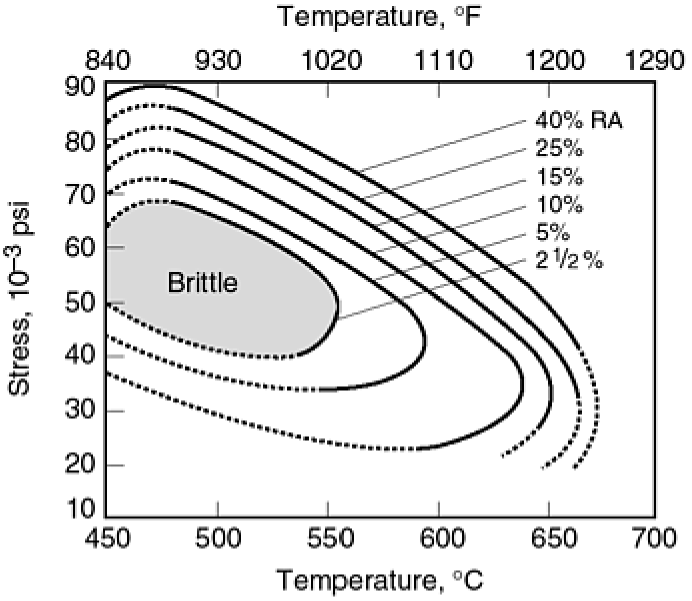

Fig. 11 Ductility contour map in stress/temperature space for a Cr-Mo-V steel. RA, reduction in area. Source: Ref 48

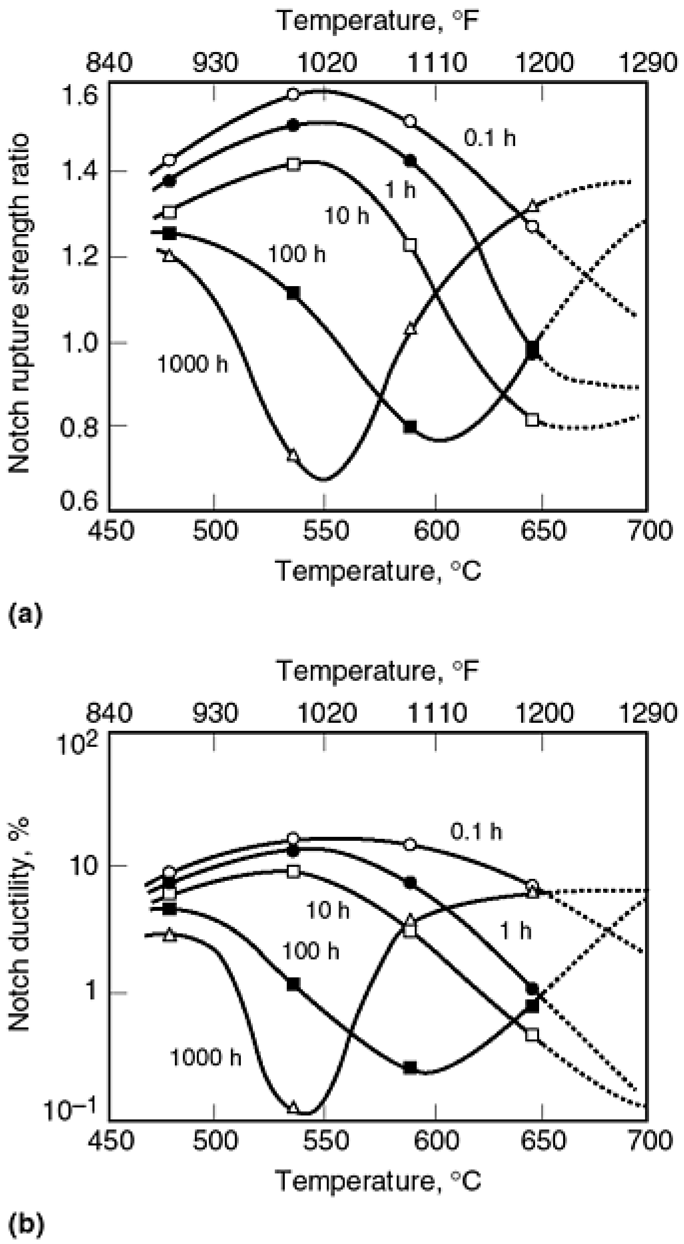

Fig. 12 Ratio of notched bar strength to smooth bar strength (a) and notch ductility (b) as a function of test temperature for various rupture times in a Cr-Mo-V steel. Source: Ref 49

The embrittlement phenomena may be associated with precipitation in the alloy that interferes with the ability to accommodate stress concentrations at grain boundaries (Ref 48), with segregation of embrittling species from the grain interior to the grain boundaries (Ref 50, 51), or with intergranular penetration of embrittling species from the environment (Ref 41).

Environmental Effects

It has long been known that test environment may affect creep-rupture behavior. Until quite recently, however, the work has been largely empirical with creep tests being conducted in various atmospheres and differences noted in creep rates and rupture lives (Ref 52). The effect on rupture life, in particular, was often less than a factor of ten in environments such as oxygen, hydrogen, nitrogen, carbon dioxide, and impure helium compared with vacuum. In many cases, it was not clear how inert the vacuum was, and little account was taken of specimen thickness. Often, effects on ductility were not reported, and there were very few studies of crack propagation.

A renewed interest developed in the 1970s as a result of observations of a dominant role played by the environment in high-temperature fatigue crack growth of superalloys (Ref 53). There were subsequent studies of sustained-load crack propagation that also showed very strong effects (Ref 54, 55, 56). In some cases at high stresses, the test environment was so severe, as in the case of sulfur, that profound changes were seen in smooth bar rupture life. Such an example is shown in Fig. 13, in which the time to rupture in common superalloys was reduced by several orders of magnitude in tests in a sulfate/chloride mixture at 705 °C (1300 °F) (Ref 57). These results were explained in terms of grain-boundary penetration of sulfur, which leads to rapid crack propagation. The coated specimen was far less susceptible, and the addition of a grain-boundary modifier (in this case, boron) in Udimet 720 gave an enormous improvement relative to Udimet 710.

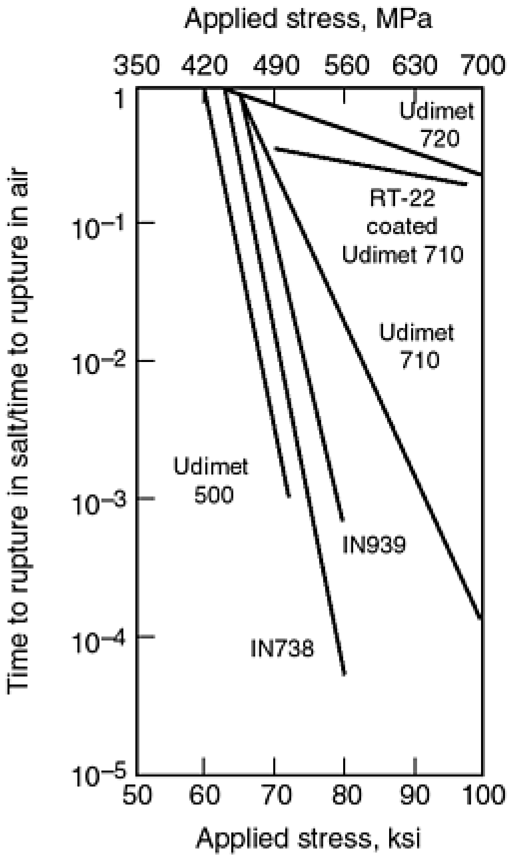

Fig. 13 Relative reductions in rupture life due to sulfate/chloride salt at 705 °C (1300 °F) for several superalloys. For RT-22 coated Udimet 710, rupture time in salt for coated alloy divided by time in air for uncoated alloy. Source: Ref 57

Embrittling Effects of Oxygen. At about the same time that the ideas on environmental attack at an intergranular crack tip were being developed, it was also shown that short-term prior exposure in air at high temperature (greater than about 900 °C, or 1650 °F) could lead to profound embrittlement at intermediate temperatures (700 to 800 °C, or 1290 to 1470 °F) (Ref 41, 58, 59, 60, 61). This was shown to be caused by intergranular diffusion of oxygen that penetrated on the order of millimeters in a few hours at 1000 °C (1830 °F). The embrittlement was monitored using measurements of tensile ductility at intermediate temperatures in iron-, nickel-, and cobalt-base alloys (Ref 41). An example of the results for the Fe-Ni-Co alloy, IN903A, is shown in Fig. 14, which also confirms the extent of damage penetration from tests in which the specimen diameter of 2.54 mm (0.1 in.) was reduced by half. Post-exposure tests on cast alloys showed that this embrittlement could also lead to a reduction in rupture life of several orders of magnitude. An example for alloy IN738 is shown in Fig. 15.

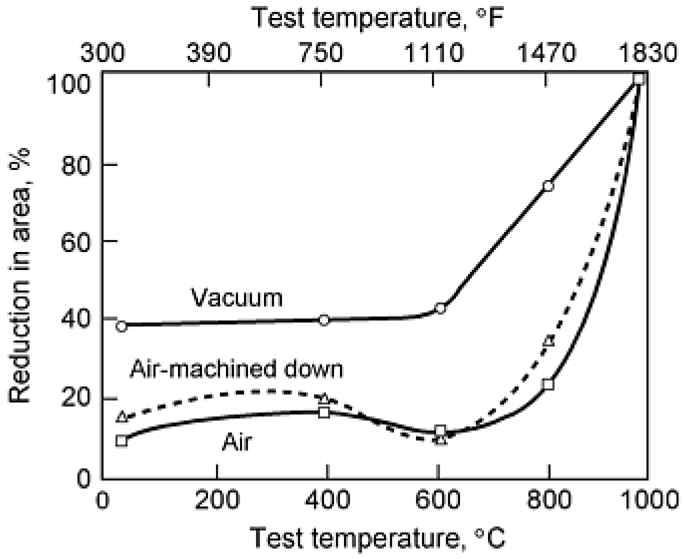

Fig. 14 Tensile ductility of IN903A after air and vacuum exposures at 1000 °C (1830 °F) for 100 h as a function of test temperature in vacuum tests. Embrittlement remained after reducing to half the initial diameter. Source: Ref 41

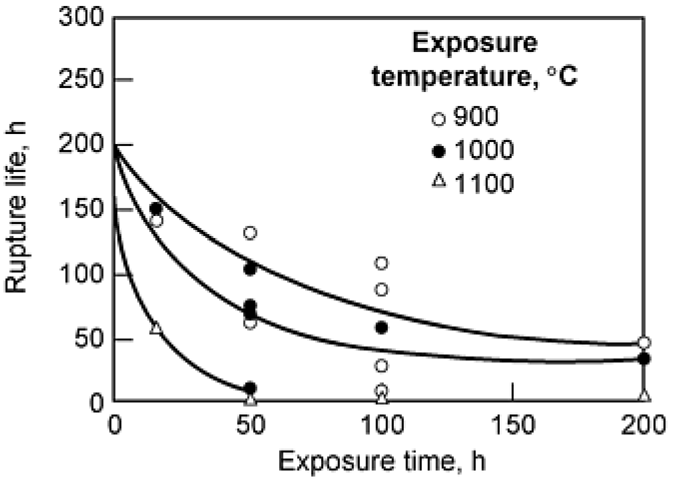

Fig. 15 Effect of exposure in air at various temperatures on stress-rupture life of IN738 at 800 °C (1470 °F) and 400 MPa (58 ksi). Source: Ref 59

Using model alloys based on nickel, it was shown that oxygen in the elemental form in high-purity nickel did not embrittle; a chemical reaction was necessary (Ref 41). Three embrittling reactions were confirmed: a reaction with carbon to form carbon dioxide gas bubbles; a reaction with sulfides on grain boundaries to release sulfur, which does embrittle in the elemental form; and a reaction with oxide formers to form fine oxides that act to pin grain boundaries. These phenomena are believed to be the same processes that serve to embrittle the region ahead of a crack tip. Thus, oxygen attack may occur dynamically to account for the accelerated advance of a crack in air tests compared with inert environment tests, and it may occur during higher-temperature exposure with or without an applied stress to set up an embrittlement situation. Thermal fatigue in combustion turbines is a particularly challenging situation for oxygen attack since maximum strains develop at intermediate temperatures in the cycle, but holding may be at the maximum temperature (Ref 62).

Combined Effects of Oxygen and Carbon. Of special interest relative to the previous discussion of creep cavitation is the reaction between diffusing oxygen and carbon. In nickel, it was found that if this reaction were prevented, creep cavitation could not develop during creep tests. Prevention was achieved either by removing the carbon (decarburizing) or

by applying an environmental protective diffusion or overlay coating (Ref 63). Air tests at 800 °C (1470 °F) and at various stresses showed an enormous increase in rupture life (Fig. 16) if the gas bubble formation did not occur. Since nickel has been used as an archetypical metal for the study of creep cavitation, the confirmation that the cavities are nucleated as gas bubbles now solves the problem of nucleation (Ref 44). The observation that even in superalloys gas bubbles are frequently nucleated at carbides, which may serve as cavity nuclei (Ref 59), and that cavitation during creep is often concentrated near the specimen surface (Ref 64), points to the likelihood that oxygen attack may be invariably associated with creep cavitation. The gas pressures developed in the bubbles appear to be quite adequate for nucleation (Ref 65).

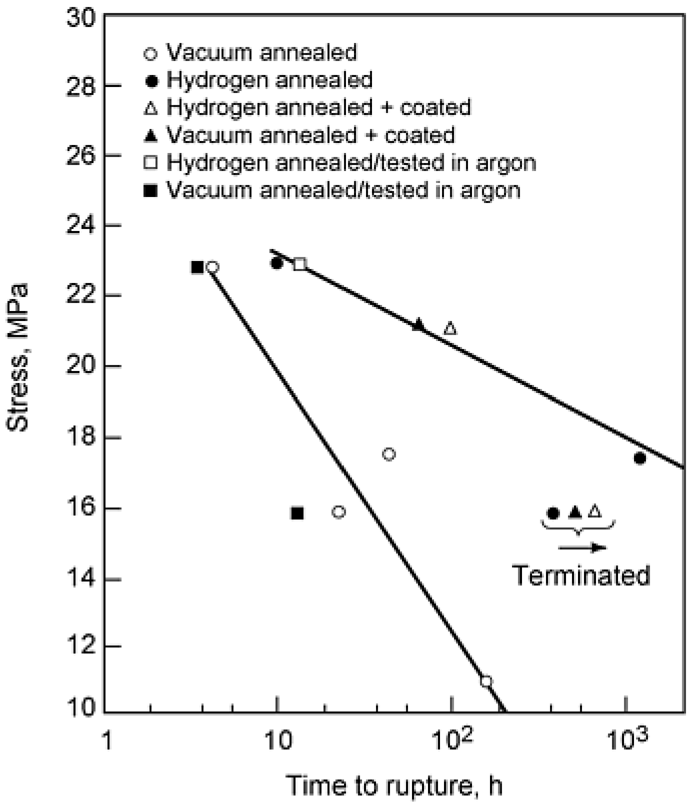

Fig. 16 Effect of environmental interaction on rupture life of Ni270 at 800 °C (1470 °F). Longer lives are obtained by preventing cavitation nucleation from carbon dioxide gas formation. This is achieved by decarburizing to eliminate carbon or by coating to prevent oxygen penetration. Source: Ref 63

Effect of Other Gaseous Elements. Hydrogen, chlorine, and sulfur may also embrittle as a result of penetration. Sulfur is particularly aggressive in that it diffuses more rapidly and embrittles more severely than does oxygen (Ref 66). It is also frequently found in coal gasification and oil-refining processes as well as industrial gas turbines operating on impure fuel.

Design Methodology

This section describes the basic presentation and analysis methods for creep rupture that are currently widely used. In addition to the application of these methods to materials selection and the setting of basic design rules, some consideration will be given to their application to remaining life assessment of operating components. The interaction with fatigue will not be included since some discussion of that complex topic is covered in the article "Creep-Fatigue Interaction" in the *ASM Specialty Handbook: Heat-Resistant Materials.* Also omitted from this discussion are multiaxial stress effects and sustained load (or creep) crack growth. However, it should be recognized that components in service normally operate under multiaxial stress systems, and detailed procedures are used for analysis that are based on effective stresses and strains. The considerable amount of work conducted in recent years on sustained-load crack growth, and the other topics alluded to, are reviewed in several recent texts (Ref 20, 39, 67) and in *Mechanical Testing,* Volume 8 of the *ASM Handbook.*

Creep Rupture Data Presentation. Laboratory creep tests are typically run between 100 and 10,000 h, although a few are run for shorter times (for example, for acceptance tests), and occasionally some testing is conducted for longer times. Since most high-temperature components are expected to last ten years or more, service stresses are obviously lower than those used in the longest creep tests to generate data for most of the alloys used. Therefore, to provide data for creep rates and rupture lives that are appropriate for the setting of design stresses, it became necessary to develop methods for extrapolation. Over the years, a tremendous amount of effort has gone into optimizing methods of data extrapolation (Ref 68, 69).

One of the major considerations in such procedures must be statistical issues, such as the best estimate of the stress associated with a given median life or creep rate, the use of stress or time as the dependent variable in the data fitting, the treatment of variability among heats of the same alloy, and the analysis of data with run-outs. All of these issues have been treated with considerable rigor and shown to be important relative not only to the proper interpretation of data, but to the proper design of experiments (Ref 69). In addition, there are different practices among testing laboratories that may have appreciable effects on results. These include specimen geometry, loading procedure, specimen alignment, furnace type, and temperature control.

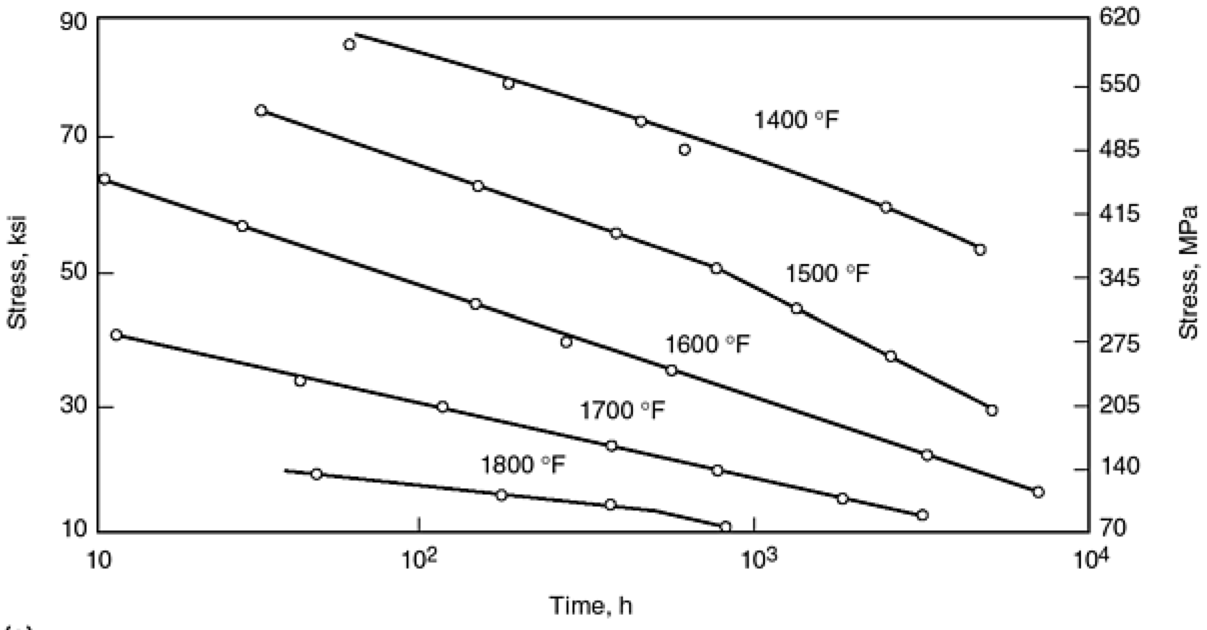
Despite all these concerns regarding proper statistical treatment of data, a methodology has been developed based on time-temperature parameters that is now in widespread use. The approach may be used to achieve the following major design objectives:

- It allows the representation of creep rupture (or creep) data in a compact form, allowing interpolation of results that are not experimentally determined.
- It provides a simple basis for comparison and ranking of different alloys.
- Extrapolation to time ranges beyond those normally reached is straightforward.

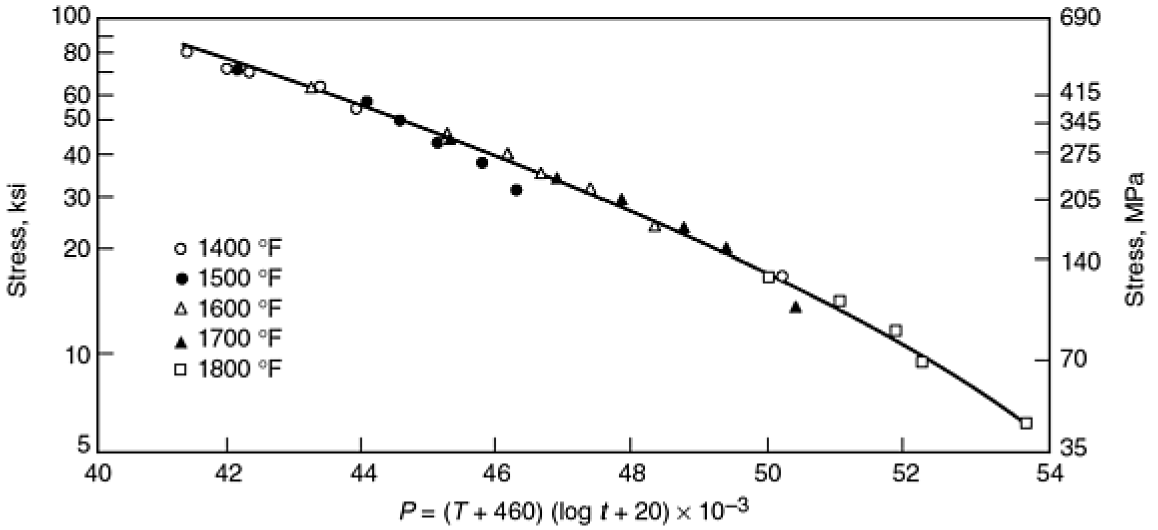
Based on the Arrhenius rate equation and a previous tempering parameter (Ref 70), Larson and Miller (Ref 71) developed the most commonly used parameter:

$$P = f(\sigma) = T(C + \log t_r) \qquad \textbf{(Eq 10)}$$

where σ is stress, T is absolute temperature, and t_r (or t_R) is time to rupture. In their original paper, the constant C was set equal to 20, which provided a good fit for a variety of alloys, and is still widely used today. A set of σ versus log t_r data for the alloy Astroloy and the parametric master curve derived from it is shown in Fig. 17.



(a)



(b)

Fig. 17 Stress-rupture behavior of Astroloy. (a) Stress versus time curves. (b) Larson-Miller plot. Source: Ref 69

Many other parametric forms have been developed (Ref 68, 69), the most common of which are described in the article "Assessment and Use of Creep-Rupture Data" in the *ASM Specialty Handbook: Heat-Resistant Materials.* The time-temperature parameter provides the means for interchanging time and temperature so that a long time may be computed from a short-time test at higher temperature. Figure 18 provides two parametric forms, the shape of which depend on whether isostress lines are parallel or converge on plots of log t versus $1/T$ (the Larson-Miller parameter in Fig. 18a) or T (the Manson-Succop parameter in Fig. 18b). The Manson-Succop parameter (Ref 72) has been used extensively by the Japanese National Research Institute for Metals in compiling data sheets on a wide range of alloys. For example, the data shown in Fig. 19 are for Ni-19Cr-18Co-4Mo-3Ti-3Al-B superalloy castings (Ref 73). The rupture data are statistically treated based on a Manson-Succop correlation, and the tensile data show 95% prediction intervals (dashed lines).

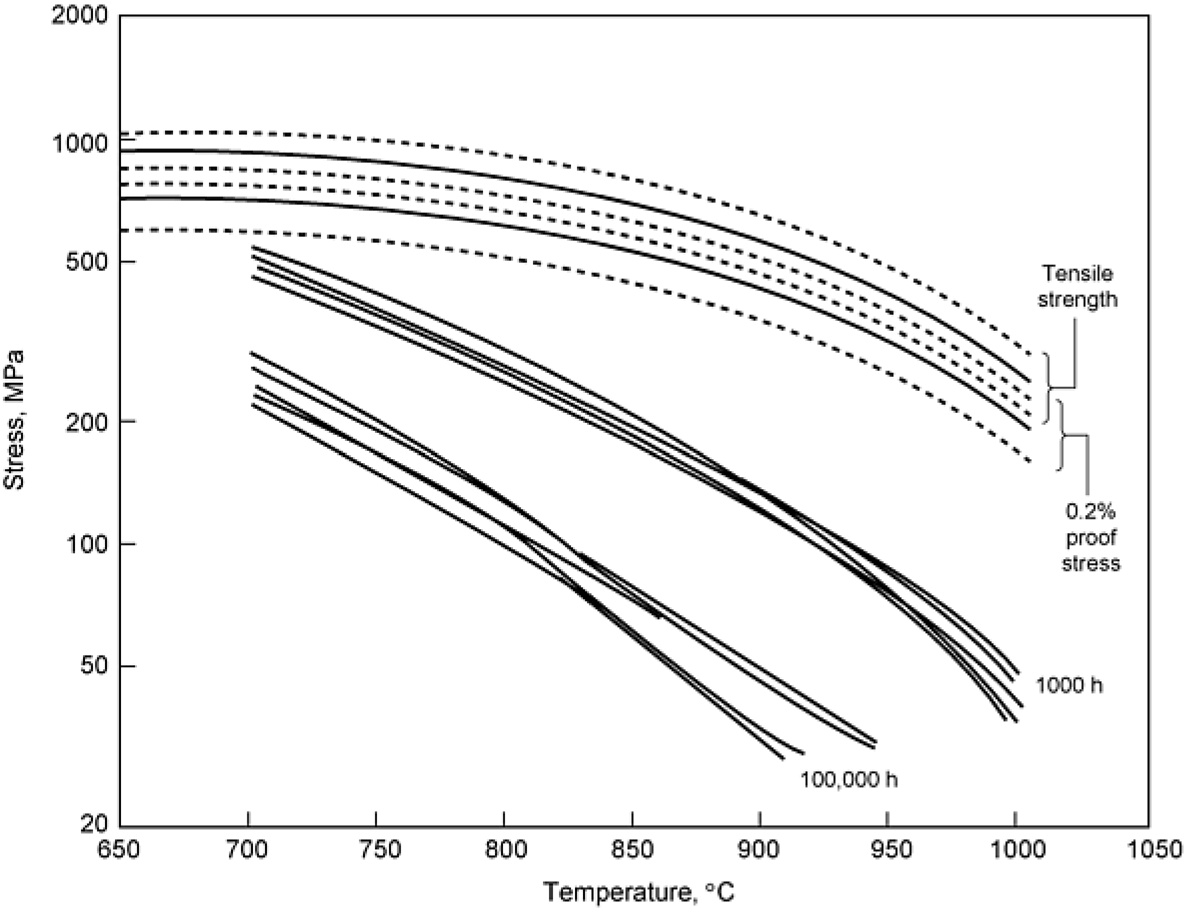

Fig. 19 Temperature dependence of 0.2% yield stress, tensile strength, and creep rupture strength at 1000 and 10,000 h for a nickel-base superalloy casting. Source: Ref 73

At least two approaches have been used to allow a given data set to determine objectively the best of the common parameters or to provide new parametric forms. The minimum commitment method (MCM) (Ref 74) and the graphical optimization procedure (GOP) (Ref 75) provide optimal data presentation but lose the advantage of representing different alloys on the same parametric plot. The GOP method uses the fact that all parameters are in the form of one variable

expressed as the product of functions of two others, for example, $t_r = H(\sigma)Q(T)$ or $T = H(\sigma)C(t_r)$. These functional forms are solved graphically to optimize the parameter. For example, Fig. 20(a) shows data on Cr-Mo-V steel plotted according to a Larson-Miller parameter. The curves at each temperature are clearly ordered, whereas Fig. 20(b) shows the same data using a parameter determined using the GOP method, which includes the optimized values of the $C(t_r)$ function. There is in this case no separation of the isothermal segments. The optimized value of the Larson-Miller "constant" actually varied from 28.5 at 10 h to 13.6 at 100,000 h (Ref 76) for this data set.

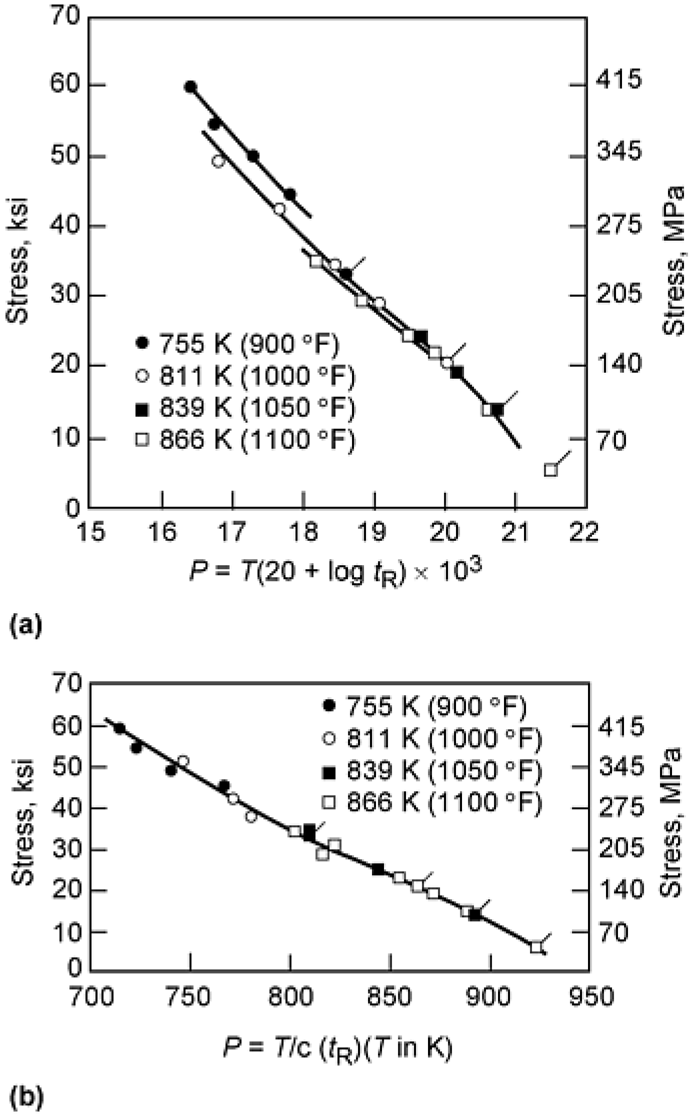

Fig. 20 Creep parameters for a Cr-Mo-V steel. (a) Larson-Miller plot using a constant of 20 showing segmenting of the data. (b) Same data using an optimized parameter based on the graphical optimization procedure (GOP) method. Source: Ref 76

Design rules for high-temperature time-dependent deformation and fracture may be established based on formal codes or on proprietary manufacturers specifications. For example, an ASME code (Ref 77) is used for the design of fossil-fuel boilers and for pressure vessel and piping systems in the petroleum and chemical process industries. The allowable stresses are to be no higher than the lowest of:

- 100% of the stress to produce a creep rate of 0.01% in 1000 h
- 67% of the average stress to produce rupture in 100,000 h
- 80% of the minimum stress to produce rupture in 100,000 h

These stresses may be determined from parametric plots or from derived curves, such as those shown in Fig. 19. It is of interest to note that it is implicit in these rules that the rupture life provides a measure of creep strength. The connection between creep rate and rupture life may be made through the Monkman-Grant relationship (Ref 38) or through the Gill-Goldhoff correlation (Ref 78), which relates stress for rupture with stress for creep to a specific strain for a fixed time and temperature. Both of these methods are described in the article "Assessment and Use of Creep-Rupture Data" in the *ASM Specialty Handbook: Heat-Resistant Materials.*

With nickel-base superalloys, it has been found that surface cracks related to environmental attack may develop at strains as low as 0.5% (Ref 79). Since these cracks result in severe loss in fatigue life, this is an appropriate failure criterion rather than rupture life. Gas turbine blades may therefore be designed on the basis of time to 0.5% creep with a suitable safety factor on stress.

Design for High-Temperature Applications

David A. Woodford, Materials Performance Analysis, Inc.

Damage Accumulation and Life Prediction

Engineering procedures for life management of operating components assume that the material is progressively degraded or damaged as creep strain increases and operating time accumulates. Damage may be in the form of precipitate changes that may result in softening (overaging) and reduced creep strength, or embrittlement and reduced resistance to fracture. The embrittlement may be due to segregation of harmful species, either from the interior or from the external environment, to interfaces, especially grain boundaries. Damage may also occur as a result of progressive intergranular cavitation and cracking, as previously described. Some of this damage may be reversible by suitable heat treatment or by hot isostatic pressing and may allow the possibility of component rejuvenation. However, for the purposes of component life management, which allows decisions to be made regarding part replacement, repair, or rejuvenation, there is a critical need to quantify the accumulation of damage as a function of operating conditions.

There are two basic approaches to using the concept of damage accumulation for life assessment:

- Based on a detailed knowledge of the operating conditions, including temperature and stress changes, the remaining life is estimated from the known original properties of the material of construction.
- Remaining life estimates are made using post-exposure measurements of microstructural changes, intergranular cavitation, or mechanical properties such as hardness, impact energy, or stress-rupture life.

Creep under Nonsteady Stress and Temperature. There are two common approaches to analyzing creep when the temperature and/or the stress change. The strain-hardening law assumes an equation of state of the form:

$$\dot{\varepsilon} = f_1(\sigma, T, \varepsilon_c) \quad \textbf{(Eq 11)}$$

which defines the state of the material in terms of creep strain (ε_c). The time-hardening law:

$$\dot{\varepsilon} = f_2(\sigma, T, t) \quad \textbf{(Eq 12)}$$

defines the state in terms of time. It should be clear that neither of these is physically rigorous. However, they provide analytical options, for example, when a stress change calls for a transfer to a new creep curve at the same strain or time, respectively. Although strain is intuitively a better compromise as a state variable, the time-hardening law is often easier to handle analytically for complex sequences of stress and temperature changes. Moreover, if the sequences involve multiple increases and decreases in stress and temperature, the two approaches may produce similar results. Modifications of the laws including normalizing the strain with the fracture strain, normalizing the time with the failure time, or using a mean function have also been used.

These same ideas have been extended to predict failure either in terms of strain fractions or time fractions. In this case, however, by far the most extensively used in design analysis and life prediction has been the life-fraction approach. This concept was first introduced by Robinson (Ref 80, 81) as an accounting system for materials in which the rupture time is a power function of stress and the log rupture time is a linear function of temperature. The analytical solutions for such a material subjected to various temperature and stress cycles were given by Robinson (Ref 81), but the concept is now generally presented in the form:

$$\sum_{i=1}^{n} \frac{\Delta t_i}{t_{Ri}} = 1 \quad \textbf{(Eq 13)}$$

where t is time spent at temperature T or stress σ, t_R is rupture time at temperature T or stress, and n is the number of temperature or stress changes.

Each fractional expenditure of life, or accumulated damage, is considered to be independent of all others. Failure is predicted when the sum of the fractions of life equals unity. This hypothesis remains a widely used tool for life assessment.

Considerable experimental work has attempted to confirm or refute the rule. However, when the results of multiple-stress or temperature-change experiments are analyzed in terms of the life-fraction rule, it is only possible to determine whether

the rule is appropriate, but not why it fails. Only when damage is defined in terms of remaining life rather than used life is it possible to formulate the appropriate damage law (Ref 82). Figure 21 illustrates the procedure schematically for a stress-change experiment where the abscissa is the logarithm of the remaining life. The continuous line represents remaining life for the virgin material, that is, the stress-rupture data for the initial condition. Point 1 is the remaining life on two specimens exposed at stress σ_2. One of these specimens is then tested to failure at σ_3, and the measured remaining life is represented by point 1A. The stress on the second specimen is then reduced to σ_1, resulting in a measured remaining life indicated by 1B. The dashed line drawn through the points 1A, 1, and 1B is then defined as a constant damage line in terms of remaining life. Clearly, any number of lines such as 2A, 2, 2B may be constructed.

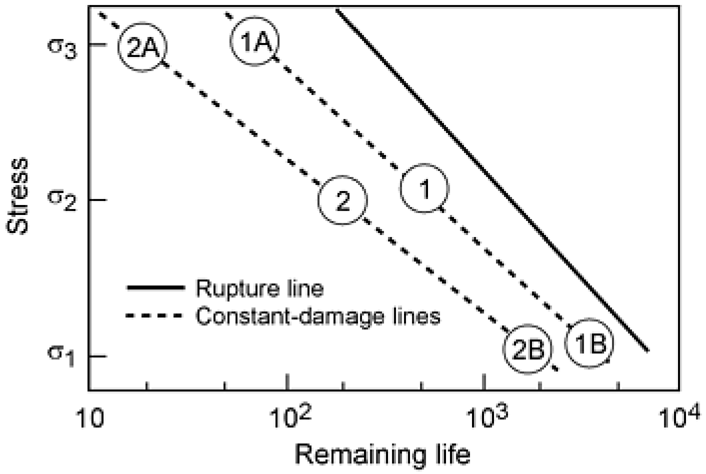

Fig. 21 Schematic plot illustrating construction of constant damage curves in terms of remaining life for different stresses. Source: Ref 83

A necessary condition for the life-fraction rule to apply is that the constant damage lines should be displaced horizontally by a constant distance when remaining life is plotted on a logarithmic scale for both temperature and stress changes. For low-alloy steels, the life-fraction rule applies quite well for temperature changes but not for stress changes. For stress changes, the curves often converge at low stresses, leading to a loading sequence effect. For example, a stress increment leads to a life fraction at failure less than one and a stress decrement leads to a life fraction at failure greater than one. This behavior may be combined on a parametric plot (Fig. 22), where a sequence of both temperature and stress changes may be represented. For detailed discussion on the construction and use of the remaining life curves for nonsteady conditions and component life assessment, see Ref 82, 83, and 84.

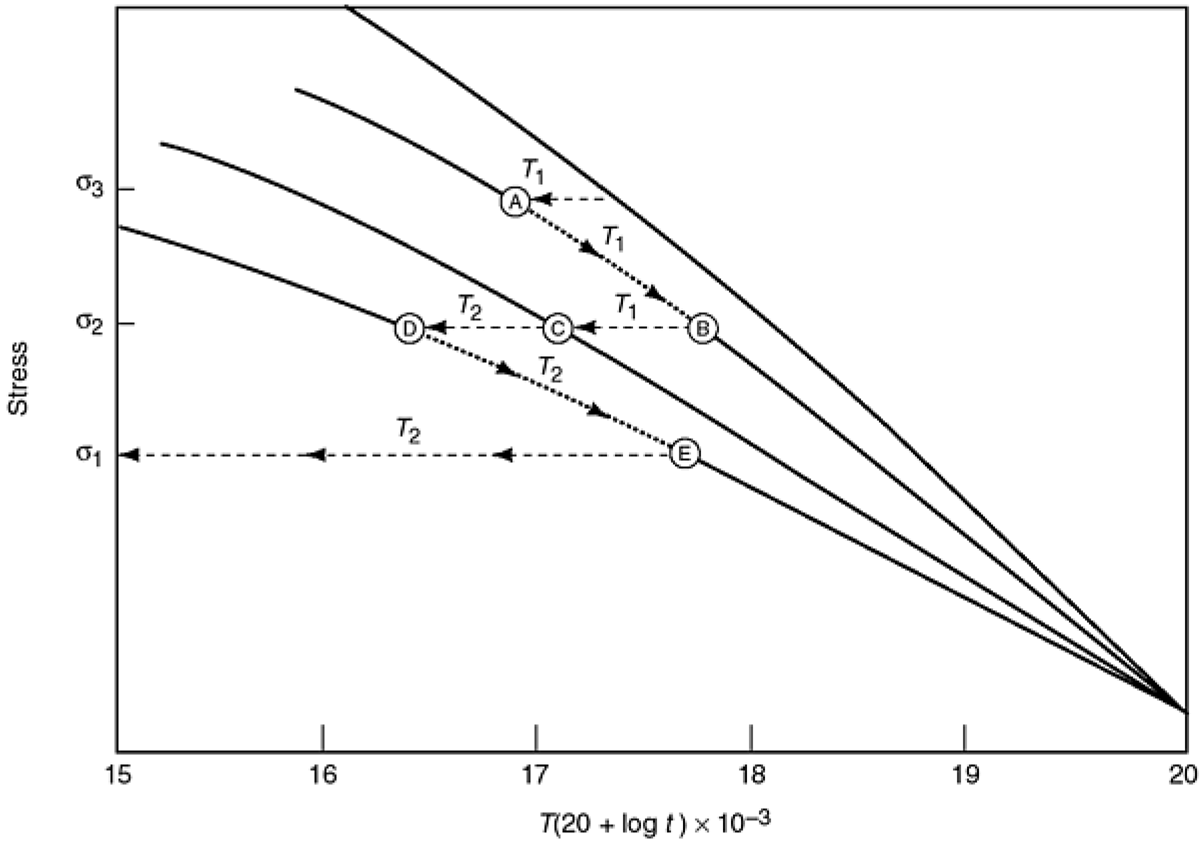

Fig. 22 Schematic plot illustrating construction of constant damage curves in terms of the Larson-Miller parameter. The sequence ABCDE is an example of a particular stress-temperature path. Source: Ref 83

Post-Exposure Evaluation. Ideally, a microstructural characterization or mechanical property should change linearly with life fraction and independently of the test conditions, as shown in Fig. 23. In fact, the changes are invariably nonlinear and nonunique with life fraction. Both cavitation changes and creep strength changes are dependent on the test conditions (Ref 45, 46, 83). Thus, the amount of damage at failure or at a given life fraction is a strong function of the stress in particular.

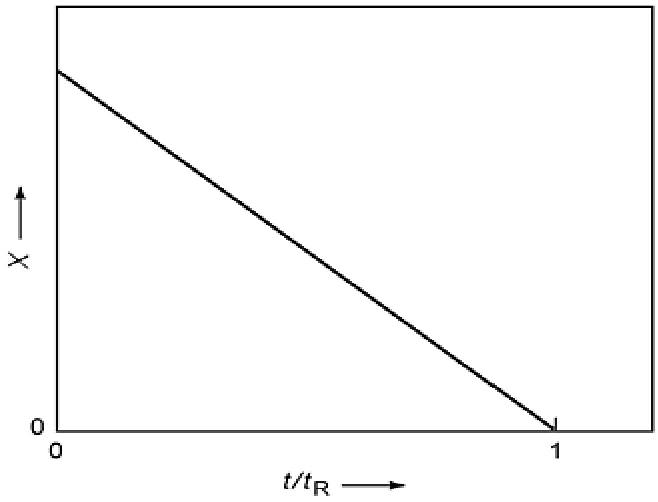

Fig. 23 Ideal behavior of a property suitable for damage monitoring as a function of life fraction

A comprehensive study of a low-alloy steel in which miniature stress-rupture specimens were taken from large specimens, which had previously been exposed to various strains and times up to 60,000 h at four temperatures over a range of stresses, confirmed this complexity (Ref 85). The initial exposure led to progressive softening, which correlated well with the post-exposure rupture life (Fig. 24) in a standard test at 540 °C (1000 °F) and 240 MPa (35 ksi). Using parametric correlations with the original exposures, a series of damage curves were generated (Fig. 25) in which the ordinate is one minus the ratio of the post-exposure rupture life (t_p) divided by the mean rupture life of the unexposed material (t_c) under the same test conditions. This definition of creep damage increases to a limiting value of unity as t_p approaches zero.

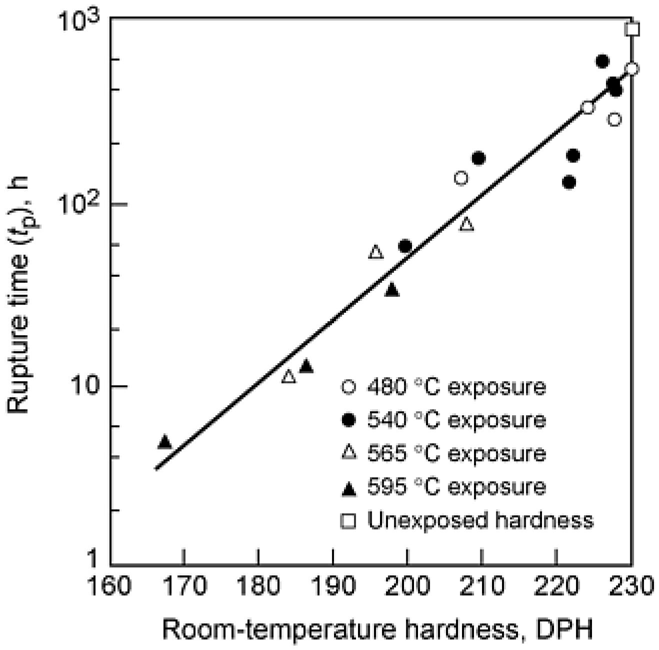

Fig. 24 Correlation between post-exposure rupture life for a Cr-Mo-V steel tested at 240 MPa (35 ksi) and 540 °C (1000 °F) and room temperature hardness. DPH, diamond pyramid hardness. Source: Ref 85

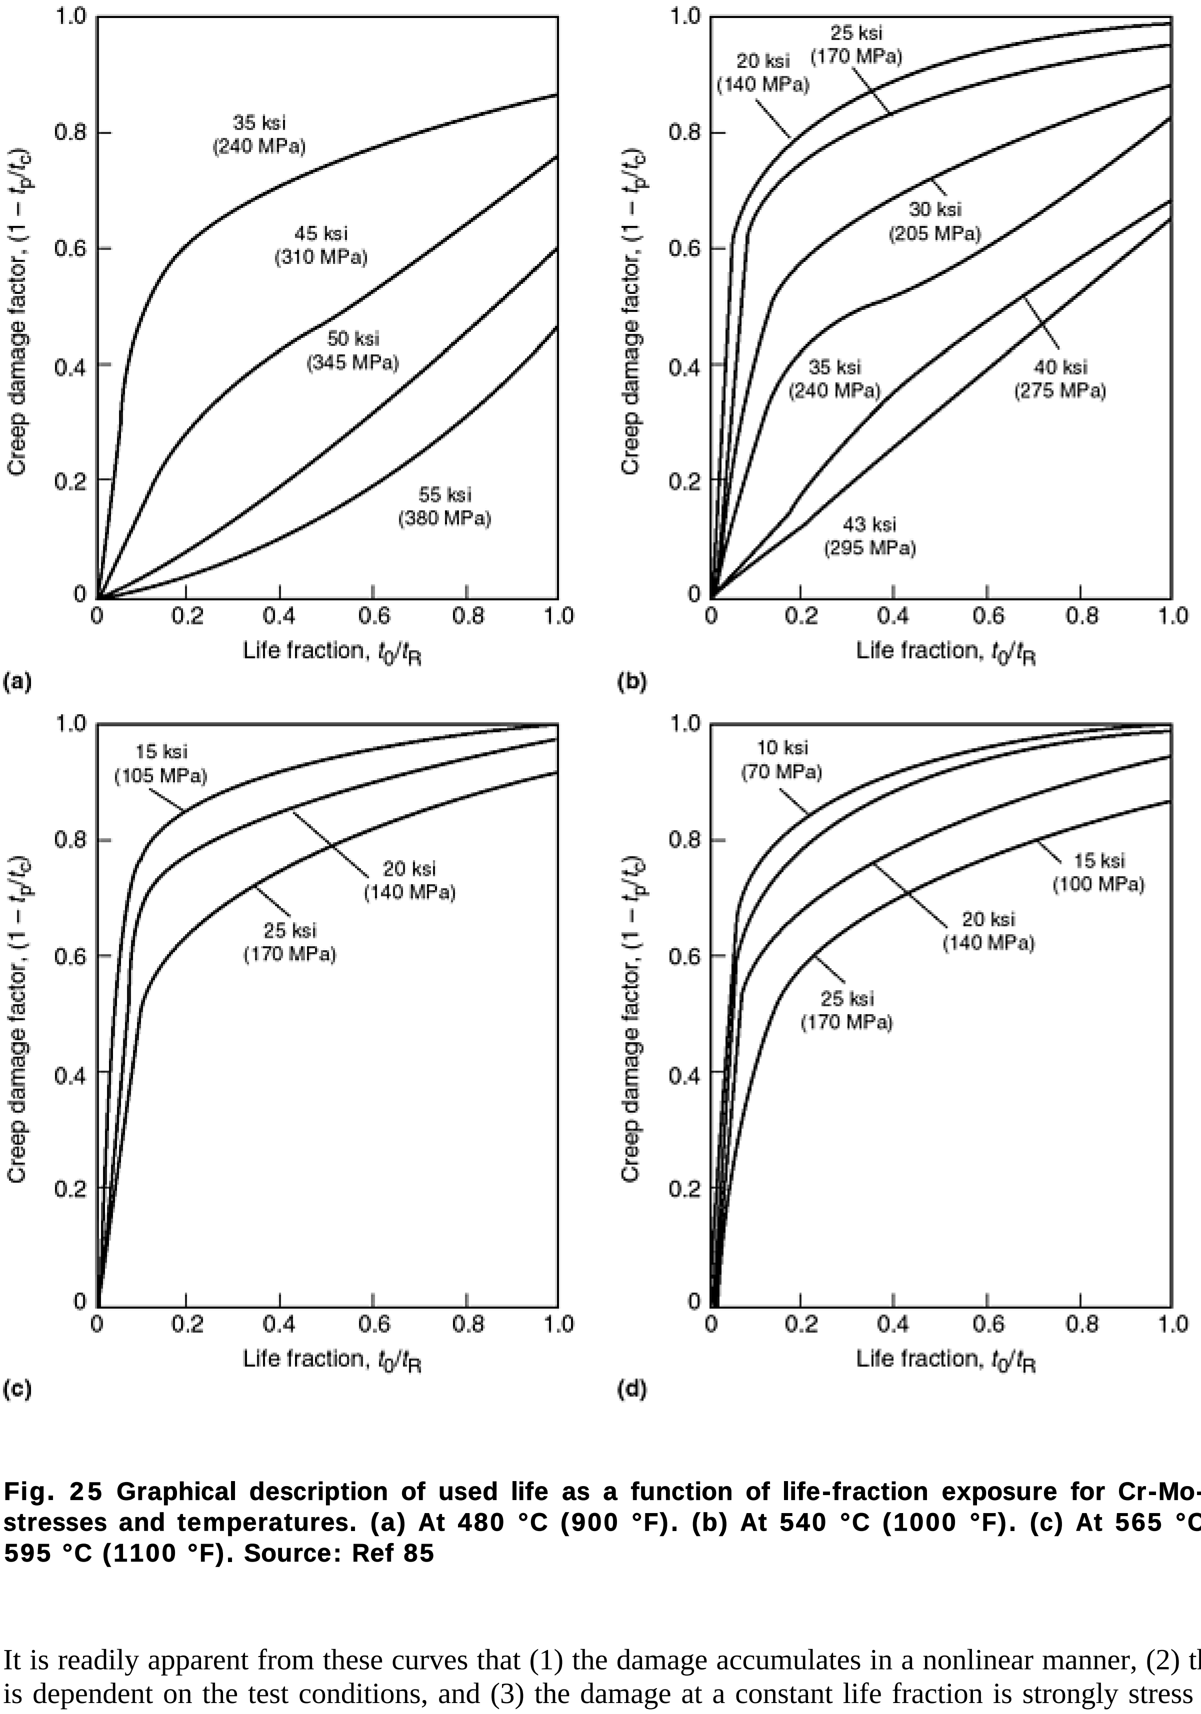

Fig. 25 Graphical description of used life as a function of life-fraction exposure for Cr-Mo-V steel at various stresses and temperatures. (a) At 480 °C (900 °F). (b) At 540 °C (1000 °F). (c) At 565 °C (1050 °F). (d) At 595 °C (1100 °F). Source: Ref 85

It is readily apparent from these curves that (1) the damage accumulates in a nonlinear manner, (2) the damage at failure is dependent on the test conditions, and (3) the damage at a constant life fraction is strongly stress dependent but quite insensitive to temperature for a given stress. These points are consistent with the previous commentary on the limitations of the life-fraction rule and with the general applicability of time-temperature parameters.

Despite similar concerns with the use of microstructural observations of cavitation to predict remaining life, there have been extensive reported studies of such measurements (Ref 39, 86). The first detailed attempt to relate remaining life of power plant to cavitation observed on replicas was that of Neubauer and Wedel (Ref 87), who set up recommended procedures based on the observation of four levels of cavitation severity in steam pipes (Fig. 26). There were subsequent

attempts to quantify the cavitation in terms of mechanistic concepts (Ref 88). Other studies have examined the cavitation in nickel-base alloys for gas turbines (Ref 89) and set up similar criteria for end of useful life.

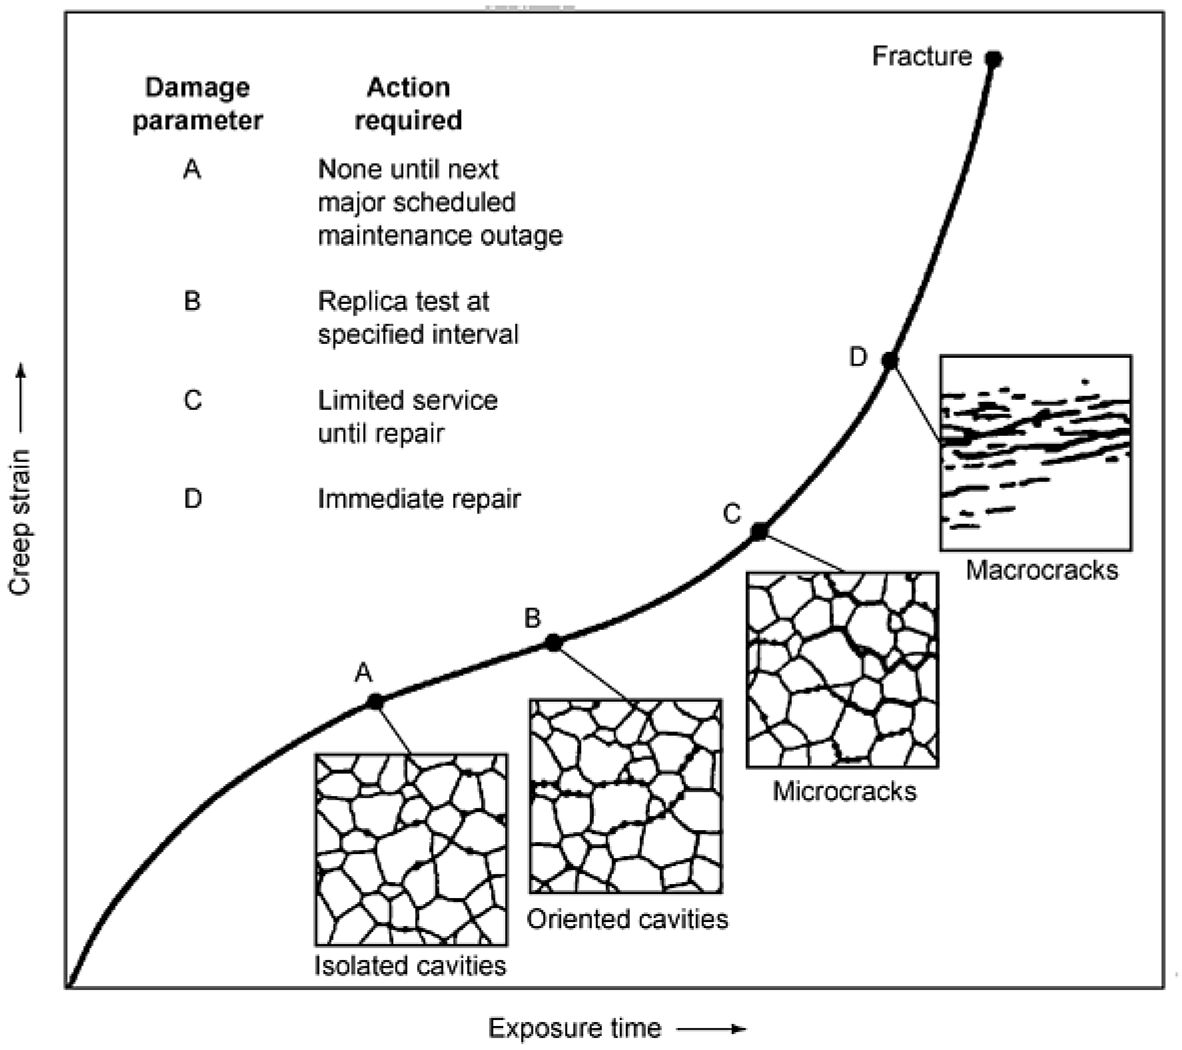

Fig. 26 Creep life assessment based on cavity classification in boiler steels. Source: Ref 87

The replica studies in particular have usually been limited to surface observations so that the possibility of environmental interaction is strong (see the section "Environmental Effects" in this article). Also, many of these studies have recently been criticized on the basis that the observation of cavities is very sensitive to preparation techniques (Ref 90).

Design for High-Temperature Applications

David A. Woodford, Materials Performance Analysis, Inc.

Limitations and Alternative Design Approaches

In the increasingly competitive global market for manufactured components operating at high temperatures, there are three primary technical objectives:

- The development cycle for new materials and new designs must be reduced.
- The designs must be optimized for efficiency and performance.
- Procedures must be developed for component life management to allow timely repair or replacement.

Current Limitations. The primary design of most high-temperature components involves the application of some proportion of the stress for failure in a given time (usually in the range of 20,000 to 100,000 h) calculated from extrapolated constant load stress-rupture tests. It might appear, therefore, that the most direct method of measuring remaining life after extended service would be to compute it based on the current remaining life of a sample taken from the component. Accordingly, methods are being developed to take miniature stress-rupture samples from components and assess remaining life based on extrapolation from such data. There are a number of reasons why this approach may be unsound:

- Component failure is often localized with little or no material degradation or damage remote from the failure.
- Cracks frequently initiate from the surface so that any post-exposure property measurement on material taken from the interior has limited value.
- Interactions with the operating gaseous environments, which may have profound effects on crack initiation and propagation, are generally ignored.
- The changing stress in a constant load test is not normally accounted for in summing life fractions to predict remaining life.

- The sources of scatter in experimental property measurement (for example, alignment, temperature control, precision of stress and strain measurement, specimen geometry) bear little connection to the sources of scatter in service.
- Time to rupture in an unnotched ductile alloy is principally a measure of deformation behavior rather than fracture resistance.

The failure to establish a clear separation of a strength requirement from a failure criterion (an appropriate analogy might be between yield strength and fracture toughness for many low-temperature components) leads to a paradox (Ref 91). This may be stated: When a component fails, the material of the component has a finite life, sometimes approaching the original design life, at the operating conditions of the component. It thus follows that a remaining life estimated from a sample taken from an operating component may bear no relationship to the actual component remaining life.

Low-temperature design is dominated by properties that uniquely characterize the mechanical state in terms of stiffness (modulus), strength (yield), and fracture resistance (K_c). If service-induced changes in state occur, for example, radiation hardening and embrittlement, these changes are monitored in terms of their effects on changes in the same short-time properties. Thus life management decisions are based on the same performance criteria as in the original design: There is no remaining life paradox in this case.

The basis for current methods of high-temperature design is different in that the objective is to incorporate time-dependent changes in the test methodology. The creep rates and rupture lives relate to the starting material only in terms of the specific deformation path being imposed, for example, a variable strain rate or a variable true stress test with an arbitrary interaction between creep deformation and fracture processes. This history is quite different from any real service history. To measure these properties, unlike in the low-temperature situation, the structural and mechanical states must be changed. As an example, the minimum creep rate at a given temperature and stress is a measure of the creep strength of the material in its current state; it relates to its initial state only for the particular deformation history. The designer may claim that long-time data are required for component creep strength evaluation, but in reality what is needed is low strain rate data. It will be shown that such data may be obtained with precision in short-time tests.

Simulating service complexity in material testing involves a hierarchy of increasing complexity and expense. Thus long-term creep tests are inadequate; nonsteady test conditions, complex stresses, cyclic stresses, environmental effects, and the synergism among them must be taken into account. Even with the most complex test plan, most service operations cannot be simulated.

Alternative Design Approaches and Tests. An alternative approach is to simplify the test methodology and develop tests to measure separately the high-temperature creep strength and fracture resistance, ideally to evaluate the current state in terms of these properties. The consequences of microstructural evolution, induced in service or in laboratory simulations, can then be assessed using the same short-time tests. Design is then based on minimum acceptable performance levels (Ref 92).

The concept is illustrated in Fig. 27 for three fundamental properties, including an environmental damage criterion, which could be critical in a number of high-temperature applications. Additional criteria could be added. However, it might not be necessary to include some important failure processes, such as high-cycle fatigue and thermal fatigue, because these in principle are either derivable from, or correlatable with, the other properties or are too complex and parameter sensitive to be assigned minimum performance values.

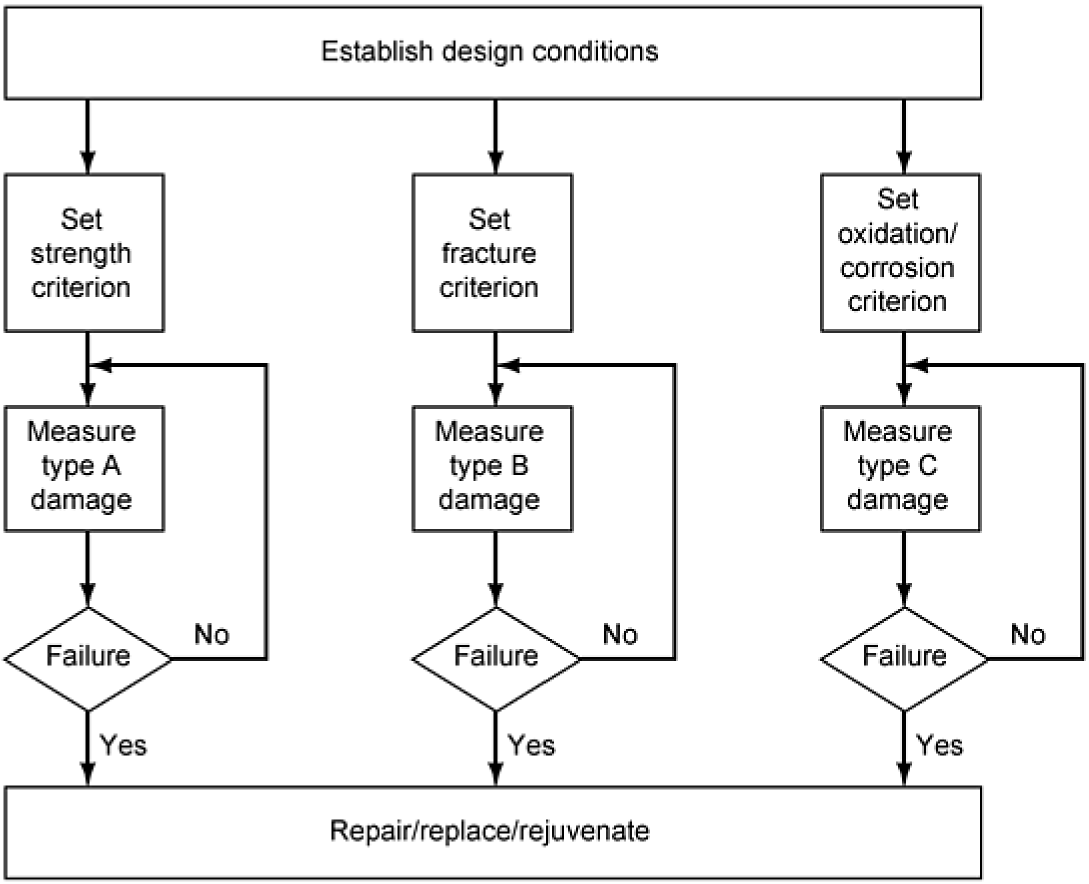

Fig. 27 The design-for-performance concept. Source: Ref 92

The creep strength criterion for high-temperature applications may be developed from a series of carefully conducted stress-relaxation tests (SRT). The stress versus time response is converted to a stress versus creep strain-rate response (Ref 92, 93). This is, in effect, a self-programmed variable stress creep test. Typically, a test lasting less than one day may cover five decades in creep rate. The accumulated nonelastic strain is usually less than 0.1%, so that several relaxation runs at different temperatures and from different stresses can be made on a single specimen with minimal change in the mechanical state. Thus an enormous amount of creep data can be generated in a short time.

A constant displacement rate (CDR) test (Ref 92, 94), in which a crack is enabled to initiate naturally at a grain boundary and propagate slowly under closed-loop displacement control, was developed as a separate basis to evaluate the fracture resistance. Both types of tests were first performed on large specimens to establish the broad principles of the methodology and then compared with data taken from miniature specimens machined from actual gas turbine blades (Ref 95). It was established that environmental interaction, specifically gas phase embrittlement (GPE) resulting from intergranular penetration of oxygen, could drastically reduce the fracture resistance with little or no effect on the creep strength (Ref 92, 95).

Figure 28 is an example of four relaxation runs at 900 °C (1650 °F) showing no appreciable effect of severe high-temperature exposure in air or vacuum on the stress versus creep-rate response for a cast nickel-base gas turbine blade made of alloy IN738. By contrast, Fig. 29 shows that there is a profound degradation in the CDR fracture resistance for high-temperature air exposures. This approach is clearly valuable for assessing performance and continued operation when embrittlement occurs with minimal effect on creep strength. It can also be used directly as a basis for creep design. For example, Fig. 30 shows how relaxation runs at different temperatures can be fitted by horizontal displacement of the strain-rate scales to allow stresses corresponding to very low creep rates to be estimated. In fact, this procedure allows design creep rates to be attained based on several one-day tests (Ref 92). It also allows comprehensive determination of the effect of prior exposure, either from laboratory simulations or component service, to be evaluated.

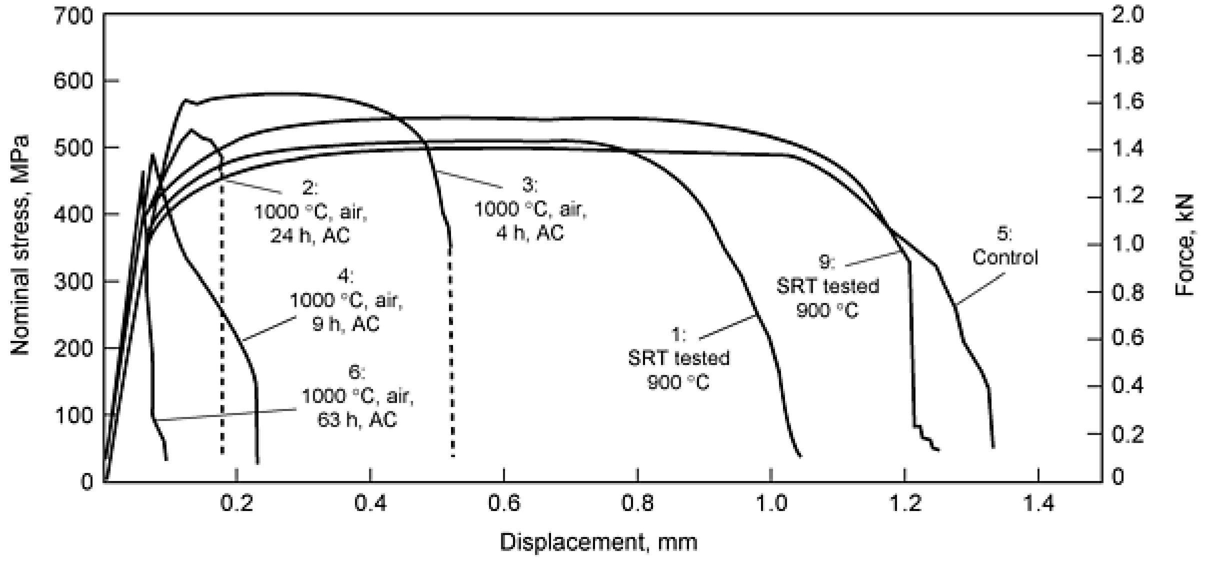

Fig. 29 Embrittlement of IN738 with increasing severity of exposure in air demonstrated in constant displacement rate (4 × 10^{-5} mm/s) tensile tests at 800 °C (1470 °F). SRT, stress-relaxation tests. AC, air cooled. Source: Ref 95

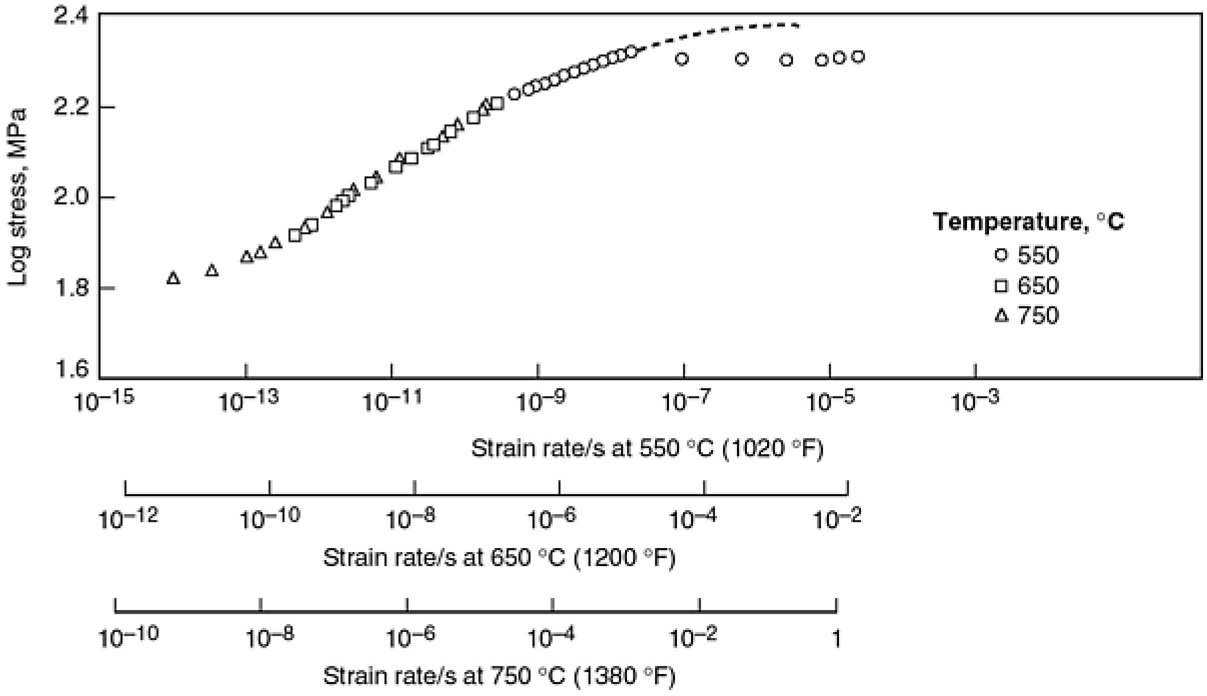

Fig. 30 Master stress versus creep-rate curve for Incoloy 800H between 550 and 750 °C (1020 and 1380 °F) achieved by horizontal translation of data generated on one specimen. Source: Ref 95

Recently, it has been shown how creep data obtained from stress-relaxation testing can be compared directly with long-time creep data in terms of time to specific creep strains. Since the two approaches use different deformation histories, neither of which is fundamentally preferred compared with component deformation, precise conformity should not be anticipated or required. However, for a number of alloys (Ref 95) and polymers (Ref 96), the agreement is surprisingly good. Figure 31 shows such a comparison for an iron-base superalloy.

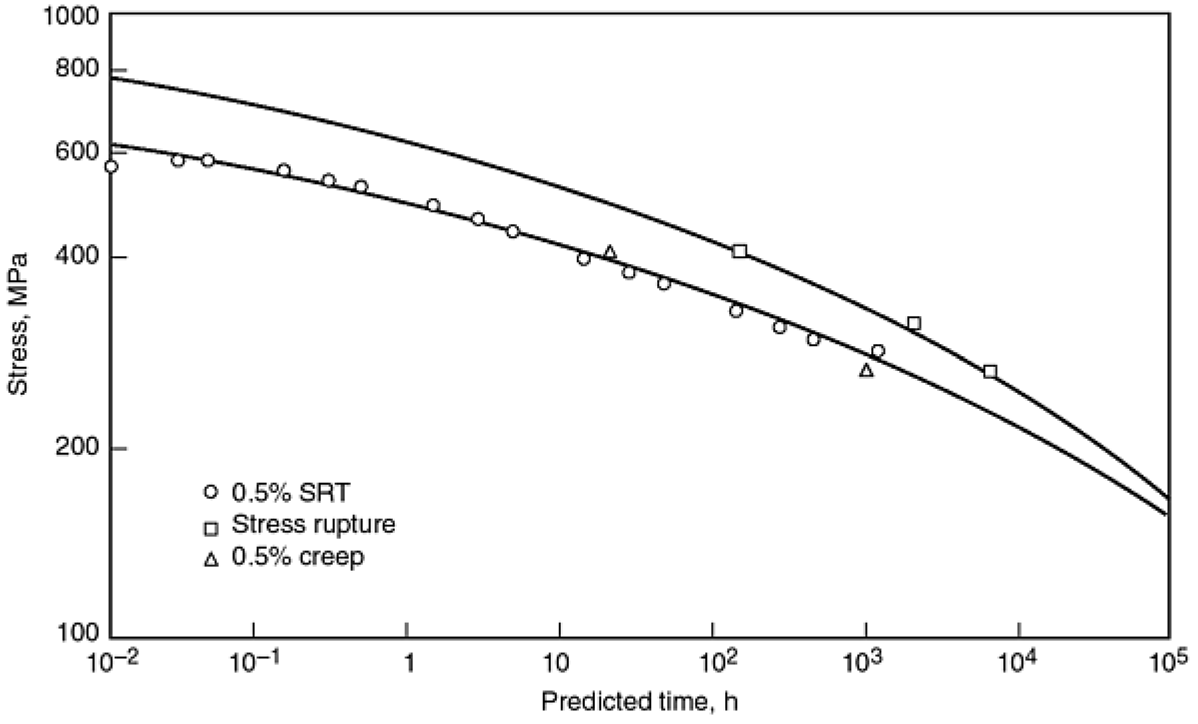

Fig. 31 Comparison of predicted time to 0.5% creep based on stress-relaxation measurements at 650 °C (1200

°F) for an austenitic iron-base alloy with measurements made on conventional creep tests. SRT, stress-relaxation tests

Thus the approach offers accelerated creep strength evaluation, which may be used either directly or through calibration with long-time tests, and may be used to assess the creep strength of operating components. In particular, by recognizing high-temperature fracture as a property that is not uniquely connected to creep strength, the approach offers a basis to understand why some components fail very early in their design lives and why others appear undamaged after exceeding their design lives.

Conclusions

Time-dependent deformation and fracture of structural materials are among the most challenging engineering problems faced by materials engineers. The critical role played by high-temperature energy-conversion machines in modern society attests to the remarkable success of the design methodology developed during the present century. However, modern design needs, including accelerated evaluation and development of advanced materials, and improved remaining life assessment methods for operating equipment have identified some ways in which the methodology might be improved. It has been pointed out in this article that it is desirable to decouple the creep strength and fracture resistance criteria. It has also been shown how this could lead to new accelerated short-time testing in which the objective is not to attempt to incorporate microstructural evolution and damage-development in the test, as in the traditional long-time creep-to-rupture test. Rather, the accelerated test may be used to measure separately the consequences of these changes on creep strength and fracture resistance.

The generally neglected anelastic or time-dependent recoverable component of creep may be the dominant strain component in many service situations at low stresses and needs to be incorporated in design analysis. This is true for ceramics and metals as well as polymers. It may also provide, in some cases, a critical link between deformation and fracture.

Design for Oxidation Resistance

James L. Smialek and Charles A. Barrett, NASA Lewis Research Center; Jon C. Schaeffer, General Electric Aircraft Engines

Introduction

ALLOYS intended for use in high-temperature environments rely on the formation of a continuous, compact, slow-growing oxide layer for oxidation and hot corrosion resistance. To be protective, this oxide layer must be chemically, thermodynamically, and mechanically stable. Successful alloy design for oxidative environments is best achieved by developing alloys that are capable of forming adherent scales of either alumina (Al_2O_3), chromia (Cr_2O_3), or silica (SiO_2).

In this article, emphasis has been placed on the issues related to high-temperature oxidation of superalloys used in gas turbine engine applications. Despite the complexity of these alloys, optimal performance has been associated with protective alumina scale formation. As will be described below, both compositional makeup and protective coatings play key roles in providing oxidation protection. Other high-temperature materials described include nickel and titanium

aluminide intermetallics, refractory metals, and ceramics. Additional information on the oxidation resistance of other structural alloys, including chromia-forming ferrous alloys for industrial applications can be found in the many references provided and in the *ASM Specialty Handbook: Heat-Resistant Materials.*

Design for Oxidation Resistance

James L. Smialek and Charles A. Barrett, NASA Lewis Research Center; Jon C. Schaeffer, General Electric Aircraft Engines

The Oxidation Process

Except for a few noble metals, such as gold, platinum, and palladium, all metals will react with oxygen when exposed to air at high temperatures. This is due to basic thermodynamics, that is, highly negative free energies for the general oxidation reaction:

$$aM + \frac{1}{2}bO_2 = M_aO_b \quad \textbf{(Eq 1)}$$

where M is the reacting metal, M_aO_b is its oxide and *a* and *b* are the moles of the metal and oxygen, respectively, in 1 mol of the oxide. This fact can be readily assessed from the Ellingham diagram of the free energies of formation of the oxidation product. In general, the most reactive or oxygen active (least noble) metals are found in the alkali and alkaline earth (groups IA and IIA of the periodic table), the scandium group IIIA (including the lanthanide and actinide series), and the titanium group IVA metals. The common high-temperature structural base metals (iron, cobalt, and nickel group VIIIA) are more noble, but still oxidize readily in typical oxygen-containing environments. The partial pressure of oxygen below which oxidation will not occur is defined by the thermodynamic relationship for Eq 1 as:

$$\Delta G = -RT \ln (1/p_{O_2}^{b}) \quad \textbf{(Eq 2)}$$

where ΔG represents the Gibbs energy change, *R* is the gas constant, and *T* is the absolute temperature, and where the metal and oxide are in pure, standard states.

Consumption of the metal and loss of its engineering properties are determined by the oxidation rate. The rate of oxidation is determined by the slowest step in the oxidation process. In some less-common cases a volatile, gaseous oxide, or highly porous solid oxide scale may form where the consumption rate may be controlled by the metal-oxygen reaction or by diffusion through a gaseous boundary layer. However in the vast majority of applications of high-temperature materials, a relatively dense external solid scale forms. The rate of oxidation in this case is controlled by counter-current diffusion of oxygen and metal ions through an ionic oxide layer. As is the case with most diffusion-controlled processes, the instantaneous rate is inversely proportional to the thickness of scale that must be penetrated to sustain the process. This leads to the classic parabolic growth rate:

$$x^2 = k_p t \quad \textbf{(Eq 3)}$$

where *x* is the oxide scale thickness or mass (weight) gain per unit area, k_p is the parabolic growth rate constant with the units cm^2/s for scale thickness measurements and the units $g^2/cm^4 \cdot s$ for mass gain measurements, and *t* is time.

Thus, slow-growing scales are made up of oxides with low diffusion constants. It can be seen from Fig. 1 that, over the temperature regime of most practical interest, scales based on Al_2O_3, Cr_2O_3, or SiO_2 produce the most desirable rates (Ref 1). (BeO and B_2O_3 have also been shown to exhibit low growth rates, but are subject to special problems, such as moisture-enhanced growth or toxicity, and are not widely employed as protective oxides.) Accordingly, high-temperature alloy design for oxidation resistance is based on the ability to form these three simple elemental oxide scales. Although more complex oxide phases, such as $NiAl_2O_4$ and $NiTa_2O_6$ may form on many commercial alloys, none are known to possess lower diffusion and growth rates than the single Al_2O_3, Cr_2O_3, or SiO_2 oxides. However, the rate and specific type of ionic diffusion can be altered to varying degrees by small amounts of dopants of secondary cations, especially at the oxide grain boundaries.

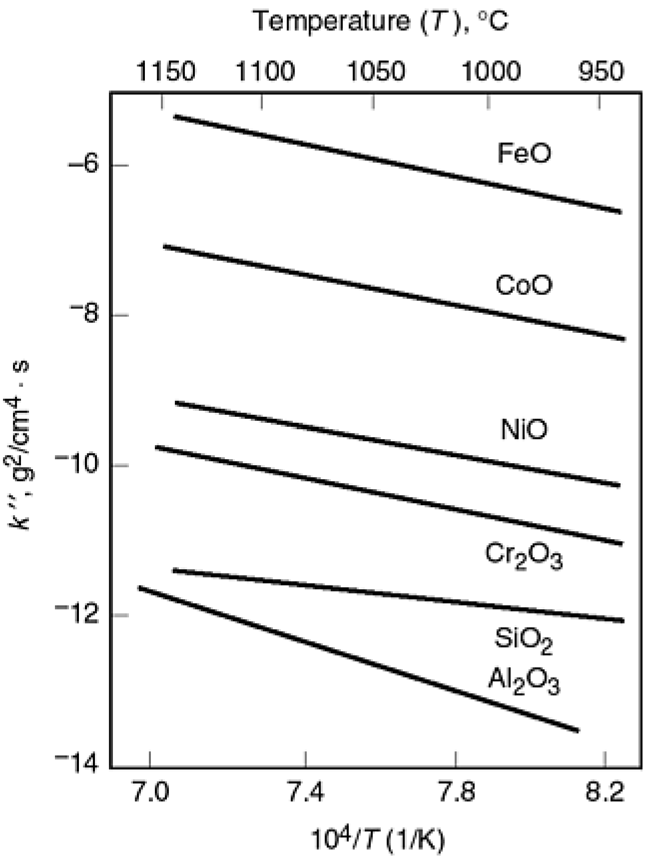

Fig. 1 Parabolic oxidation rate of various oxide scales (Arrhenius plot). The relationship between *k*" and k_p (parabolic rate constant described by Eq 3) is *k*" = $(8/V)^3$ k_p, where V is the equivalent volume of the oxide. Source: Ref 1

Design for Oxidation Resistance

James L. Smialek and Charles A. Barrett, NASA Lewis Research Center; Jon C. Schaeffer, General Electric Aircraft Engines

General Methodologies

The basic test methods to evaluate oxidation resistance are to expose the material, monitor the kinetics, and subsequently characterize the oxidation products and substrate material. Exposures are most often done in air, but can be in any controlled mix of corrosive gases, such as H_2/H_2S, CO/CO_2, or O_2/SO_2. Oxidation kinetics are usually recorded as weight changes, but may also be followed as changes in scale thickness. Continuous weight change is usually obtained by thermogravimetric analysis (TGA), in which the sample is suspended from the bottom of an analytical balance into the hot zone of a vertical tube furnace. Continuous oxidation kinetics can also be observed by a manometric apparatus in which the pressure drop caused by oxygen consumption in a closed system is monitored and converted to weight of oxygen gained per unit area of sample. Cyclic oxidation is widely used to characterize the resistance of the scale to spallation. Here automated retraction of samples from the hot zone (by means of timers, counters, switches, and motors or pneumatic actuators) can easily expose multiple samples for thousands of cycles of a specified duration. The most simple

test is that of interrupted oxidation, where samples are oxidized continuously, except for the limited cycle that occurs during the periodic withdrawal needed for weighing and examination.

More complex rigs are used at dedicated research laboratories if oxidation under more realistic conditions is the primary objective of the test. Thus, rigs with natural-gas or jet-fuel burners are common in the land-based and aircraft gas turbine industries. Petrochemical reaction chambers, exhaust flue gas, carburizing or nitriding heat-treating furnaces, and heat exchangers for coal-fired power stations are other examples of special cases where testing should simulate the actual environment to obtain a faithful representation of the corrosion process.

Weight change data provide a very useful measure of the amount of metal converted to oxide and provide a succinct, helpful comparison among alloys. However, the ultimate engineering criteria of the oxidation resistance of a material is retention of mechanical properties after exposure. This depends not only on the reduction of a load-bearing section from oxidation, but also on the morphology of the oxidation product. Consequently, environmental attack is further categorized by a thorough characterization of the corrosion products in conjunction with weight change data. For example, a simple metallographic cross section can illustrate the remaining unaffected metal core of the specimen. The nature of the attack (irregular intrusions, preferential phase attack, intergranular oxidation, internal oxidation, uniform planar external scales, and depletion zones) can also be readily distinguished. Scanning electron microscopy/energy dispersive spectroscopy (SEM/EDS) provides the next level of detail, with higher magnification and chemical analysis capability. This tool is especially useful in characterizing the morphology and distribution of features on the external surfaces. It is also used to determine the grain size of the oxide scales, the growth rate of which is often controlled by short-circuit grain-boundary diffusion. X-ray diffraction (XRD) of the external surface is widely used to determine the scale phases, and electron microprobe analysis of cross sections can accurately determine scale compositions and alloy-depletion profiles. More elaborate studies may employ transmission electron microscopy/scanning transmission electron microscopy (TEM/STEM), Auger spectroscopy, x-ray photoelectron spectroscopy, or chemical analyses of stripped corrosion products.

Design for Oxidation Resistance

James L. Smialek and Charles A. Barrett, NASA Lewis Research Center; Jon C. Schaeffer, General Electric Aircraft Engines

Alloy Design for Optimal Performance

The most general rule followed in alloy design for oxidation is that the alloys must form scales composed primarily of either Al_2O_3, Cr_2O_3, or SiO_2. For model iron-, cobalt-, or nickel-base binary alloys, this occurs at approximately 15 wt% Al, 20 wt% Cr, or 5 wt% Si. Unfortunately, these levels of aluminum, chromium, and silicon result in brittle alloys, and--in the case of silicon--very low melting temperatures. Silicon then is only used in small (1-3 wt%) additions to help stabilize Al_2O_3 or Cr_2O_3 scales. Many high-temperature alloys are, however, based on M-chromium systems having a good compromise of high-temperature mechanical properties and oxidation resistance. Small additions of manganese and silicon are widely used to stabilize Cr_2O_3 scales at concentrations below 20 wt% Cr. Similarly, chromium is widely used at 5 to 15 wt% levels to help stabilize the formation of Al_2O_3 scales at lower aluminum levels near 5 wt%.

The rationale for these secondary additions derives from the opposing trends of transient versus selective oxidation. Here, the initial oxidation process has been described as concurrent oxidation of all the major alloying elements present on the surface, even though one oxide is usually greatly favored from a thermodynamic standpoint. This proceeds until the initial rapid kinetics have transitioned to lower rates and the pO_2 at the oxide-metal interface has been lowered, both of which favor the formation of a healing layer of the most stable oxide. If silicon or chromium are added to a nickel-aluminum alloy, the contributions of slow growing SiO_2 or Cr_2O_3 nuclei during this transient period allow a complete transition to an Al_2O_3 inner healing layer at lower amounts of aluminum. The reduced aluminum level due to chromium additions can be seen in the Ni-Cr-Al ternary oxidation map of Fig. 2 that indicates which compositions form protective Al_2O_3 scales.

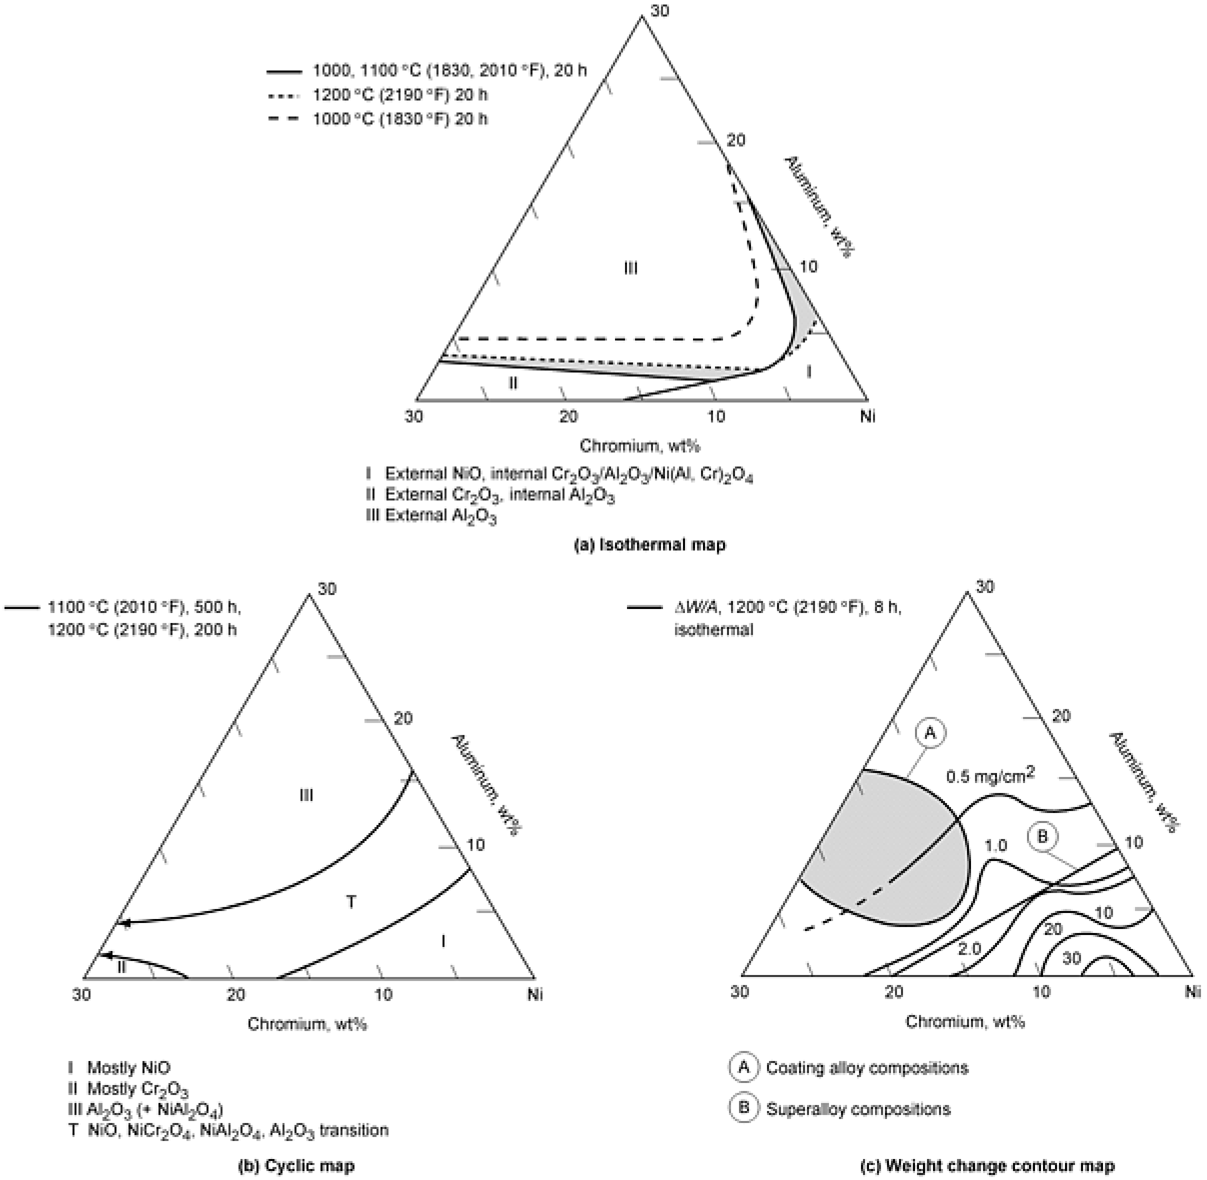

Fig. 2 Ternary oxidation maps for the Ni-Cr-Al system showing regimes for Al_2O_3, Cr_2O_3, $NiAl_2O_4$, $NiCr_2O_4$, and NiO formation. Source: Ref 1

Another important consideration is that of scale adhesion during thermal cycling. The thermal expansion of oxides is much lower than that of most engineering metals such that large compressive stresses are built up in the scale upon cooling. As the scale thickens, these stresses eventually cause some form of scale fracture and spallation. For a strongly adherent scale, spallation often takes the form of microscopic segments in outer portions of the scale, thus relieving stresses without severe degradation. However, a weakly bonded scale can spall at the oxide/metal interface, exposing bare metal upon reheating. This results in more rapid consumption of the critical scale-forming elements, as indicated by Eq 3. Also, depletion zones are more likely to form, and subsequent oxidation products can now include more of the nonprotective transition scales, such as NiO.

The spalling process is of course directly reflected in the weight-change curve (Fig. 3), where each heating cycle is associated with a weight gain, and each cooling cycle produces a superimposed weight loss. For many alloys, the amount of scale spalled has been found to be a function of the (scale thickness)^2 times a spalling constant, Q_o. This process has been modeled in great detail, such that gravimetric curves can be predicted for various k_p growth rates and Q_o (or k_s) spall constants as shown in Fig. 4 (Ref 2, 3, 4, 5).

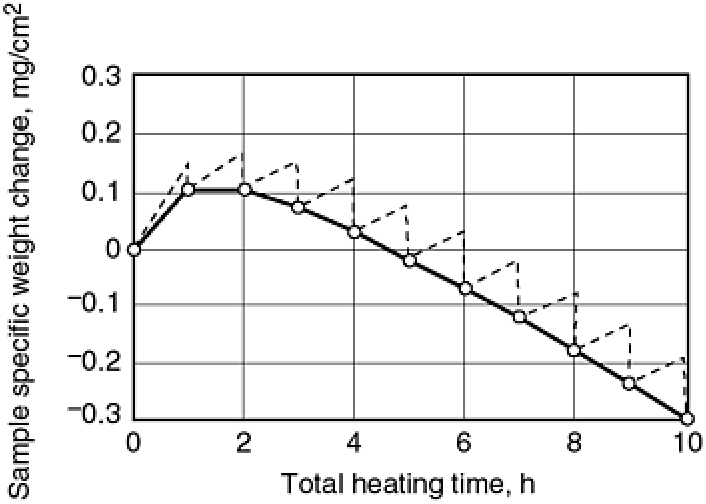

Fig. 3 Idealized cyclic oxidation weight change curve showing parabolic growth legs, punctuated by fractional spall events upon cooldowns. Source: Ref 2

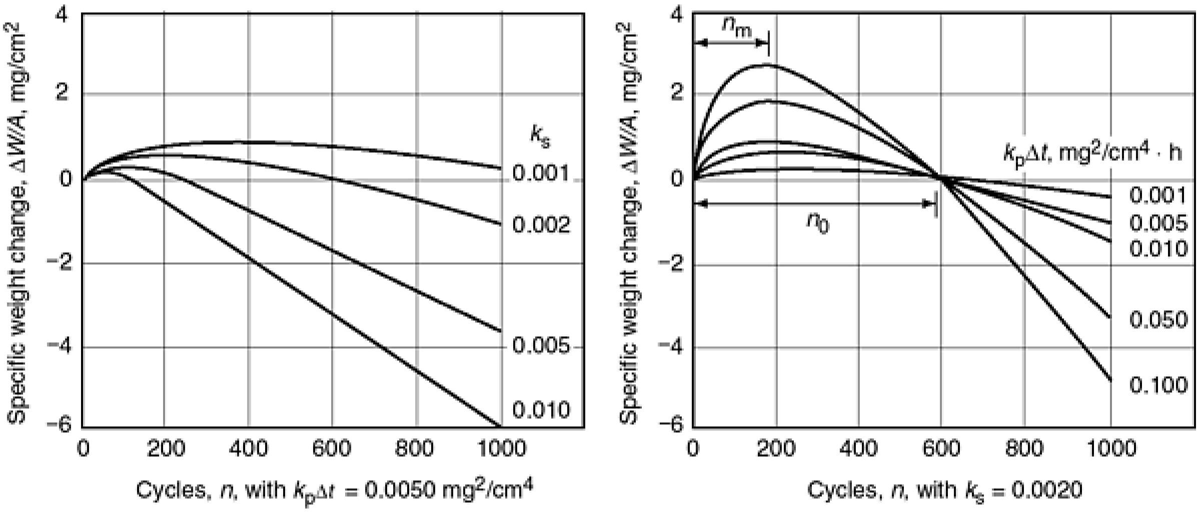

Fig. 4 Family of model cyclic oxidation curves for various parabolic rate constants, k_p, and spall constants, k_s. Source: Ref 5

Adherence is dramatically improved in alloys and coatings by the addition of about 0.01 to 0.1 wt% Y. An example of this effect is shown in Fig. 5. An explanation of the detailed mechanism is still evolving, but many critical experiments have indicated that interfacial segregation of sulfur is associated with scale debonding, presumably by weakening the interfacial bonds (Ref 6, 7). Conversely, the absence of sulfur segregation in desulfurized alloys is associated with good adhesion, even without the use of yttrium (Ref 8). When yttrium is added, it is believed to tie up the sulfur, present as a 1 to 10 ppm impurity in the bulk, by forming stable yttrium-sulfur sulfides or complexes. Other sulfur active elements, such as scandium, lanthanum, zirconium, and hafnium, have also shown this effect and are occasionally present in engineering alloys or coatings. The phenomenon is especially important for single-crystal superalloys, which have the potential of being very oxidation resistant, but are not easily manufactured with yttrium.

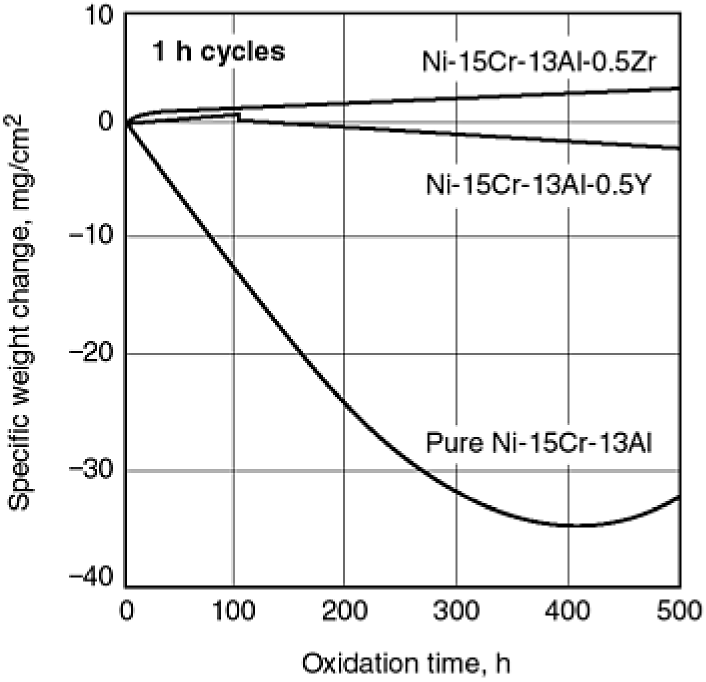

Fig. 5 The effect of a small addition of reactive elements (yttrium of zirconium) on scale adhesion and the 1100 °C (2010 °F) cyclic oxidation resistance of a model Ni-15Cr-13Al (wt%) coating alloy

While the adhesion effect is prominent for Al_2O_3 and Cr_2O_3 scales, it has not been well documented for SiO_2 scales. Cr_2O_3 scales are also subject to fast outward growth when the alloy is not doped with reactive elements. Furthermore, all Cr_2O_3 scales are subject to degradation by formation of a volatile CrO_3 gaseous species and are therefore less suitable for high-velocity applications. Many other phenomena may be encountered in the oxidation of high-temperature alloys, such as the preferential oxidation of carbide phases or grain boundaries. The fundamentals of these phenomena are not widely reported nor easily generalized. However, in practice some alloy-specific process may override otherwise protective behavior, such that performance cannot be projected without consulting test data of the alloy in question.

The preceding is a brief introduction to some general aspects of oxidation that apply to typical high-temperature alloys. They apply equally well to intermetallic compounds, aluminide and MCrAlY coatings, and bond coats for thermal barrier coatings. Excellent treatments of the fundamental aspects can be found in reference books by Kofstad (Ref 9) or Birks and Meier (Ref 10). More detailed information on a wide range of commercial alloys in a variety of environments (carburizing, nitriding, halogens, salts, liquid metals) can be found in Lai (Ref 11). Supplementary information on superalloy oxidation, corrosion, and coatings is present in Ref 1, 12, 13, 14, 15, and 16 and in the review of high-temperature oxidation of iron-, nickel-, and cobalt-base alloys in Ref 17.

Design for Oxidation Resistance

---

Performance Characteristics of Superalloys

Cyclic Oxidation. The oxidation resistance of commercial superalloys can vary dramatically with alloy type, temperature, and specific environment. Thus, although many of the mechanisms referred to in the previous section are usually applicable, it is difficult to generalize the complex oxidation behavior inherent to these multielement systems. One can obtain a better appreciation of this fact by examining the behavior of a large number of commercial superalloys tested in one study (Ref 18). Here, 34 alloys were tested in cyclic oxidation in air at 1100 °C (2010 °F) for 200 h, often with multiple samples, and characterized by weight change and scale phases. Selected alloys were also tested at 1000 °C (1830 °F) for 500 h and at 1150 °C (2100 °F) for 100 h. The result is a database allowing alloy comparisons on a one-to-one basis as well as an illustration of broad, overall compositional effects.

The weight change curves were described by paralinear or linear kinetics, which had been previously correlated to metal loss by means of an attack parameter, K_a (Ref 4). This parameter defines the combined effect of parabolic-scale growth rates and spalling rates on the consumption of metal. It can therefore be used as an engineering design figure-of-merit related to the residual load-bearing cross section of a component.

The results are summarized in a ranking table (Table 1), which orders the alloys according to K_a, along with the final weight change, number of duplicates, and standard deviations. For the most part, weight change and K_a, track each other, to the extent that the 200 h weight loss at 1100 °C (2010 °F) equals 7.6 K_a, in mg/cm^2, from regression analysis. Exceptions occur when an unusually large spread in the data occur for duplicate samples. These spreads may bias the average performance parameters differently than weight change.

Table 1 Ranking of 34 superalloys by the 1100 °C (2010 °F), 200 h cyclic oxidation attack parameter, K_a, and primary composition makeup

Also shown are model K_a values calculated from Eq 5 (see text), final weight changes, ΔW/A, given in mg/cm^2, standard deviations, Σ, and number of duplicates, *n*.

(a) Ni = balance.

(b) Rare exceptions out of the typical composition range.

The compositions of the 34 alloys are also listed in Table 1. In most cases, multiple elemental changes occur with progression down the table, thus obscuring any simple compositional effects on performance. However, many broad general trends can be discerned. For example, fairly consistent compositional blocks have been drawn in. These show consistently high aluminum (>5%), high tantalum (>3%), and low titanium (<1%) for the top-performing alloys. Conversely, lower aluminum (<5%), lower tantalum (<2%), and higher titanium (3-5%) occur more commonly for the poorer-performing alloy groupings. The highest levels of chromium (20-25%) did not necessarily ensure good performance, but 5 to 15% Cr was present in all the best-performing alloys. The very high chromium alloys (20%) did not rank very highly because they also typically contained low aluminum (0-2%). In fact, it has been pointed out that chromium and aluminum contents are usually inversely correlated in commercial superalloys (Ref 1), such that:

$$\frac{1}{2}\text{Cr} + \text{Al} = 10 \qquad \textbf{(Eq 4)}$$

The value of this compositional parameter is also listed in Table 1 and can be seen to vary primarily between the narrow range of 8 to 13.

A graphical illustration of the points made above can be seen in Fig. 6. Here the chromium, aluminum, tantalum, and titanium contents of a select group of eight alloys is plotted against the 1100 °C (2010 °F) cyclic oxidation attack parameter. The broad trend of improved performance (low K_a) with higher aluminum, higher tantalum, and lower titanium contents is apparent. It also appears that good performance is associated with a low chromium content. However, because chromium is inversely correlated with aluminum content so strongly, a separable chromium effect cannot be claimed from this figure alone.

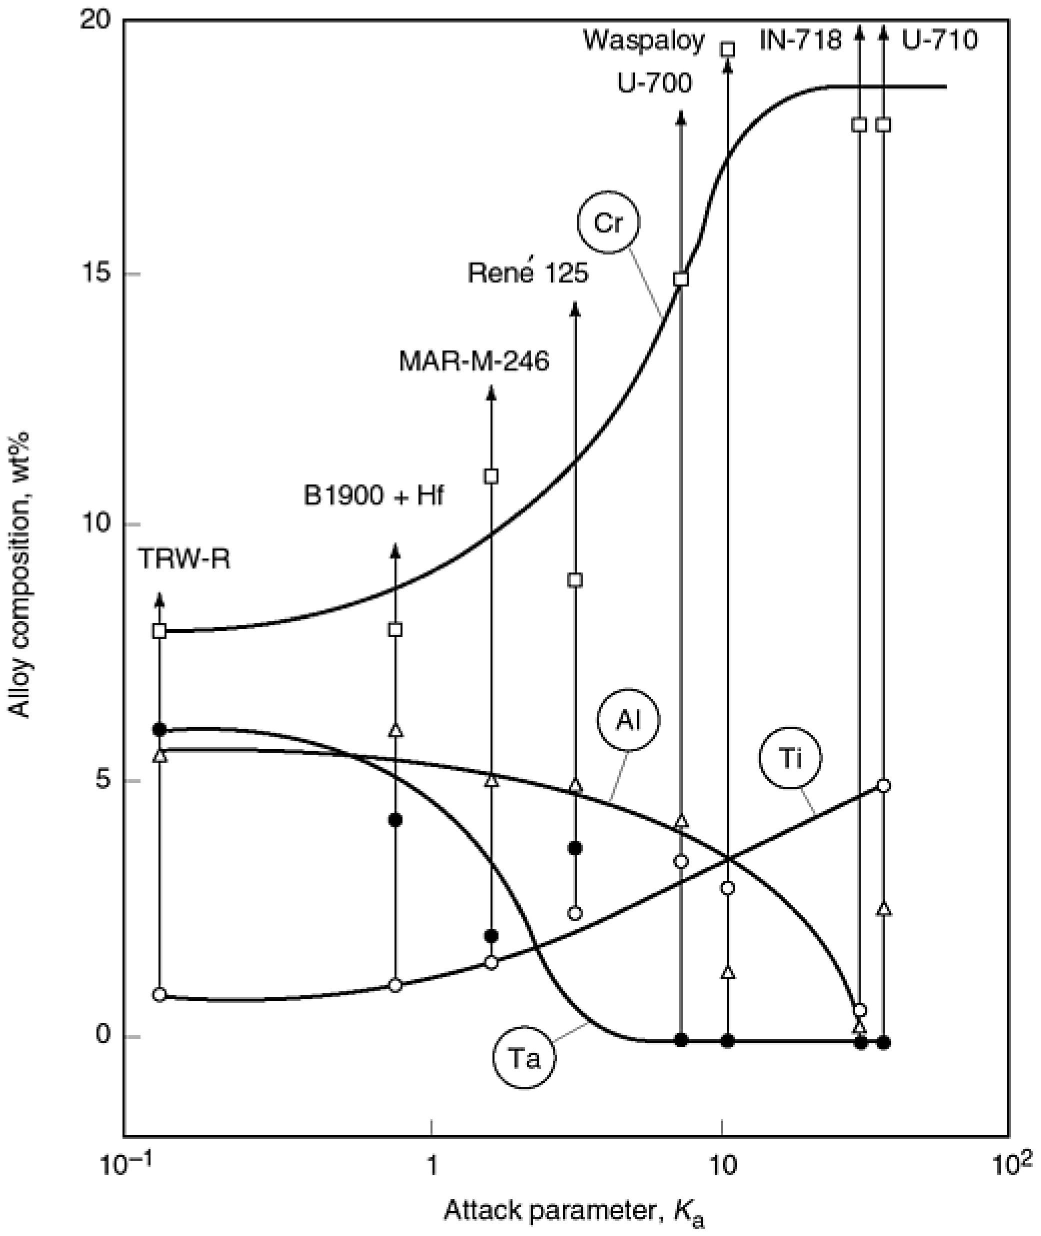

Fig. 6 Compositional trends of eight commercial superalloys with their 1100 °C (2010 °F) cyclic oxidation attack parameter. Source: Ref 18

These eight alloys in Fig. 6 were selected from the master database in Table 1 because their chromium, aluminum, tantalum, and titanium contents all varied in a more or less monotonic fashion with increasing K_a. There were nonsystematic variations in other alloying elements, such as molybdenum, tungsten, and niobium, which are considered to have only secondary effects. Within reason, some compositional trends can be concluded from this simple two-dimensional plot. However, the complexity and interactions of systems containing ten or more alloying elements often obscures individual elemental effects and compositional dependencies. As a result, multiple linear regression was appropriately used to extract more precise compositional parameters affecting performance (Ref 18). An equation thus results that gives the best overall fit (R^2 = 0.84) and accounts for the simultaneous variations of 11 elements and temperature:

$$\log_{10} K_a = x_1(1/T_K) + x_2(\text{Cr}/T_K) + x_3(\text{Cr}) + x_4(\text{CrW}) + x_5(\text{Al}^2) + x_6(\text{AlTa}) + x_7(\text{AlMo}) + x_8(\text{AlV}) + x_9(\text{TaNb}) + x_{10}(\text{TaTi}) + x_{11}(\text{NbTi}) + x_{12}(\text{NbHf}) + x_{13}(\text{Ti}) + x_{14}(\text{Re}) + x_{15} \quad \textbf{(Eq 5)}$$

where:

x_1 = **-28,734**
x_2 = **924.75**
x_3 = **-0.71874**
x_4 = **0.00373**
x_5 = **-0.05162**
x_6 = **-0.03008**
x_7 = **0.01273**
x_8 = **0.16396**
x_9 = **0.05346**
x_{10} = **0.01932**
x_{11} = **0.08140**
x_{12} = **0.24155**
x_{13} = **0.08345**
x_{14} = **0.21293**
x_{15} = **22.756**

Equation 5 can be used to show the relative importance of various elemental changes to a hypothetical superalloy, where, for illustration purposes, only one element was varied at a time. For example, this technique allows the effects of aluminum and chromium to be decoupled. A base alloy was chosen near the composition of the best-performing group of alloys (i.e., Ni-8Cr-6Al-6Ta-4Mo-4W-1Nb-0Ti-0Hf-0V). The variations covered the compositional ranges typical for most of the superalloys in Table 1. Attack parameters predicted by Eq 5 for 1100 °C (2010 °F) oxidation are shown in Fig. 7. The performance of the base alloy is shown as the horizontal dashed line and its intersection with each of the elemental curves. It can be seen that aluminum additions are the most effective in reducing K_a. Tantalum and now chromium can be seen to be beneficial, in that order. Vanadium and titanium were the most deleterious alloying elements. Detrimental effects were also predicted for separately adding the upper limit of the compositional range for niobium, hafnium, tungsten, or molybdenum. Alternatively, improved performance is predicted for removing the base levels of 4Mo, 4W, and 1Nb. No significant trend with cobalt content was found. It should be noted that although some of the modeled behavior exhibits K_a <0.1, these low values were not experimentally observed in this database. The intent of this plot is to address broad trends rather than pinpoint the precise performance of alloys not included in the database.

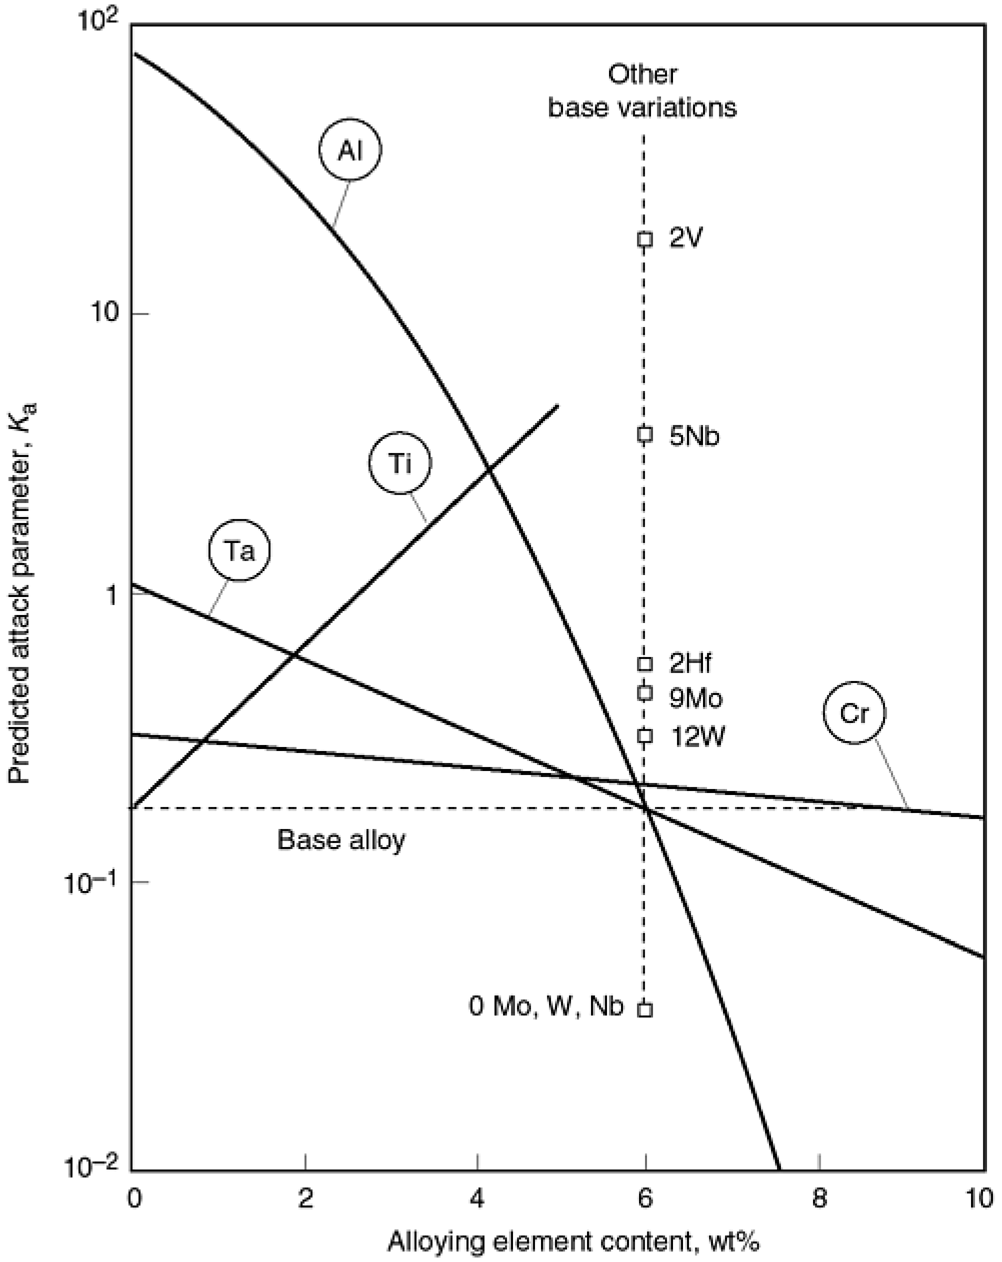

Fig. 7 Modeled (individual element) compositional effects on the 1100 °C (2010 °F) cyclic oxidation attack parameter for a Ni-8Cr-6Al-6Ta-4Mo-4W-1Nb base alloy

A simplified equation was also obtained from a regression model that did not use any cross-term interactions. The resulting equation (R^2 = 0.80) thus extracts coefficients that apply only to individual elements:

$$\log_{10}K_a = \sum x_i(y_i) + x_{12} \qquad \textbf{(Eq 6)}$$

where:

y_i =	x_i =
$1/T_k$	-17,305
Chromium	-0.08308

Aluminum	-0.33925
Tantalum	-0.15488
Titanium	0.26408
Molybdenum	0.04527
Niobium	0.24172
Hafnium	0.17782
Zirconium	0.37654
Rhenium	0.87295
Carbon	2.00000
x_{12} =	14.77172

Again, the relative benefits of aluminum, tantalum, and chromium and the detriment of titanium are evident. Negative effects of niobium, hafnium, zirconium, rhenium, and carbon are also indicated. It should be noted that of these only niobium and rhenium are typically added in excess of 1 wt%. Low hafnium additions (0.1 wt%) are generally considered beneficial to scale adhesion. However, "overdoping" with up to 2 wt% Hf to prevent grain-boundary cracking in columnar-grained superalloys can be detrimental to overall oxidation performance.

Finally, the 1100 and 1150 °C (2010 and 2100 °F) data, along with that from the few alloys tested at 1000 °C (1830 °F), was also incorporated by the model to obtain temperature effects. Thus, for the base alloy Eq 5 produced an Arrhenius relationship for the attack parameter, namely:

$$K_a = 6.5 \times 10^{14} \exp \{(-97{,}570 \text{ cal/mole}) / RT\} \quad \textbf{(Eq 7)}$$

The apparent activation energy, 98 kcal/mole, is quite in line with those generally observed for diffusion in, and growth of nickel-, chromium-, and aluminum-base oxide scales (i.e., 50-125 kcal/mole).

Interrupted Long-Term Oxidation. Another large database was developed for a wider representation of high-temperature alloys (Ref 19). This study tested 68 commercial alloys, including iron-base ferritic and austenitic stainless steels, at 982 °C (1800 °F) for 10,000 h in air, cycled 10 times for 1000 h each. The results are summarized in Tables 2(a), 2(b), 2(c), and 2(d). These tables list the performance (final weight change) and major chemistry by 4 categories:

- Iron-base alloys (Table 2(a))
- Cobalt-base alloys (Table 2(b))
- Nickel-base sheet alloys (Table 2(c))
- Nickel-base superalloys (Table 2(d))

Table 2(a) Ranking of iron-base ferritic alloys and austenitic stainless steels in a 10,000 h, 982 °C (1800 °F), interrupted oxidation test

See Tables 2(b), 2(c), and 2(d) for the rankings of cobalt- and nickel-base alloys that were also tested. A total of 68 commercial high-temperature alloys are ranked.

Source: Ref 19

The best-performing group of alloys was the ferritic alloys with aluminum. These alloys typically contained from 2 to 32% Al and 0 to 18% Cr. They gained between just 1 to 4 mg/cm^2 and formed primarily protective Al_2O_3 scales, as expected from the composition (FeCrAl, FeAl, or Fe_3Al). Conversely, the ferritic alloys without aluminum (Croloys and ferritic stainless steels) oxidized the most as a group, gaining between 100 to 300 mg/cm^2 for all but one sample that lost 165 mg/cm^2. The major scales phases were Fe_2O_3 and occasionally Cr_2O_3 or $(Ni,Fe)Cr_2O_4$ spinel. The austenitic stainless steels performed midway between these groups, with weight changes of 19 to 228 mg/cm^2. One exception was alloy RA-310, which ranked among the better alloys with a gain of only 0.4 mg/cm^2. The major scale phases among this group were $(Ni,Fe)Cr_2O_4$ spinel and Cr_2O_3 or Fe_2O_3.

The cobalt-base alloys exhibited weight changes between a gain of 1 mg/cm^2 and a loss of 10 mg/cm^2 with two exceptions: L-605 samples lost 70 to 100 mg/cm^2 and WI-52 lost 414 mg/cm^2. All alloys exhibited MCr_2O_4 spinel and Cr_2O_3 as the primary scale phases, with no correlation with performance.

The nickel-base sheet alloys with aluminum were often among the best-performing alloys, with maximum weight changes less than 3 mg/cm^2.

The nickel-base alloys with iron exhibited a wide span of performance, with gains as low as 3 mg/cm^2 for IN-601 or losses ranging from 7 mg/cm^2 for Hastelloy X to 510 mg/cm^2 for Hastelloy N. The primary scale phases were usually $(Ni,Fe)Cr_2O_4$ and Cr_2O_3, except for the $NiMoO_4$ and MoO_4 observed on Hastelloy N.

The nickel-base alloys without iron also exhibited widely varying behavior, with weight gains ranging from 0.5 mg/cm^2 for U-700 to 178 mg/cm^2 for WAZ-20, and with weight losses ranging from 1.7 mg/cm^2 for Hastelloy S to -300 mg/cm^2 for IN-100. The scale phases were $Ni(Al,Cr)_2O_4$, NiO, Cr_2O_3, Al_2O_3, or $Cr(Ta,Mo,W)O_4$//$Ni(Ta,Mo,W)_2O_6$ tri-rutile phases, without an overall correlation with performance. However Al_2O_3-forming alloys did the best within this group.

The general picture obtained from this work is that Al_2O_3 formers and some Cr_2O_3 formers can be very oxidation resistant at 982 °C (1800 °F) for 10,000 h. The iron-base materials (ferritic and austenitic stainless steels) containing no aluminum were the least-protective classes of alloys, with a wide range of intermediate to excellent behavior exhibited by the nickel- and cobalt-base alloys.

Similar ranking behavior was observed for the same test conducted at 815 °C (1500 °F) for the majority of alloys (Ref 20). However, now a considerable number of chromia-formers performed almost as well as the alumina-formers. Especially notable improvements, on a relative basis, were observed for Hastelloy C-276, IN-600, IN-706, and type 304 stainless steel when tested at 815 °C (1500 °F) as compared to 982 °C (1800 °F).

Performance Characteristics of Single-Crystal Superalloys

A great deal of current interest in the field of oxidation centers around advanced nickel-base single-crystal alloys. These alloys are used in the most demanding high-temperature applications of gas turbines. Some of the most common of these alloys are PWA 1480, 1484, and 1487 (Pratt and Whitney), René N4, N5, and N6 (General Electric), CMSX-4, -6, and -10 (Cannon-Muskegon), and SRR 99 and RR 2000 (Rolls-Royce). Most of these alloys fall within the following compositional range:

Element	wt%
Chromium	5-10
Aluminum	5-6
Tantalum	2-8
Molybdenum	1-3
Tungsten	4-6
Niobium	0-1
Rhenium	0-6
Titanium	0-5
Hafnium	0-0.3
Cobalt	5-10

These levels make possible, first and foremost, a continuous Al_2O_3 film, upon which excellent oxidation resistance depends. Many of the other elements also participate in scale formation as $Ni(Al,Cr)_2O_4$, $(Al,Cr)TaO_4$, and $NiTa_2O_6$ oxides. These phases, when located as an outer layer, may take part in a relatively innocuous transient growth process. Other nonprotective scales--(NiO, $NiTiO_3$, Cr_2O_3, Ta_2O_5, or $(Mo,W)O_3$--can form after an interval of cyclic oxidation if scale adhesion is lacking.

While this alloy class was not included in the 34 alloy database described earlier (see Table 1), Eq 5 can be used to predict attack parameters. For example, the 1100 °C (2010 °F) K_a for René N5 was calculated to be 0.22, which is comparable to the low value of 0.19 obtained for the base alloy in Fig. 7. Furthermore, the oxidation resistance of these alloys can be dramatically improved by maximizing Al_2O_3-scale adhesion. This is accomplished by the addition of reactive elements or by desulfurization by melt purification and/or hydrogen annealing (Ref 21, 22, 23, 24, 25). Examples of these effects can be seen in Fig. 8, 9, and 10 for René N5, CMSX-4, and PWA 1480, respectively. Yttrium is difficult

to homogeneously incorporate at high levels, but can be effective at just 15 ppm when the sulfur content is low (<2 ppm) (Ref 24). Alternatively, good adhesion is obtained without yttrium if the sulfur content is extremely low (<0.5 ppm).

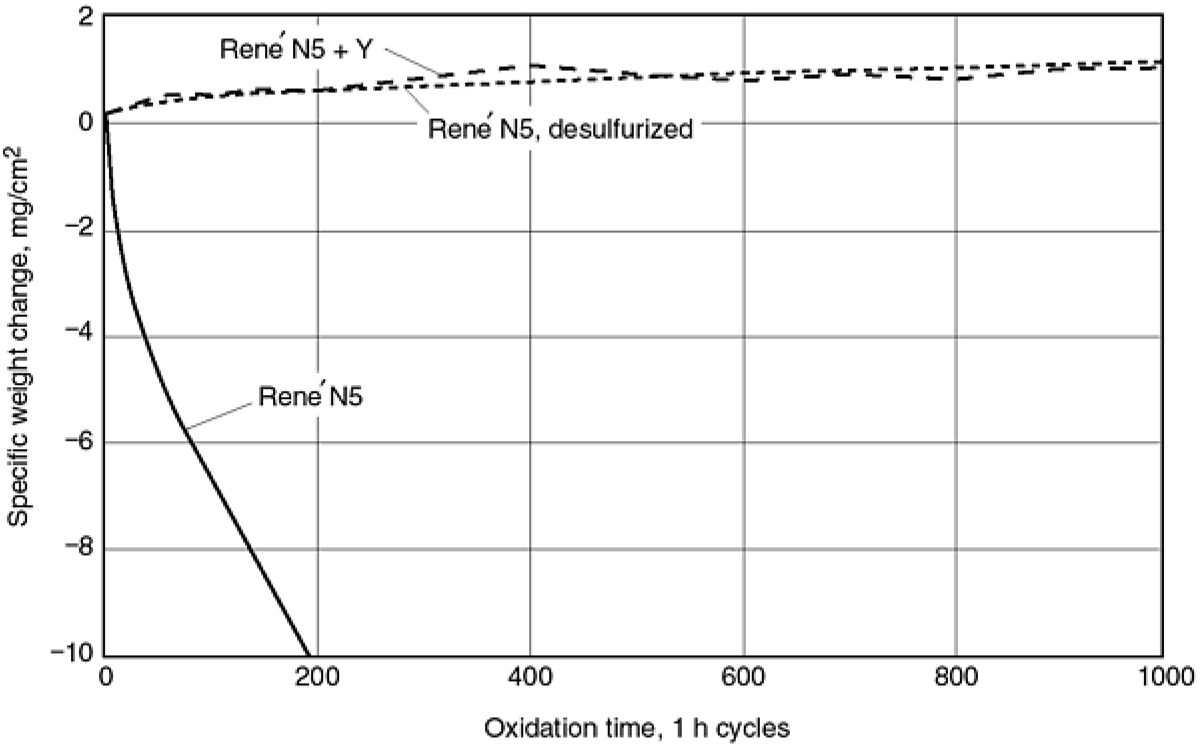

Fig. 8 The effect of desulfurization (1280 °C, or 2335 °F, 100 h hydrogen anneal) or yttrium additions (100-150 ppm) on the 1150 °C (2100 °F) cyclic oxidation behavior of René N5. Source: Ref 8

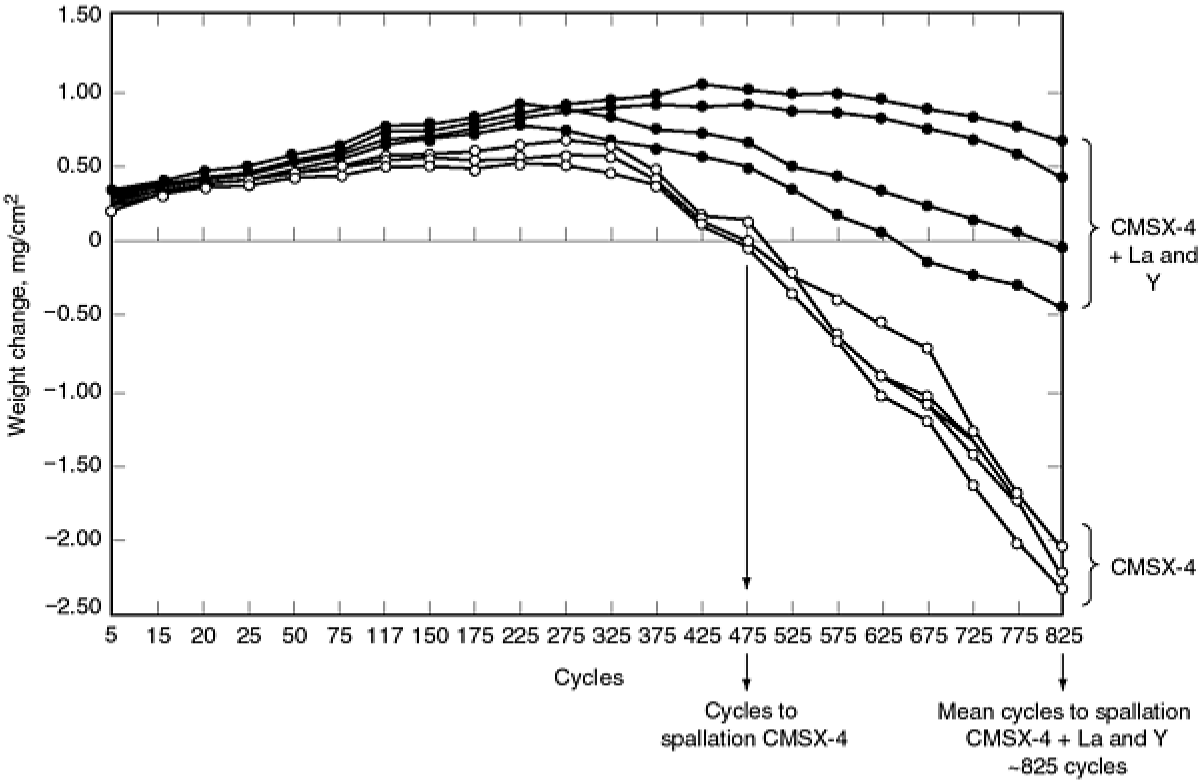

Fig. 9 The effect of 15 to 20 ppm of lanthanum and yttrium on the 1177 °C (2150 °F) cyclic oxidation behavior

of low sulfur (<2 ppm) CMSX-4. Source: Ref 24

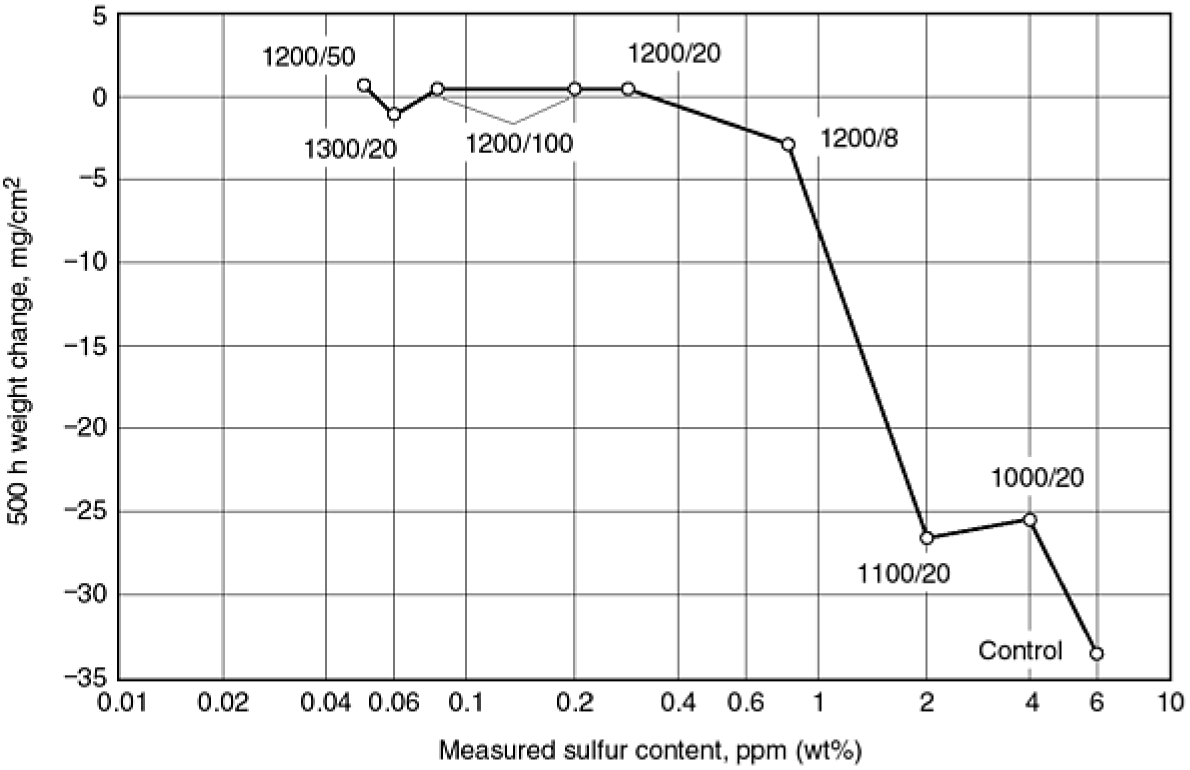

Fig. 10 The effect of sulfur content on the 500 h (cycles), 1100 °C (2010 °F) cyclic oxidation weight change of hydrogen-annealed PWA 1480. The values given inside the figure represent the annealing temperature/time in °C/h. Source: Ref 25

Although some of the best oxidation resistance has been documented for single-crystal alloys, it is not due to the unique monocrystalline structure. Rather, the primary oxidation response stems from the high aluminum and tantalum contents, dopant levels of yttrium and hafnium, low sulfur, and the remainder of the compositional makeup. The absence of grain-boundary carbide strengtheners may also contribute to a more continuous Al_2O_3 scale.

The previous discussion has outlined some of the oxidation issues applying to bare (uncoated) alloys. High-temperature test data have been used for the purpose of discriminating compositional effects. It should be noted that many of the alloys will exhibit acceptable performance for intermediate- to low-temperature applications. But, for the most demanding applications, oxidation-resistant coatings combined with the best alloys become the most practical defense against aggressive environments.

Coating Concepts for Superalloys

Aluminides. The most widely used coating in gas turbines is the intermetallic compound NiAl. The monolithic material has been extensively studied and shown to form protective Al_2O_3 scales, even to the lower aluminum limits of the single-phase stoichiometry. However, in a cyclic mode, the hypostoichiometric compositions have been shown to exhibit degradation because the aluminum depletion from scale spallation can result in depletion zones with reduced oxidation resistance (Ref 26, 27). The use of reactive elements such as zirconium or yttrium have been shown to reduce interfacial spalling and produce some of the highest oxidation resistance ever measured for nickel-base material (Ref 28, 29, 30).

The coatings are generally produced by chemical vapor deposition (CVD) processes (aluminum halide gas or aluminum powder pack) by diffusional reaction with the superalloy substrates. Depending on the temperature and the aluminum activity of the pack, the coatings may be formed by outward nickel or inward aluminum diffusion (Ref 31). Inward diffusion coatings may require a higher temperature anneal to convert a very brittle Ni_2Al_3 phase into NiAl. Inward coatings also have a higher level of substrate elements present. At or below 1000 °C (1830 °F), very long oxidative lifetimes can be expected due to the low growth rate of Al_2O_3 scales and limited spalling. As temperature exceeds 1100 °C (1830 °F), interdiffusion with the substance becomes a major mode of aluminum loss, which then triggers initial coating degradation (Ref 27, 32). Once this dilution takes place, less-protective scales may form with excessive spalling and eventual failure. Interdiffusion is also responsible for potentially embrittling carbide or σ-Widmanstätten phases in the coating/substrate interdiffusion zone.

Dopant elements have been found to beneficially affect aluminide coating performance. Hafnium, zirconium and yttrium increase alumina scale adhesion. Silicon modifications can serve in this regard, but they are especially effective in stabilizing Al_2O_3-scale formation at very low aluminum concentrations. The most widespread aluminide modification is platinum. For example, a 20 μm layer of platinum is first electroplated onto the superalloy and then aluminized to form a $PtAl_2$-(Ni,Pt)Al two-phase mixture or layered structure. Platinum serves many purposes: it stabilizes an aluminum-rich surface phase for continued Al_2O_3 formation; it improves Al_2O_3-scale adhesion; and it improves the hot corrosion resistance of NiAl (Ref 33).

An example of a platinum-aluminide coating on a single-crystal superalloy, exposed in a high by-pass turbofan engine, is shown in Fig. 11. The outer layer is depleted NiAl, with particles of Ni_3Al forming at grain boundaries. The inner layer is an interdiffusion zone, enriched in alloying elements due to nickel dilution in forming the outer layer. Finally, a modified substrate structure is formed beneath this, with topologically closed-packed chromium-rich phases (σ).

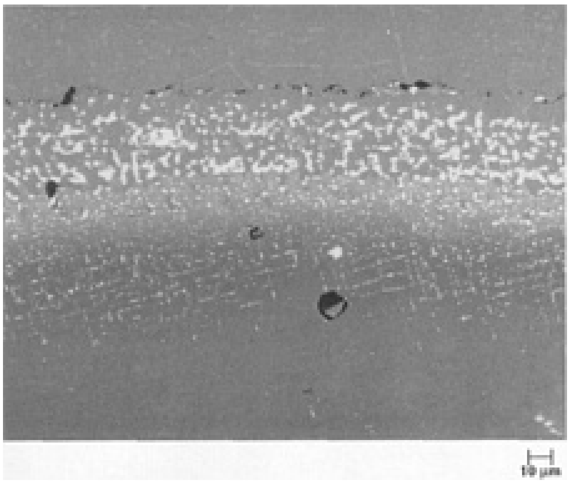

Fig. 11 Microstructure of a platinum-modified pack aluminide coating on a single-crystal superalloy after engine exposure. 600×

Ni(Co)CrAlY. M-(10-30)Cr-(5-20)Al-(0.1-1)Y coatings are also widely used to solve the oxidation/corrosion problems of high-temperature turbine materials. They are generally applied by physical vapor deposition (PVD) or low-pressure (vacuum) plasma spraying (LPPS or VPS). These coatings are also based on excellent Al_2O_3-forming capability (see Fig. 2) but at lower aluminum levels and with an increase in low-temperature ductility. The presence of chromium gives an added defense against sodium sulfate hot corrosion, for which Al_2O_3 formers are not as resistant as Cr_2O_3-formers. Because of the "overlay" coating process and the compositional similarity to the superalloy substrates, these coatings are much less susceptible to diffusional wearout than the aluminide conversion coatings. However, there is a reduced aluminum reservoir to sustain Al_2O_3-scale growth or reformation after spallation.

Thermal barrier coatings (TBCs) enable a large improvement in turbine durability or performance by reducing the operating temperature of the superalloy surface or by allowing hotter gas temperatures. The insulating layer is generally about 125 to 250 μm of 6 to 8% Y_2O_3-ZrO_2, generally referred to as yttria partially stabilized zirconia (YSZ). It is usually applied by plasma spraying (PS) or electron beam (EB)-PVD. A preliminary bond coat is necessary for optimal adhesion. For PS-YSZ, an LPPS NiCoCrAlY type of bond coat is conventionally used, whereas for EB-PVD coatings, a platinum aluminide diffusion coating is used.

The failure mechanism of the TBC in clean environments is a combination of bond-coat oxidation and thermal fatigue (Ref 34). As the Al_2O_3 scale thickens at the YSZ-bond coat interface, it increases the stresses on the adjacent zirconia. During cooldown, the higher-expansion substrate puts large compressive thermal stresses on the zirconia, encouraging it to buckle and pull the thermally grown Al_2O_3 scale off the bond coat. Continued cycling results in crack growth until a critical length is achieved and macrospalling of the ceramic coating occurs (failure).

The surface roughness of the plasma-sprayed system enhances the bond strength by the increased contact area and mechanical interlocking. However, this roughness also produces tensile stress concentrations at the tips of the bond coat asperities and thus initiates interfacial cracking. The porosity and weak, microcracked splat boundaries in the PS-YSZ accommodates much of this stress. In contrast, the EB-PVD coatings with aluminide bond coats have a much smoother interface and less stress concentration, albeit with less mechanical bonding. The thermal stress is accommodated by the columnar structure of the EB-PVD zirconia, which demonstrates a propensity to crack along column boundaries, rather than buckle and debond at the oxide/metal interface. An example of an EB-PVD coating applied to a platinum-aluminide-coated René N5 alloy is shown in Fig. 12. Both systems are expected to benefit by improved Al_2O_3-scale adhesion. This can be accomplished by low-sulfur alloys, low-sulfur coatings, and by reactive element dopants to both.

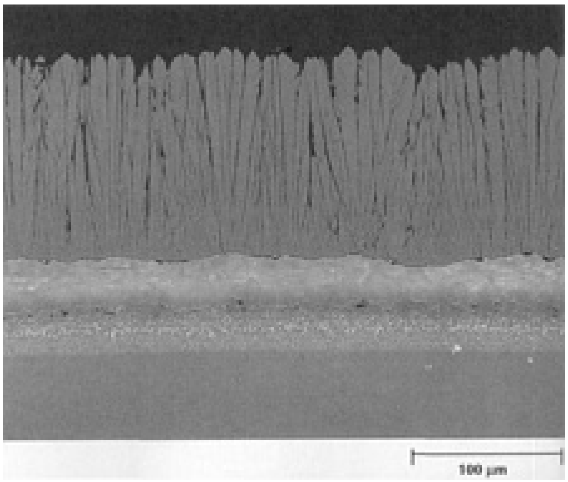

Fig. 12 Columnar structure of an EB-PVD 7% yttria-zirconia thermal barrier coating on a platinum-aluminide-coated single-crystal superalloy. 250×

For more corrosive environments, such as shipboard marine-power turbines, low-melting $NaVO_3$ deposits may destabilize YSZ by leaching out the yttrium to form YVO_4. Destabilization allows a martensitic transformation to monoclinic zirconia accompanied by a large volume expansion and powdering of the coating. Scandia (+india)-stabilized zirconia has been found to be resistant to vanadate corrosion and may provide a benefit in the presence of sea salt and vanadium impurities in the fuel (Ref 35).

The state-of-the-art of processing, stability, service experience, thermal and stress modeling and design, and advanced concepts have been summarized in a recent NASA workshop on TBCs (Ref 36). In addition to aeroturbine components, the applications of this concept to diesel engine and land-based turbines has been described.

Chromizing. In the latter stages of the turbine (low-pressure turbine), the temperatures are reduced to below 900 °C (1650 °F). Thus, high-temperature oxidation is much less of a concern, but the conditions are optimal for Na_2SO_4 deposition and high-temperature corrosion (see the section on "Hot Corrosion" in this article). Chromizing is the CVD or pack deposition of elemental chromium, followed by a diffusion anneal to a nickel-chromium outer layer. This enrichment of chromium provides protection against the scale-fluxing attack that occurs under a molten sulfate deposit.

Performance Characteristics of Other High-Temperature Materials

Nickel and Titanium Aluminides. The oxidation resistance of NiAl has been actively studied since 1970. The fundamental mechanisms were described by Pettit, and regimes of protective behavior were mapped over the equilibrium diagram (Ref 37). Al_2O_3 was found to be stable over the entire temperature range for aluminum concentrations above about 30 at.%. Cyclic oxidation showed rapid spalling and depletion at 1100 °C (2010 °F) for compositions below about 40 at.% (Ref 27). Zirconium and other reactive element additions produced large improvements in scale adhesion, allowing protective behavior at 1200 °C (2190 °F) for 3000 h as shown in Fig. 13 (Ref 28, 29). Reactive element oxide dispersoids were also effective in this regard (Ref 30). Long-term durability is directly keyed to the large aluminum reservoirs in Ni-50Al-base alloys and the ability to supply aluminum to the surface with minimal depletion-zone formation until the bulk composition has dropped to 40 at.% (Ref 26). Impressive gains in low-temperature ductility and high-temperature strength were made for microalloyed single-crystal NiAl alloys (Ref 38, 39). However, widespread use as a free-standing structural material has not yet been realized.

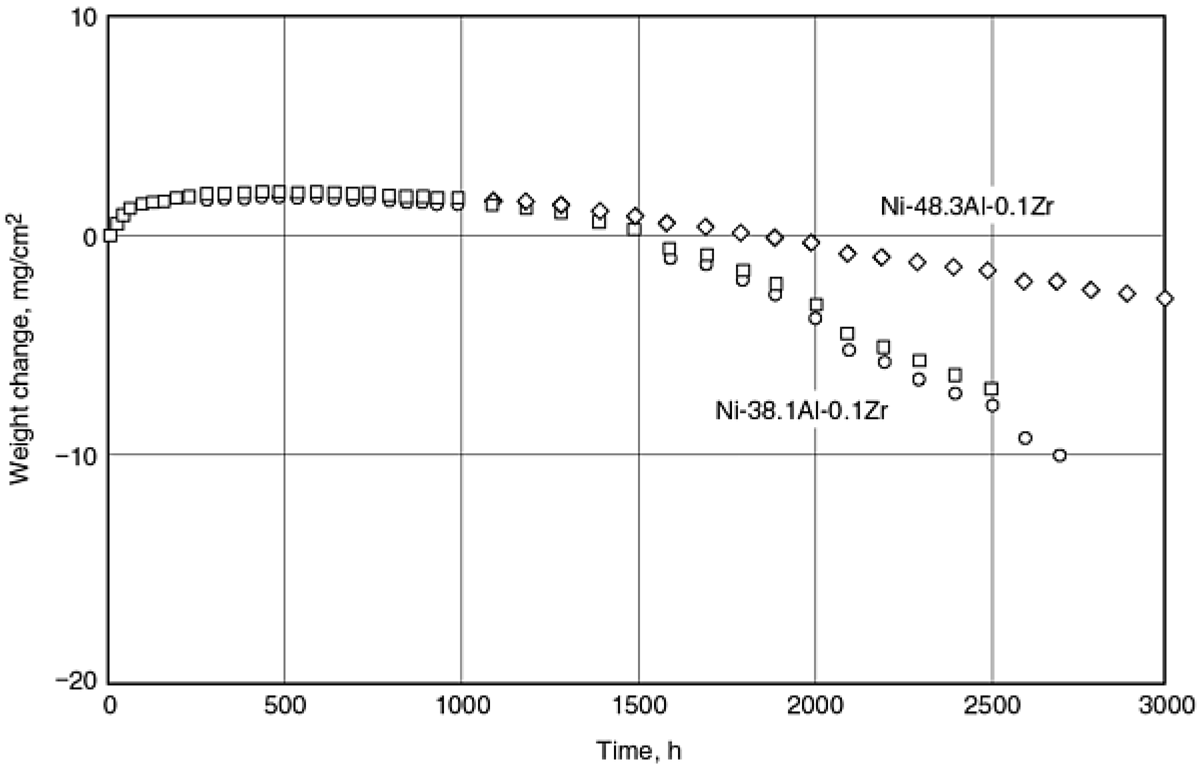

Fig. 13 Long-term protective 1200 °C (2190 °F) cyclic oxidation behavior of NiAl + 0.1 at.% Zr. Source: Ref 28

Ni_3Al has been ductilized (by 0.1% B additions) to a much greater extent and has moderate oxidation resistance below 1000 °C (1830 °F) (Ref 40). However, an intermediate temperature embrittlement phenomenon is observed. Similarly, Fe_3Al and FeAl alloys have been engineered with moderate ductility (1-5%) and moderate oxidation resistance (Ref 41, 42). Some of the iron aluminide alloys have exhibited exceptional sulfidation resistance in recuperator environments from coal gasification plants and are also a low-cost alternative to nickel-base candidates.

Various titanium aluminides are being actively researched and considered for the latter stages of the compressor or turbine sections and have also found application in automotive valves and turbochargers. Ti-24Al-11Nb (at.%), Ti-22Al-24Nb (at.%), and Ti-48Al-2Cr-2Nb (at.%) (called the α_2-, orthorhombic-, and γ-phase alloys, respectively) have very attractive specific strength values because of their very low densities. The oxidation behavior has proved to be very complex, in that layered, intermixed TiO_2 + Al_2O_3 scales are the rule, with possible beneficial or detrimental effects of air versus oxygen environments (due to titanium nitride) (Ref 43, 44, 45). In general, the oxidation rate becomes excessive above 900 °C (1650 °F) for the α_2 and orthorhombic alloys. Furthermore, at 700 °C (1290 °F), surface hardening (embrittlement) of these two alloys has been observed due to oxygen interstitial diffusion (Ref 45). An effective coating would be very desirable; however, most attempts at aluminide, silicide, or MCrAlY coatings have only resulted in lowering fatigue lives.

The oxidation rate of γ-phase TiAl-base alloys is much more acceptable, and the embrittlement phenomena are much less prominent, requiring exposure above 800 °C (1470 °F) to achieve measurable hardening (Ref 45). However, TiAl alloys are inherently brittle, with maximum tensile ductilities on the order of just 1 to 2%. A predominance of Al_2O_3 in the scale on γ-phase alloys results in moderate oxidation resistance at 800 °C (1470 °F) as shown in Fig. 14. Considerable improvements are indicated by some experimental coatings that are based on the TiAl + Cr alloys (Fig. 15).

The oxidation behavior of nickel, iron, and titanium aluminides, as well as a number of other developmental intermetallic compounds, have been extensively reviewed. Recently published reviews can be found in Ref 46, 47, 48, and 49.

Refractory metals such as niobium, molybdenum, tantalum, tungsten, and rhenium are natural candidates for high-temperature applications because of their extremely high melting points (2250 to 3400 °C, or 4080 to 6150 °F). However, they exhibit some of the highest oxidation rates of structural metals to the extent that they are rarely used in oxygen-containing environments without coatings. Even with coatings, the potential for catastrophic failure generally limits their applications to less-critical components or short missions (e.g., rocket nozzles or exhaust nozzles of military turbines).

Coatings for refractory metals and their alloys are typically based on disilicides (MSi_2) that form protective SiO_2 scales. Some additives enable lower-melting silicates to flow and seal through-cracks that inevitably form because of thermal expansion mismatch stresses with the substrate. The coatings are generally applied by slurry spraying followed by vacuum sintering, where other additives are used to lower the processing fusion temperature of the coating. Typical components include molybdenum, niobium, titanium, iron, cobalt, chromium, and silicon (Ref 50).

While maximum lifetimes of hundreds of hours at 1500 °C (2730 °F) may be expected in an isothermal exposure for, say, a defect-free $MoSi_2$ coating, repeated cycling will trigger degradation by cracking. For example, bars of FS85 (Nb-28Ta-10W-1Zr) were slurry fusion coated with a commercial R512E coating (20Cr-20Fe-60Si) and tested in a 30 min cycle Mach 0.3 burner rig (Ref 51). This exposure produced coating breaches (defined by -5 mg/cm^2 weight losses) at 170, >200, 120, and 110 cycles for 982, 1093, 1260, and 1371 °C (1800, 2000, 2300, and 2500 °F) exposures, respectively. Except for the 1093 °C (2000 °F) exposure, all samples showed catastrophic oxidation pits or massive substrate attack at the specimen edges. Oxidation products were friable mixtures of Nb_2O_5, $FeNbO_4$, SiO_2, and amorphous silicates.

$MoSi_2$ has also been developed as a free-standing structural material. Its most common application is as ultrahigh temperature heating elements (SuperKanthal) for furnaces (up to 1700 °C, or 3090 °F). Its oxidation resistance is derived from extremely slow-growing SiO_2 scales (Fig. 1). However, at low temperatures (500 to 700 °C, or 930 to 1290 °F), $MoSi_2$ exhibits a classic "pest" catastrophic oxidation mechanism, where a sample literally turns to dust in a short amount of time. This mechanism has been shown by TEM techniques to be caused by stresses from a voluminous oxidation product of an inward-growing SiO_2 and MoO_x microfilament mixture (Ref 52, 53). Rapid inward diffusion of oxygen is allowed by the MoO_x microfilaments. In a defect-free and stress-free material, pest can be avoided or at least delayed. In practice, pest is prevented by compositing with silica-base glass, boron compounds, or silicon nitride (Ref 54). At high temperature, MoO_3 is very volatile and leaves the scale by vaporization, with little effect on the silica growth rate. More detailed information on high-temperature silicides can be found in Ref 55.

Ceramics also have very high melting (or decomposition) temperatures and are candidate materials for high-temperature applications. The primary corrosion and oxidation mechanisms and considerations have been reviewed in a number of publications by Jacobson (Ref 56, 57). From the standpoint of oxide ceramics, the conventional oxidation reaction is precluded. In actual combustion environments, however, there may be reactions with combustion products leading to volatile species and surface recession. For example, the reaction of water vapor with SiO_2 and some silicates leads to gaseous $Si(OH)_4$, with loss rates that could measurably decrease component thickness in high-temperature, high-velocity, high-pressure environments. Conversely, the reactivity of Al_2O_3 in a combustion environment is very limited, without any serious conversions to gaseous products, and zirconia reactions are virtually nonexistent.

The nonoxide ceramics, silicon carbide (SiC) and silicon nitride (Si_3N_4), are very refractory, oxidation-resistant materials that have been widely studied for high-temperature applications. In pure oxygen, these materials, like $MoSi_2$, are among the most oxidation-resistant (nonoxide) materials known. The low scale-growth rate is due to slow-growing SiO_2 scales, which may be amorphous below about 1300 °C (2370 °F) or for short oxidation times. At extremely high temperatures (1700 °C, or 3090 °F) the evolution of CO or N_2 reaction products may produce large bubbles that could disrupt the protective scales (Ref 58). In addition, at low pO_2 and high temperatures, a passive-to-active oxidation transition occurs in which the reaction product is now a nonprotective SiO gas. These silica-formers are also subject to the volatility issues in water vapor discussed above.

Other corrosive reactions with ceramics are not widely encountered. However, if alkali-containing deposits appear on silicon-base systems, a particularly damaging reaction may occur (Ref 56). For example, the catalyst for sea salt hot corrosion in turbine alloys, Na_2SO_4, has been shown to react with SiO_2 scales formed on SiC or Si_3N_4. A molten sodium-

silicate product rapidly results, with bubble and pit formation in the substrate and fracture strength reductions of up to 50% (Ref 59, 60).

Design for Oxidation Resistance

James L. Smialek and Charles A. Barrett, NASA Lewis Research Center; Jon C. Schaeffer, General Electric Aircraft Engines

---

Degradation Due to Hot Corrosion and Particulate Ingestion

Most of the preceding discussions have evaluated alloy and coating performance on the basis of oxidation resistance and the appropriate mechanisms. However, there are other common environmental durability issues that in some cases supersede oxidation as the primary mode of attack of gas turbine components. As described below, these include hot corrosion of superalloys and airfoil degradation due to deposits resulting from ingested particles or sand.

Hot Corrosion

The subject of hot corrosion of superalloys is extremely complex and to a certain degree controversial. It entails the detailed chemical reactions involved with the effects of a molten Na_2SO_4 deposit on the oxidation process and the dissolution of oxide scales coupled with the formation of sulfides in the alloy. Na_2SO_4 forms from the reaction of ingested NaCl salt with the sulfur impurity in the fuel. Because deposition is not favored at high temperatures (>1000 °C, or 1830 °F), hot corrosion is generally limited to lower temperatures. Increased corrosion results from higher deposition rates (higher sodium and sulfur impurity levels, higher pressure, and lower temperature).

The propagation modes for hot corrosion are intimately related to the reactions between the molten deposits and the alloys. In particular, the deposits cause nonprotective reaction products to be formed. As will be briefly described below, the nonprotective reaction product is formed because of a "fluxing" action of the molten deposit. A more detailed review of the overall formalisms of hot corrosion is provided by Pettit and Giggins (Ref 14).

The thermodynamics of Na_2SO_4 dissociation define an SO_3 pressure and oxide ion (O^{2-}) activity product (equilibrium constant). This equilibrium is used to assess whether certain oxides will dissolve in the molten deposit. The term basic fluxing describes oxide dissolution when O^{2-} combines with the scale to form a soluble MO^{2-} radical. It is generally

associated with temperatures >900 °C (1650 °F) and is so termed high-temperature hot corrosion (type I). Sulfide formation and alloy depletion ahead of the corrosion front is a typical characteristic.

The term acidic fluxing defines dissolution when a soluble metal M^{2+} ion and O^{2-} are produced from the scale. Acidic fluxing is generally associated with a temperature range of 650 to 800 °C (1200 to 1470 °F) and is thus termed low-temperature hot corrosion (type II). However, the presence of molybdenum, tungsten, or vanadium in the alloy can also induce these soluble M^{2+} ions to form, even at higher temperatures. Type II corrosion does not generally exhibit a depletion zone or sulfides ahead of the corrosion front.

For protection against hot corrosion, a high chromium content is the best alloying strategy under all conditions, unlike the recommendations outlined for simple oxidation. For basic fluxing, a sufficiently high aluminum content (10%) to ensure continuous Al_2O_3 formation can physically inhibit corrosion, but is not as chemically resistant as Cr_2O_3. Chromium also decreases the O^{2-} concentration and prevents NiO basic dissolution. Thus high chromium can protect both physically and chemically. For acidic fluxing, a high aluminum content is not effective in preventing corrosion. High molybdenum, tungsten, or vanadium contents exacerbate acidic corrosion, while chromium decreases the rate of acidic corrosion.

Hot Corrosion Data. A large database of alloy hot-corrosion resistance has been developed (Ref 61). Here 96 commercial and laboratory superalloys were exposed to a Mach 0.3 burner rig test, at 900 °C (1650 °F) for 300 h in 1-h cycles, using 0.5 ppm NaCl in the combustion air and jet A-1 fuel with 0.05 to 0.07 wt% S. The extent of corrosion was monitored by the percentage of metal cross section consumed, as determined by quantitative metallography.

The top 12 alloys exhibited less than 2.0% of consumed cross-sectional area. The only compositional distinction was that the chromium content varied from 12.6 to 17.9% and the aluminum content varied from 2.1 to 6.9%. Conversely, the 12 poorest-performing alloys contained 4.0 to 10.7% Cr and 4.9 to 6.5% Al. Thus, improved performance was definitely biased toward high-chromium alloys. High-aluminum/low-chromium alloys were not especially corrosion resistant. No distinction in the titanium, tungsten, molybdenum, tantalum, niobium, cobalt, or zirconium content was apparent in these two extreme groups.

Sulfur-Induced Hot Corrosion. Sulfidation is another corrosion mechanism that is of great concern in coal-fired power systems (boiler tubes, exhaust gas heat exchangers, etc.). Basically, nickel-, cobalt-, and iron-base alloys are not sulfidation resistant in high pS_2 or pSO_2 (low pO_2) environments because diffusion is very rapid in the sulfide scales that form on these alloys. Nickel sulfide has a parabolic rate constant seven orders of magnitude higher than that of nickel oxide. These sulfides have a very defective (nonstoichiometric) lattice, allowing fast cation transport. Low-melting sulfides are common, which only intensifies the problem. The addition of chromium (>50 at.%) will decrease the nickel sulfidation rate by three orders of magnitude, but this rate is still a factor of 10^5 times that of Cr_2O_3 growth. A similar effect occurs with the addition of 20 wt% Al to Fe-20Cr, where the resulting improvement is vastly inferior to that produced in oxidation environments.

The corrosion products and mechanisms are much dependent on the partial pressures of the sulfur-containing gas, for example, H_2S/H_2, S_2/Ar, SO_2/O_2, as well as on temperature. Preoxidation has been found to delay the onset of sulfidation, especially with Al_2O_3 scales; however, the oxides of nickel, cobalt, iron, chromium, and aluminum have all been found to allow sulfur penetration. Thus, the design of materials for ultimate sulfidation resistance is lacking. Alloy design for immediate levels of sulfur-containing gases has been fruitful (Ref 40). More detailed information on sulfidation can be found in Ref 9, 10, and 11.

Airfoil Degradation Caused by Particulate Deposits

In particularly dusty or sandy terrain (the Middle Eastern countries and the southwestern United States), substantial amounts of particulates can be ingested from airborne particles. These have a geological connection with the region and have been identified as silica sand, complex silicates, dolomite/calcium sulfates, and salts. The chemistries vary from pure SiO_2 sand to Ca-Al-Fe-Mg silicates, $(Ca,Mg)CO_3$, $CaSO_4$, and NaCl (Ref 62, 63). When passed through the combustor, these particles melt and are splat deposited on the surfaces of airfoils. The deposits have chemistries similar to the fines analyzed from sand samples. However, the carbon content is reduced because of gaseous CO_2 formation and the sulfur content is increased because of calcium and magnesium reactions with the sulfur impurity in the fuel which leads to sulfate deposits.

Although the calcium-magnesium-aluminum-silicate (CMAS) deposits are relatively refractory, they easily cover over cooling holes and decrease cooling effectiveness at the outer airfoil surfaces. The consequent temperature increase has an obvious structural debit, but it also increases the oxidation rate of the alloy. In extreme cases, burn-through was apparent in helicopter turbine airfoils. Furthermore, it poses the probability of accelerated release and diffusion of foreign elements from the deposit into the protective scales and alloy surfaces. Thus, sulfide formation or very low melting calcium-aluminum or magnesium-aluminum eutectics might result. For TBC-coated airfoils, these deposits have been found to infiltrate the porous zirconia and degrade resilience by filling beneficial microcracks and by increased high-temperature sintering (Ref 63). Any defense against this type of attack, however, is difficult to imagine from the standpoint of improved alloy/coating design. Filters for helicopter turbines and frequent inspections or washdowns would be more appropriate for known high-risk service routes or land-based turbine locations.

Limitations: Testing Techniques and Life Prediction

Isothermal thermogravimetric tests and cyclic furnace tests are relatively standard throughout the industry such that the measured k_p or weight change curves from different laboratories can be compared. Some ramifications occur because of variations in the length of the tests or the cycle duration. Burner rig testing becomes more problematic in that different rigs may operate at different velocities, may be pressurized, or may be operated at various levels of impurity dopants (salts) to the fuel. The most common Mach 0.3 atmospheric rig, with 1 h cycles is probably the closest standard oxidation rig test. However, to screen systems for corrosion resistance, individual laboratory preferences for salt level and cycle profile vary and depend on proprietary correlations with engine experience or models of atmospheric salt ingestion. Furnace corrosion tests are almost exclusively targeted toward basic understanding because of the high levels of salt deposits and unrealistically short incubation times. Thermal barrier coating performance is also difficult to faithfully simulate because the failure modes are stress related and the true stress state on a cooled airfoil is substantially different than that on a furnace coupon (no thermal gradient) or uncooled burner rig bar. Mechanical degradation of stressed high-temperature components (turbine airfoils) may also have an oxidation component, but the synergistic mechanisms are not as widely studied or recognized.

Design for Wear Resistance

Raymond G. Bayer, Tribology Consultant

Introduction

WEAR is damage to a solid surface as a result of relative motion between it and another surface or substance (Ref 1). The damage usually results in the progressive loss of material. The scientific measure used for wear is volume loss. However, in engineering the concern with wear is usually associated with dimensional or appearance changes that eventually affect performance and not with volume loss. As a result other measures are often used in practice, such as depth of the wear scar on a mechanical component or the degree of haze with optical components.

For any material, wear can occur by a variety of mechanisms, depending on the properties of the material and the situation in which it is being used. Wear resistance is, therefore, not an intrinsic material property like hardness or elastic modulus. Both wear and wear resistance are system properties or responses.

Collection of all the mechanical, chemical, and environmental elements that can affect wear and wear behavior is referred to as the tribosystem. Typical factors that can affect wear behavior are the properties of the materials, the nature of the relative motion, the nature of the loading, the shape of the surface(s), the surface roughness, the ambient temperature, and the composition of the environment in which the wear occurs. Tribosystem design parameters are those parameters that affect wear and that the designer can specify and alter. Designing for the control of wear involves selecting values for tribosystem design parameters in order to obtain acceptable wear behavior or life. The process for doing this is called wear design.

Fundamentally, wear design consists of identifying those design factors that can affect wear and then determining values for them on the basis of their effect on wear rate. The aim is to achieve an acceptably low wear rate. Common tribological design parameters are materials, surface contours, lubrication, and roughness. However, these are not the only ones that can be considered design parameters. For example, loading, type of relative motion, and various environmental parameters may be utilized as design parameters in some situations.

Different design parameters influence wear rate in different ways. There are four fundamental ways to reduce wear rates: by modifying the surface to make it more wear resistant, by using a more wear-resistant material or material pair, by increasing the separation between the surfaces, and by reducing the severity of the contact (i.e., by modifying those features of the wear situation that tend to increase wear rate). Often, the wear rate reduction associated with a design parameter comes from a combination of these methods.

For example, one common method for reducing wear rate is to use a lubricant. A lubricant can reduce wear rate by reducing surface shear forces, by reacting with the surface to form a more wear-resistant surface layer, or by acting as an interposing layer that decreases the amount of contact between the contacting surfaces. In most situations all three elements are present. A lubricant can also conduct heat away from the contact region. In situations where temperature of the contacting surfaces is a factor in wear behavior, this is another way by which a lubricant can affect wear.

Wear design methodology consists of four general activities: system analysis, model selection, data selection, and verification. In order to perform these activities successfully, it is necessary to have a basic understanding of wear behavior and a familiarity with engineering models for wear. Consequently, this article provides a brief overview of these topics in the sections "Wear Behavior," "Lubrication," "Material Selection for Wear Applications," and "Wear Models." Wear design principles and practices are addressed in the sections "Wear Design" and "Methods for Wear Design." Additional comprehensive information on tribology is provided in *Friction, Lubrication, and Wear Technology,* Volume 18 of the *ASM Handbook.*

Raymond G. Bayer, Tribology Consultant

Wear Behavior

Three general types of wear situations are common. The first occurs when two solid bodies are in contact and move relative to one another. This first situation is generally subdivided by the predominant nature of the relative motion, such as sliding, rolling, or impact. The second situation occurs when the wear is caused by a liquid moving relative to a solid surface. Wear in that situation is often called erosion or erosive wear. The third situation, which is generally referred to as abrasive wear, occurs when the wear is caused by hard particles. Erosion and abrasive wear situations can also be subdivided into more specific categories. Examples of these are cavitation erosion, solid particle erosion, gouging abrasion, and slurry erosion.

Wear Mechanisms

There are four general ways by which a material can wear in the aforementioned situations: adhesive processes, abrasive or deformation processes, fatigue or fatigue-like processes, and oxidative or corrosive processes.

Adhesive Wear. With adhesive processes, wear occurs as a result of the bonding that takes place between two surfaces in contact. With subsequent separation of the two surfaces, material from either surface may be pulled out, resulting in wear.

Abrasive wear processes are those fracture, cutting, and plastic deformation processes that can occur when a harder surface engages a softer surface. These mechanisms tend to produce machining-chip-like debris.

Fatigue or fatigue-like wear processes are those associated with crack initiation and propagation or progressive deformation as a result of repeated contact, such as the ratchet mechanism proposed by K. Johnson (Ref 2, 3).

Corrosive wear processes are those associated with the loss of wear of in situ formed reaction product (e.g., oxide layers).

Interaction among Wear Mechanisms. The foregoing mechanisms are not mutually exclusive. They can coexist and interact to form more complex wear processes.

When worn surfaces are examined, features indicative of more than one mechanism are usually found. However, in most tribosystems one type of mechanism tends to predominate and ultimately be the controlling one. Except for adhesive wear processes, these processes can result from sliding, rolling, and normal impact motions. Adhesive wear processes normally occur only with sliding. However, adhesive wear processes can occur under nominal impact and rolling conditions, because of the slip that is often present in those situations.

The relative wear rates of these mechanisms can differ by several orders of magnitude, depending on the wear situation. Table 1 shows the observed range of a dimensionless wear coefficient for each of these mechanisms under sliding conditions. This coefficient is obtained by dividing the amount of wear by the distance of sliding and the load and multiplying by the hardness of the wearing surface. The value for each of the mechanisms is based on data obtained from tribosystems in which that mechanism is considered to be the predominant one. The higher the value, the more severe the wear situation. Generally, engineering applications require that this coefficient be in the range of 10^{-5} or less. In some cases, very small values are required. Automotive engine cylinder applications often require values in the range of 10^{-8}. Table 1 shows that the most severe forms of wear are associated with adhesive and abrasive wear mechanisms.

Table 1 Sliding wear coefficients

Wear mechanism	Sliding wear coefficient[(a)]
Adhesive wear	10^{-7} to 10^{-1}
Abrasive wear	10^{-6} to 10^{-1}
Corrosive wear	10^{-7} to 10^{-2}
Fatigue wear	$\leq 10^{-6}$

(a) $(V \times H)/(P \times S)$, where V is the volume of wear, H is the hardness (load per unit area), P is the applied load, and S is the sliding distance

Control Methods. Fortunately, the severity of these mechanisms can be controlled and reduced to acceptable levels by the appropriate choice of various design parameters.

Adhesive Wear Control. The severity of adhesive wear mechanisms can be reduced by the appropriate selection of material pairs and by the use of lubricants, as shown by the range in data in Table 1. Studies have indicated that adhesive wear requires a minimum stress to operate. This stress is typically a small fraction of the materials hardness. Consequently, the severity of adhesive wear can also be reduced by reducing the contact stress.

Abrasive Wear Control. The severity of abrasive wear mechanisms caused by the roughness of a counterface can be reduced by reducing the roughness of that surface. With wear by particles, the severity can be reduced by reducing the number and size of the particles causing the wear. This is shown by the range in abrasive wear coefficients in Table 1. For abrasive or deformation wear processes to occur, the wearing surface must be softer than the particle or asperity causing the wear (Fig. 1). Consequently, these mechanisms can be eliminated by making the wearing surface harder than the particles causing the wear. However, this does not mean that these particles can no longer cause wear. Wear is still possible by fatigue and fatigue-like processes, which are generally milder.

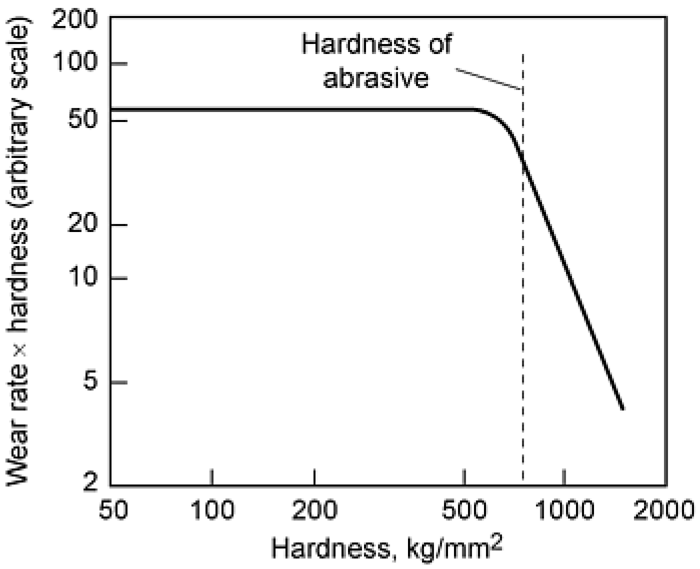

Fig. 1 Abrasive wear behavior as a function of surface hardness. Source: Ref 4

Tribofilms. In addition to these material wear processes, there are system wear processes associated with the formation of tribofilms. Tribofilms are films composed of wear debris that form on wear surfaces. If the layer is entirely composed of material from the counterface, it is called a transfer film. If it is composed of material from both surfaces, it is called a third-body film. (The term *third-body film* is also used to describe any material layer that accommodates velocity changes between two surfaces and those films resulting from environmental interactions.) With respect to wear, these films tend to

act as lubricants by separating the two surfaces. However, these films do not necessarily result in reduced friction. The relative motion between the two surfaces is accommodated by relative motion in the film or at a film and surface interface. When there is sufficient coverage, the wear rates of the surfaces are controlled by the rate at which material is lost from the tribofilms. Under these conditions, normalized wear rates tend to be in the range of 10^{-5} or less. Tribofilm formation is a major factor in the wear behavior when self-lubricating materials are used, such as the polytetrafluoroethylene-filled plastics, but the effect is not limited to those types of materials. Tribofilms have also been observed to occur with metals, plastics, and ceramics. Because lubrication tends to inhibit the formation of these films, the effect of these films tends to be more significant in unlubricated systems than lubricated ones.

Wear-In. Initial wear behavior of a tribosystem is often different from long-term behavior. There are two reasons for this. One is that wear and wear processes modify surfaces and it may take some time before stable surface or contact conditions are established. Another is that the relative mix of mechanisms can change, either as a result of the changes to the surfaces and the interface, or because some mechanisms, such as fatigue, may require some time to become significant. The most significant changes occur during the initial period, which is often called the break-in or wear-in period. During this period, conformity between surfaces is improved, roughness is modified, stable oxides and tribofilms are formed, and work hardening and thermal softening can occur. Wear rates are generally higher during this period, as well. While long-term wear rates tend to be lower than initial wear rates, they are not necessarily constant. Depending on the tribosystem, long-term wear rates may change as a result of the nature of the dominant wear mode. For example, fatigue wear modes are frequently stress dependent. For non-conformal contacts at constant load, wear rates would continue to decrease as the wear results in increased contact area and, hence, lower contact stress.

Severe versus Mild Wear. There are two broad, qualitative classifications for wear behavior: severe and mild, Wear is generally classified as severe in those situations where the features of the worn surfaces are relatively coarse and have high normalized wear coefficients. For sliding, severe wear behavior is generally associated with coefficients greater than 10^{-4}. With mild wear, the features of the worn surfaces are finer. Wear coefficients are also smaller but not insignificant. Severe wear behavior cannot be tolerated in most applications. All materials can exhibit both mild and severe wear characteristics, depending on the tribosystem in which they are used. Transitions between these two modes are often related to such parameters as load, speed, stress, and amount of lubrication, but they can also be related to other parameters (Ref 5). For example, changes in relative humidity or the type of abrasive particles encountered can also result in mild-severe wear transitions. Often these types of transitions are sharp (Fig. 2). While mild-severe wear transitions are generally the most significant in engineering, transitions can also occur in mild and severe wear behavior. Wear maps are a graphical representation of transition boundaries (Ref 7). This can be seen in Fig. 3, which shows a wear map for unlubricated sliding of a steel couple.

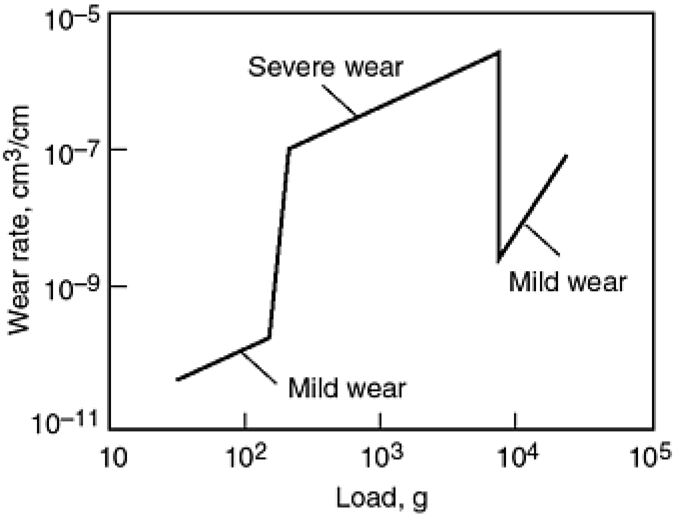

Fig. 2 Mild to severe wear transition in the case of unlubricated sliding between two steel surfaces. Transitions occur as a result of changes in the nature of the oxide formed in each region. Source: Ref 6

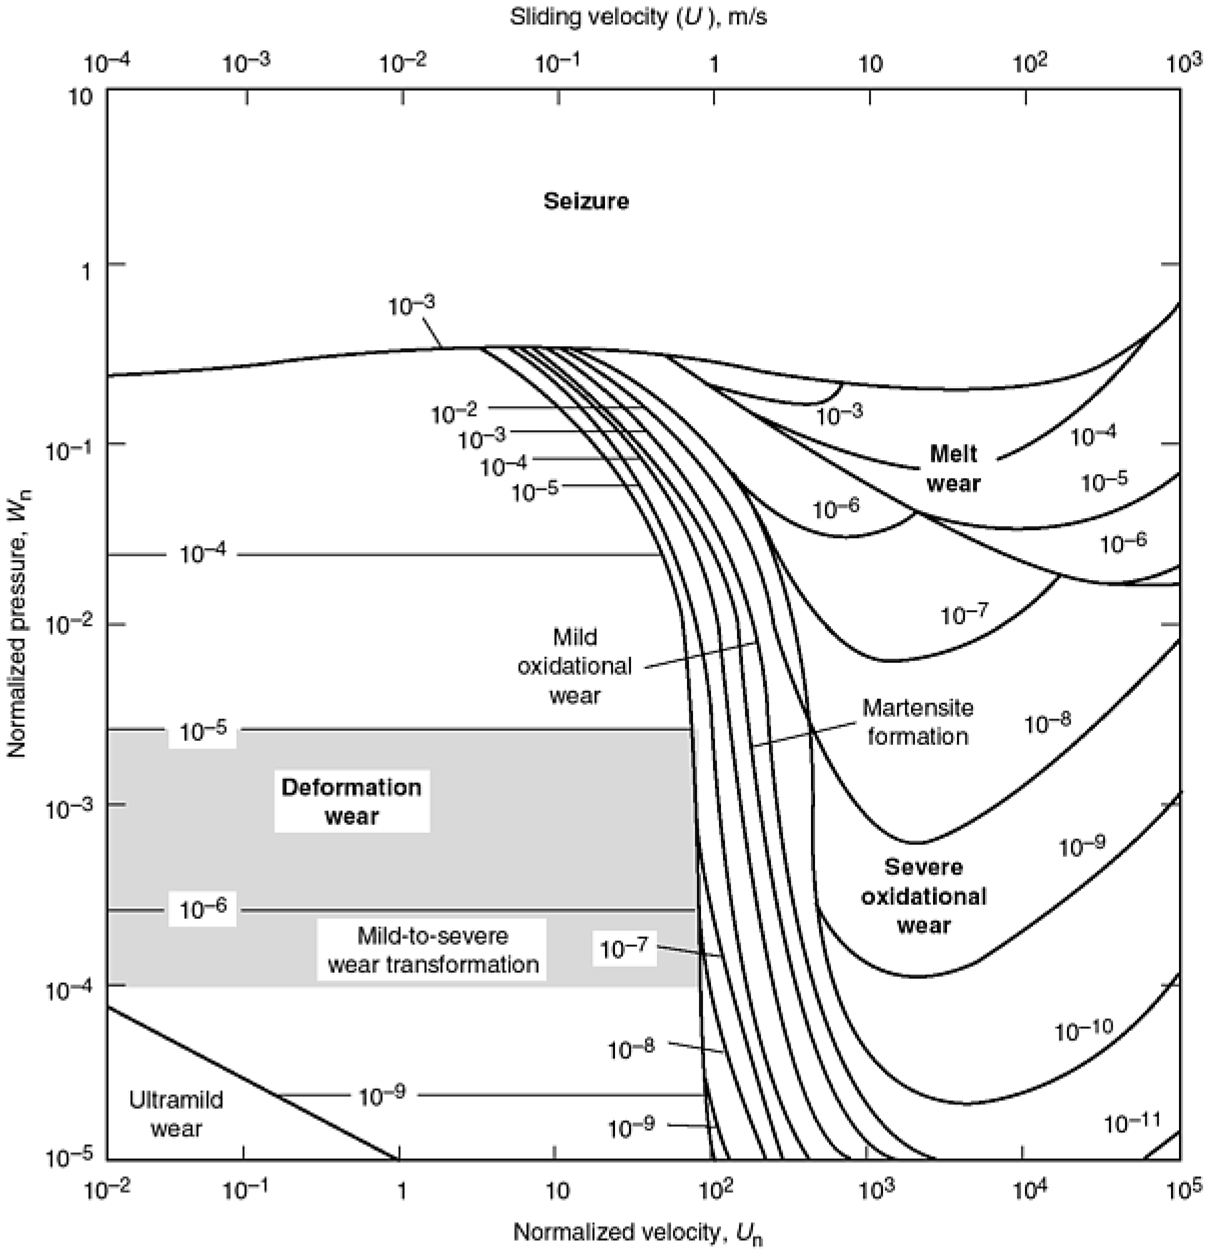

Fig. 3 Wear map for unlubricated sliding between two steel surfaces. Source: Ref 7

The relationship between wear or wear rate and design parameters depends on the nature of the wear mechanisms involved and, consequently, on the tribosystem. These relationships can be linear or nonlinear. For example, in the case of adhesive wear, simple theoretical models indicate that wear volume is proportional to load. On the other hand, models used to describe fatigue wear typically indicate that wear volume is proportional to some high power of the load. As a result, if adhesive wear is the predominant mechanism, the relationship between wear volume and load would be linear. If fatigue is the predominant mode for the tribosystem, a nonlinear relationship would exist. This is also illustrated by the different dependencies on parameters such as load, usage, and hardness found in empirical studies of different wear situations.

Table 2 provides an operational classification of tribosystems, identifying the type of wear mechanisms involved and controlling factors. Relationships that can be used to describe wear in these situations are shown in Table 3.

Table 2 Operational classification of wear situations

Motion	Environment	Mechanisms
Two-body contact		
Rolling		
With slip	Without particles	Fatigue Adhesive
	With particles	Fatigue Adhesive Abrasive
Without slip		Fatigue
Trends: Wear increases with increasing slip and presence of particles. Adhesive and abrasive wear modes can predominate but with pure rolling fatigue modes predominate. Mildest wear situation. Smooth surfaces preferred		
Impact		
With stationary body		Fatigue (elastic or plastic)
With moving body	Dry, without particles	Fatigue (elastic or plastic) Adhesive
	Dry, with particles	Fatigue (elastic or plastic) Adhesive Abrasive
	Fluid, without particles	Fatigue (elastic or plastic) Adhesive
	Fluid, with particles	Fatigue (elastic or plastic) Adhesive Abrasive
Trends: With stationary body, induced vibrations and misalignment can cause fretting, which tends to increase wear. Plastic deformation generally unacceptable except in short life applications. For lives greater than 10^6, contact stresses need to be in the elastic range. With moving object, wear increases with the amount of sliding and sliding effects can predominate. Fluid lubrication effects can be very significant. With particles, wear tends to increase.		
Sliding		
Unidirectional	Dry	Fatigue Adhesive
	Fluid	Fatigue Adhesive
	Particles	Fatigue Adhesive Abrasive
Cyclic	Large amplitude, dry	Fatigue Adhesive
	Large amplitude, fluid	Fatigue Adhesive
	Large amplitude, particles	Fatigue Adhesive Abrasive
	Small amplitude, dry	Fatigue Adhesive
	Small amplitude, fluid	Fatigue Adhesive
	Small amplitude, particles	Fatigue Adhesive Abrasive
Trends: More than one type of mechanism involved. Fatigue mechanism is mildest and conditions that minimize adhesion and abrasion preferred. Low contact stresses preferred. Mild to severe wear transitions often associated with the transition from elastic to plastic deformation. Predominant mechanisms(s) can change with wear. In mild wear situations, terminal mode often fatigue. With the presence of particles, abrasion tends to become predominant mode. Nature of contact shape, such as large area, conforming, line, and point, can be significant in wear behavior.		
One-body contact with fluid		
Impingement		
Low angle	Without particles	Fatigue
	With particles	Abrasive (cutting)
High angle	Without particles	Fatigue
	With particles	Fatigue Abrasive (deformation)
Flow		

Streamline	Without particles	None
	With particles	Abrasive (cutting)
Turbulent	Without particles	Fatigue
	With particles	Fatigue Abrasive
Trends: In flow situations, without particles, cavitation wear mechanism. Impinging fluid droplets act like particles. Corrosion effects often present		

General comments: With fluids other than lubricants, synergistic effects between corrosion and wear often occur. In all situations, oxidative wear effects are probable with metals and ceramics. Operational characterization may be different for different locations on a part.

Table 3 Wear models for design

Sliding	
General model	$V = kL^m S^n$
K factor model	$V = KLS$
Zero wear model (conditions for zero wear)	$\tau_{max} \leq 0.54\tau_y$ $2000(\gamma_R \tau_y)^9 = (S/W)(\tau_{max})^9$
Measurable wear model[(a)]	
Variable energy mode	$d[Q/(\tau_{max}W)^{4.5}] = Cd\,(S/W)$
Constant energy mode	$dQ = Cd\,(S/W)$
Impact	
Percussive impact model	$V = kv^m N$
Zero wear model (condition for zero wear)[(b)]	$N_0 = (2000/1 + \beta)\,[\Gamma_R (\sigma/\sigma_y)]^9$
Measurable wear model[(c)]	$dV = (V/N)\,dN + g(9V/\sigma)\,d\sigma$
Rolling	
General model	$V = kL^m N$
Surface endurance model (condition for surface cracks)	$N_1 \sigma_1^m = N_2 \sigma_2^m$
Load-stress factor model	$L_e = K_1 \{w/[(1/R_1) + (1/R_2)]\}$ $\log K_1 = [(B - \log N)/A]$
Abrasion	
General model	$V = kLS$
Erosion	
General model[(d)]	$e = KAI$
Liquid drops model	$e = K \sin^n \alpha M v^m$
Particles model	$e = [K_d v^n \cos^n \alpha \sin(\pi\alpha/\beta) + K_b v^m \sin^m \alpha]\,M$
Vibration-induced cavitation model	$e = K\delta^n$
Jet-induced cavitation model	$e = Kv_j^n$
Key to symbols	
A	Function of attack angle
e	Erosion rate
I	Function of stream intensity
L	Load
L_e	Endurance load
M	Erodent rate
N	Number of impacts
N_0	Zero wear life (impacts)
Q	Cross sectional area of scar
S	Sliding distance
v	Velocity of impact (impact model); velocity of drops or particles (erosion model)
V	Volume of wear
v_j	Velocity of jet
W	Length of contact area
α	Angle of incidence
β	Ratio of surface damage to subsurface damage in compound impact situations (impact model); tribosystem empirical coefficient (erosion model)

δ	Amplitude of vibration
σ	Peak contact pressure
σ_y	Yield point in tension
τ_{max}	Maximum shear stress
τ_y	Yield point in shear
$C, k, K, K_b, K_d, m, n, \gamma_R, \Gamma_R$	Tribosystem empirical coefficients

Design for Wear Resistance

Raymond G. Bayer, Tribology Consultant

Lubrication

Friction is the resistance to relative motion between two bodies in contact. A lubricant is defined as any substance that reduces the friction between two surfaces. The use of these materials is one of the principal ways of reducing wear and extending the life of mechanical equipment. Lubricants provide a low shear interface between surfaces by physically separating those surfaces and by allowing the formation or modification of surface films on those surfaces. While the principal effect of lubrication on wear behavior is associated with the reduction of adhesive wear, the other types of mechanisms can also be affected by the presence of a lubricant. For example, mechanisms that are influenced by shear stresses, such as some deformation and fatigue mechanisms, can be affected by changes in traction caused by the use of a lubricant. Oxidation wear mechanisms can be affected by the changes in surface films resulting from the use of a lubricant. Lubricants can also inhibit or modify the formation of tribofilms.

In general, lubricants tend to reduce wear. However, there are some situations in which they can increase wear. For example, they may inhibit the formation of a beneficial tribofilm without providing adequate lubrication. This is often the case in tribosystems in which self-lubricating materials are used. Another example is abrasive wear situations, where abrasive particles tend to agglomerate or where wear debris can clog an abrasive counterface. These actions tend to reduce abrasive wear rates, but in these situations, lubricants tend to prevent the agglomeration or clogging, which leads to a higher wear rate. In abrasive wear situations a lubricant can also reduce the critical angle for cutting, which also tends to increase wear.

Lubrication can also affect wear behavior in other ways. In circulating systems, lubricants can provide cooling to the interface and remove wear debris. In non-circulating systems, oil and grease films tend to hold abrasive particles in dirty environments, which can lead to increased wear.

Except for abrasive and erosive wear situations, the effective application of lubrication generally results in mild wear behavior. Severe wear behavior in a lubricated situation is often an indication of lubricant breakdown, improper lubricant selection, or an inadequate supply. Even though one of the ways a lubricant works is to separate the surfaces, thick lubricant layers are not required to obtain significant improvements in wear performance. Thin films, even down to monomolecular layers, can have significant effects provided that they are maintained.

Lubrication by thin films is often referred to as boundary lubrication. Its effectiveness primarily depends on the ability of the lubricant to coat or react with the surface. With fluids it is possible to generate thicker films as a result of squeeze film effects in the fluid. As a result of these effects it is sometimes possible to achieve complete separation of the surfaces, which virtually eliminates wear. This is referred to as fluid lubrication. (Design procedures for lubrication are beyond the scope of this article and can be found in books on bearing design and fluid lubrication.) The state of lubrication between boundary and fluid lubrication is called mixed lubrication. Wear rates are lower with mixed lubrication than with boundary lubrication (Ref 11).

By using almost any lubricant, wear rates are generally reduced by one to two orders of magnitude. However, there can be significant differences in the lubricating abilities of different lubricants, so it is often possible to obtain larger reductions (e.g., several orders of magnitude) by optimizing the selection. Lubricant selection for a wear application often involves two other elements. One is supply of the lubricant. If there is an inadequate supply, wear rate will increase, as shown in Fig. 4. The other is the chemical stability of the lubricant in the application. Generally, when a lubricant degrades, its ability to protect the surface is decreased and wear rates increase.

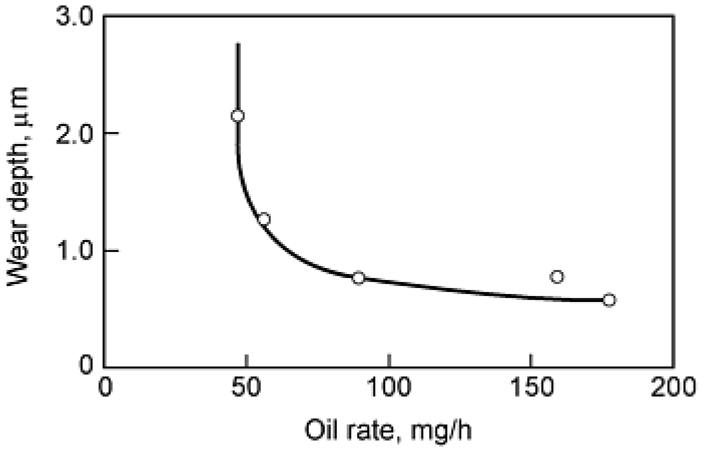

Fig. 4 Effect of oil supply rate on the wear of a high-speed printer component. Wear occurred at the interface between a pivoting type element and a type carrier backstop. The materials were hardened steel. The wear resulted from a combination of impact and fretting. Source: Ref 12

Types of Lubricants. Lubricants are either fluids or solids. The fluid category includes gases, liquids, and greases. Common solid lubricants are molybdenum disulfide, polytetrafluoroethylene, graphite, and soft metals. Because fluids tend to be displaced easily, other materials are frequently added to enhance their boundary lubrication characteristics. Solid lubricants and reactive compounds are often used in greases and oils for this reason. These types of additives are generally called extreme pressure (EP) additives. Solid lubricants are also used as fillers in plastics to make self-lubricating materials. With these materials the solid lubricants provide lubrication by forming tribofilms on the rubbing surfaces. While fluid films tend to be more easily displaced than solid lubricant films, they have the ability to self-heal. Solid lubricant layers do not. However, this limitation of solid lubricants is removed when they are used as additives and fillers (Ref 13).

While lubrication is used to reduce both friction and wear, the effects that a lubricant has on each of these phenomena can be different. As a consequence, the best lubricant for friction reduction is not necessarily the best for wear reduction.

Often the coefficients of friction can be similar for different lubricants, while wear rates can differ by orders of magnitude. Table 4 contains data that illustrate these two points.

Table 4 Effect of different lubricants on friction and wear for reciprocating sliding in a ball-plane

Oil	Steel/steel		Stainless steel/steel	
	Coefficient of friction	**Depth of wear, μm**	**Coefficient of friction**	**Depth of wear, μm**
A	0.14	1.93	0.16	0.30

Design for Wear Resistance

Raymond G. Bayer, Tribology Consultant

Material Selection for Wear Applications

Some fundamental criteria can be applied in the selection of a material for wear applications. The primary criterion is that the material remain chemically, mechanically, and thermally stable under the operating conditions. A secondary criterion is that the nominal contact stresses be within the elastic range of the material. If either of these criteria is not met, it is likely that severe wear behavior and unacceptably high wear rates will result. For long life under sliding it is generally desirable to have a 2-to-1 or larger ratio between yield point and nominal contact stress. For impact and rolling this ratio can be smaller, approaching 1, and still be acceptable, In abrasive wear situations, it is generally desirable to have the material harder than the abrasives present, or at least of comparable hardness, to minimize wear and obtain long life. A corollary is that if a particular material must be used, the conditions of use need to be changed so that these criteria are satisfied.

As stated above, material wear resistance is not an intrinsic property, like elastic modulus or density. It tends to vary with the wear situation and is best viewed as a system response. While there is a general trend for wear to decrease with increasing hardness, there is considerable scatter about that trend. As a consequence, material hardness is generally not a sufficient indicator of wear resistance or wear performance in specific situations. It is often necessary to consider other properties of the material as well. Basically this is because hardness is not the only material property that is associated with wear behavior, and because the differences between materials are not limited to hardness, particularly in the case of different types or classes of materials. Because of the many factors associated with wear behavior, different types of materials tend to be used for different wear situations (Ref 15). Table 5 provides an overview of typical wear applications for different classes of materials.

Table 5 Typical wear applications for selected engineering materials

Materials	Sliding			Rolling				Three-body abrasion	Fluid erosion	Cavitation	Drop erosion	Particle erosion

Because of the system nature of wear, rankings of materials in terms of their wear resistance often change with the nature of the wear applications or the nature of the wear test used to determine the rankings. For example, rankings obtained

from abrasive wear tests are typically not the same as those obtained from nonabrasive wear tests. Similarly, different rankings tend to be obtained in lubricated and unlubricated tests or in high- and low-speed tests, among others. Because of this, wear tests used to rank or evaluate materials for use in specific situations need to simulate the wear application in all essential details (Ref 8, 16, 17, 18, 19, 20, 21). The basic elements that need to be considered in simulation are loading conditions, contact geometry, motions involved, and environmental conditions.

Highly wear-resistant materials are often materials that maintain average wear characteristics under extreme conditions, such as high ambient temperatures or a corrosive environment. As a result, these kinds of materials may provide no better and sometimes poorer wear performance than other materials in situations where these extreme conditions do not exist.

Wear Models

Because of the complex nature of wear behavior, there is no universal wear model that is applicable to all situations. However, there are wear models that can be used for design for specific situations (Ref 8, 9, 10, 22). There are models for generic wear situations, such as rolling and sliding, as well as models for specific devices, such as journal and roller bearings. Table 3 contains a list of models used for sliding, rolling, impact, and erosion. Table 6 lists some application models. These models provide relationships between wear and design parameters in a number of forms. In some cases the relationships are for the amount of wear, others are for wear and erosion rates, and still others are for equivalent wear conditions (i.e., those combinations of load and usage that result in the same amount of wear).

All these models involve one or more empirical coefficients, which are material and environment dependent. While empirical, they tend to be heuristically related to or based on a variety of general physical concepts and mechanisms. These heuristic concepts can often be used as an aid in the application of these models to particular situations. For example, they are often of use in estimating the values for the empirical coefficients, in evaluating the applicability of a model to a given situation, or in extending a model. In-depth treatment of these models and their use can be found elsewhere (Ref 8, 9, 10).

While there are a number of different models available for design use, most wear situations encountered in design can be adequately covered with the use of relatively few. The zero wear model for sliding (Ref 8, 23), the measurable wear model for sliding (Ref 8, 24), the zero wear model for impact (Ref 8, 25), the measurable wear model for impact (Ref 8, 26), and the surface endurance model for rolling (Ref 8, 27), summarized in Table 3, are applicable in most engineering situations where abrasion is not predominant. In those situations in which abrasion predominates, the abrasive wear model given in Table 3 provides good correlation with performance.

The coefficients of the models are determined from wear tests that match the conditions required by the model. In most cases not all of the coefficients of the model can be determined simply by measuring wear after a certain amount of time, sliding distance, or number of operations. It is generally necessary to develop a wear curve or series of wear curves that can be analyzed to determine the coefficients for the model. A wear curve is a plot of wear versus time, sliding distance, or number of operations. While laboratory tests are often used to determine values for different materials and environmental conditions, it is sometimes possible to analyze existing hardware data to determine the coefficients. In situations where there is neither available data for the specific materials or environmental conditions involved in the application nor the ability to perform the appropriate tests, it is generally possible to estimate the values, based on published data regarding these models. Such information can be found in Ref 8, 9, 10 and 15.

Wear Design

Wear design involves four elements (Ref 8): system analysis, modeling, data gathering, and verification.

System analysis is the starting point of a wear design. It begins with the examination of the design and the identification of possible wear points or concerns. It then involves the characterization of the tribosystem associated with each one. Initially this characterization may be very general and more qualitative than quantitative. It might simply be the determination of the general nature of the wear situation, such as lubricated sliding at low or moderate temperatures or a particle erosion situation with possible corrosion. As the wear design proceeds, system analysis involves such elements as the determination of loads and contact stresses, detailed characterization of the environment, detailed characterization of the motions involved, and determination of the factors that affect these variables. System analysis also involves the determination of how much wear can be allowed and the establishment of a failure criterion. In general it consists of all those elements needed to implement the modeling and data gathering elements.

Modeling. The modeling phase of a wear design approach involves the selection of a model, which provides a basis for the determination of the design. Model selection is basically done by matching the characteristics of the tribosystem to the descriptions of the various wear models and selecting the most appropriate one. Once this is done, the model is then used to determine the values of the design parameters necessary to obtain the desired wear life or performance.

Data Gathering. In order to use models in the fashion described above, it is generally necessary to determine the values of one or more empirical coefficients, which generally are material and environment dependent. Existing data may be used for this purpose if they were obtained for conditions that match or simulate the conditions of the current application. If not, appropriate wear tests need to be done to determine those coefficients. Estimates for these coefficients based on theoretical considerations or extrapolation of existing data can also be used, but these are generally less accurate then those obtained from wear tests that simulate the wear situation.

In some situations it may be necessary to consider more than one model. This could be because there is inadequate information available to differentiate between models, or because the wear situation is so complex that several different conditions need to be considered. In this case the design parameters should be selected so that adequate wear performance is predicted by all the models. Alternatively, this complexity may be eliminated by doing further system analysis, doing some tests to identify the appropriate model, or introducing elements in the design to eliminate some of the possibilities. For example, damping may be introduced to eliminate possible fretting motions that may contribute to the wear, or seals may be used to eliminate the possibility of abrasive particles in the contact region.

Verification. In addition to the normal verification that the design works, it is necessary to verify the validity of different assumptions made in the other three phases. These include examinations to verify that the characteristics of the wear are consistent with the modeling (e.g., correct location and appearance of wear scar).

Theoretical versus Empirical Wear Design Approaches. In practice, wear design approaches can be completely theoretical, semi-empirical, or completely empirical. In the completely theoretical approach the basis for selection of a model is a description of the tribosystem. Also, existing empirical coefficients or estimates based on them are used to predict wear behavior using those models. In the semi-empirical approach, some testing is done to determine values for the coefficients or to verify the applicability of a model that was selected on a theoretical basis. In the completely empirical approach the model and coefficients are determined empirically. An example of this might be the use of regression analysis to determine a suitable model. While the completely theoretical approach is most desirable from a design standpoint, it tends to be the least accurate and to be associated with a higher degree of risk. As a result, such approaches should be more conservative and use larger safety factors for establishing designs than those involving some experimental elements.

Designing for Preferred Modes of Wear. An important factor in wear design is the recognition that the selection of design parameters and the overall nature of the design affects not only the wear rate but also the wear modes and behavior. Preferred modes of wear can be ensured by proper design. The primary criterion is that the design be selected to

ensure mild wear behavior. In two-body, nonabrasive wear situations this generally means that contact stresses should be in the elastic range. In the case of sliding, contact stresses should be a small fraction of the yield strength, generally less than 0.5 and less than 0.2 for very low wear rates. Some form of lubrication should also be used. For rolling and impact, the stresses can be significantly higher (i.e., greater than 0.5) for long life, provided that sliding is not involved. In abrasive wear situations, materials similar in hardness to the abrasives or, preferably, harder than the abrasives should be used. Materials should be compatible with the environment in which they are to be used. A list of other rules for wear design is given in Table 7.

Table 7 Design rules for wear applications

- Reliance on analytical design procedures increases the degree of conservatism that should be used.
- Wear is a system property; utilize all the parameters that influence wear.
- Design with the limits and characteristics of the materials in mind.
- Design so that a mild wear condition exists.
- Minimize exposure to abrasive particles.
- Optimize contact to minimize stresses.
    - Ensure good alignment.
    - Round corners and edges.
- Use a lubricant whenever possible.
- Use dissimilar materials.
- To increase system life (reduce system wear), it is sometimes necessary to increase hardness of both members.
- Rolling is preferred over sliding.
- Sliding or fretting motions should be eliminated in impact wear situations.
- Impacts should be avoided in sliding contacts.
- Elastomers frequently out perform harder materials in impact situations.
- Thickness of conventional coatings generally should be greater than 100 μm.
- Use moderate surface roughness.
- Avoid the use of stainless steel shafts with impregnated sintered bronze.
- When molded, filled plastics tend to exhibit significant difference between initial and long-term wear behavior.
- When glass or other hard fillers are used, the hardness of the counterface should be equal to or greater than that of the filler. For glass, this hardness should be >60 HRC.
- The tendency for galling can be reduced by using dissimilar and hard materials of low ductility, lubricating, and reducing contact stresses; stress level above threshold levels for galling should be avoided.
- Avoid designs in which fretting motions can occur.
- When fretting motions are present, design for optimum sliding wear life and to minimize abrasive wear.
- Sacrificial wear design should be considered when satisfactory life cannot be achieved by other means.
- Conform to vendor recommendations for optimum wear performance.
- Changes associated with design modifications or new applications should be reviewed carefully with respect to their affect on potential wear behavior.

Bracketing. One technique that is often helpful in wear design is called bracketing, which is illustrated in Fig. 5. This involves the development of two theoretical wear projections for a design. Different models may be used for each projection. For example, in the case of sliding, one projection might be based on the K-factor model and the other on the combination of the sliding zero wear and measurable wear models. One projection is an optimistic projection, using the

most favorable values for the coefficients that have been reported for the most favorable model, if two or more models are potentially applicable. The other is a pessimistic or worst-case projection, using the least favorable values for the least favorable model. If the optimistic projection exceeds the allowable wear, it is generally advisable to change the design concept. If the pessimistic projection gives acceptable wear, the proposed design is acceptable. If the two curves bracket the required wear behavior, the design is considered to be feasible but further work is required to establish a satisfactory design. This further work generally requires the determination of the coefficients for different materials. In cases where more than one model was used, this generally requires some testing to determine which model is the correct one.

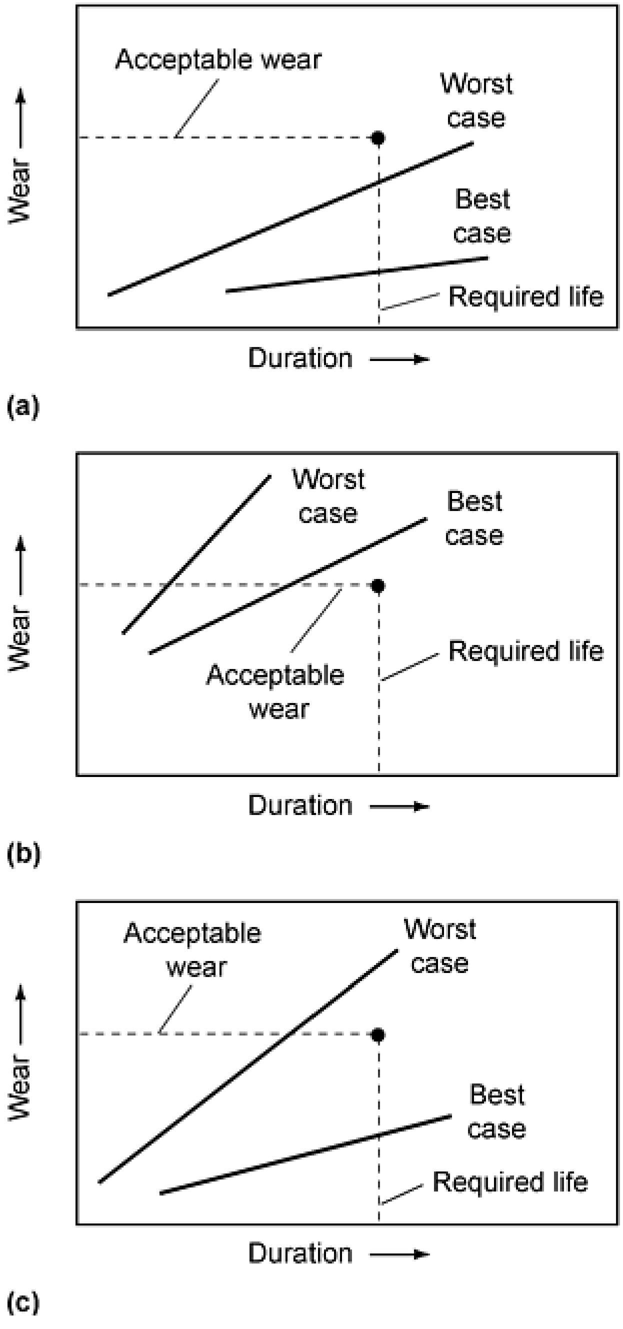

Fig. 5 Bracketing analysis. (a) The design is satisfactory and no further modifications are required. (b) A design change is needed. (c) Further work is needed to identify satisfactory materials and, if applicable, the correct model for the wear situation.

Design Modifications. While the focus of the wear design methodology is the avoidance of wear problems in new designs, it can also be applied to the resolution of existing wear problems. It provides a methodology for establishing corrective actions when a design modification is required. In these situations the existence of wear data and worn

hardware is often valuable. The failure analysis and hypothesis development activity that is normally associated with problem-solving efforts provides valuable input to the system analysis and modeling required for wear design.

Design for Wear Resistance

Raymond G. Bayer, Tribology Consultant

Methods for Wear Design

In most cases a wear design starts out with a general design outline based on function. This design outline defines the generic shapes, motions, and environment. It may also provide some limits on the type of materials and method of lubrication that can be used. Based on this input a wear model is selected, then used to determine the specifics of the design based on wear considerations. This may take the form of sequentially evaluating designs, where specific materials, dimensions, tolerances, and roughnesses are assumed, to see if any of the combinations will provide adequate wear behavior. It may also take the form of determining what material properties, dimensions, and so on are required in order to obtain adequate wear performance. In practice, the former is often tried first and if a successful design cannot be found, the latter approach is incorporated into the analysis. If a successful design cannot be obtained within this framework, it is then usually necessary to see if other general designs for that function can provide adequate wear performance. It is in these cases that the bracketing technique is often useful.

Example: Design Approach for Low-Wear Computer Peripherals.

The details of wear design methods tend to vary not only with the type of wear but also with the needs of the organization. However, a design approach used for low-wear applications in computer peripherals can be used to illustrate the general nature of a wear design approach (Ref 28, 29). Other examples of specific approaches can often be found in wear and design publications, such as *Machine Design, Wear,* and *Tribology International.* A number of wear design examples and methods can also be found in Ref 8.

The design approach used for computer peripherals is primarily a theoretical approach, which is based on the zero wear model for sliding. In this model zero wear is defined as a wear scar whose average depth is the center-line average (CLA) roughness of the surface, as illustrated in Fig. 6. This model relates material properties and stress levels so that a zero wear condition will not be exceeded. It can be used to determine the maximum load that can be applied to a design for a given lifetime and not have the depth of wear exceed the surface roughness level. Expressions for the allowable load were developed for a number of different geometries and motions, as shown and described in Fig. 7, 8, 9, and 10 and Tables 8, 9, 10, and 11.

Table 8 Key to symbols used in Fig. 7, 8, and 9

Symbol	Description
a	The radius of that circle which best fits the contour of the edge in the region of contact, in.
E	Young's modulus of elasticity, psi
H_m	Microhardness, kg/mm^2
K	Stress-concentration factor used in cases where the contact between bodies terminates abruptly
L	Length of contact in cases involving cylinders and planes, in.
L'	Width of contact in cases of flat-on-flat conforming geometry, in.
N	Number of passes
n_o	Frequency of oscillation, oscillations/min
n_r	Angular velocity of a shaft, rpm
P	Normal force between two contacting surfaces, lb

P_A	Allowable normal force for a specific geometry, material, lubrication, and life, lb
R	Principal radius of curvature, in.
x	Operation time, h/month
y	Machine life, months
z	Total linear travel for one oscillation cycle, in./cycle
α	Angle of contact in a shaft-in-hole conforming geometry, degree
γ_R	Zero-wear factor
μ	Coefficient of friction
v	Poisson's ratio
σ_y	Tensile yield stress, psi
τ_{max}	Maximum shear stress in contact region, psi
τ_y	Shearing yield stress, psi ($\tau_y = \sigma_y/2$)
ϕ	Total angular travel for one oscillation cycle, degree/cycle

Note: Subscripts 1 and 2 of these variables apply to Body 1 and Body 2 as shown in the sketches and equations in Fig. 7, 8, and 9.

Table 9 Allowable loads for mechanisms shown in Fig. 7

$$B1 = 1.535\,\alpha^{1/9}\left(\frac{RL(\sin\alpha/2)}{K}\right)\left(\frac{\gamma_R\tau_{y1}}{\sqrt{0.25+\mu^2}}\right)\left(\frac{1}{xyn_r}\right)^{1/9}$$

$$B2 = 2.953\left(\frac{RL(\sin\alpha/2)}{K}\right)\left(\frac{\gamma_R\tau_{y2}}{\sqrt{0.25+\mu^2}}\right)\left(\frac{1}{xyn_r}\right)^{1/9}$$

$$B3 = 2.953\,L^{10/9}\left(\frac{R}{K}\right)\left(\frac{\gamma_R\tau_{y1}}{\sqrt{0.25+\mu^2}}\right)\left(\frac{1}{xyzn_o}\right)^{1/9}$$

$$B4 = 2.734\,\frac{RL}{K}\left(\frac{\gamma_R\tau_{y2}}{\sqrt{0.25+\mu^2}}\right)\left(\frac{1}{xyn_o}\right)^{1/9}$$

$$B5 = 1.476\,L^{10/9}\left(\frac{L'}{K}\right)\left(\frac{\gamma_R\tau_{y1}}{\sqrt{0.25+\mu^2}}\right)\left(\frac{1}{xyzn_o}\right)^{1/9}$$

$$B6 = 1.367\,\frac{LL'}{K}\left(\frac{\gamma_R\tau_{y2}}{\sqrt{0.25+\mu^2}}\right)\left(\frac{1}{xyn_o}\right)^{1/9}$$

$$B7 = 4.638\,\alpha^{1/9}\left(\frac{R^2\sin^2\alpha/2}{K}\right)\left(\frac{\gamma_R\tau_{y1}}{\sqrt{0.25+\mu^2}}\right)\left(\frac{1}{xyn_o}\right)^{1/9}$$

$$B8 = 4.294\left(\frac{R^2\sin^2\alpha/2}{K}\right)\left(\frac{\gamma_R\tau_{y2}}{\sqrt{0.25+\mu^2}}\right)\left(\frac{1}{xyn_o}\right)^{1/9}$$

Stress-concentration factor for B1-B4:

$$K = \frac{0.6318}{\left[\left(\frac{1-\nu_1^2}{E_1}+\frac{1-\nu_2^2}{E_2}\right)\frac{aP}{RL^2\sin\alpha/2}\right]^{1/3}}$$

Stress-concentration factor for B5 and B6:

$$K = \frac{0.4778}{\left[\left(\frac{1-\nu_1^2}{E_1}+\frac{1-\nu_2^2}{E_2}\right)\frac{\delta P}{LL'}\right]^{1/3}}$$

Stress-concentration factor for B7 and B8:

$$K = \frac{0.181}{\left[\left(\frac{1-\nu_1^2}{E_1}+\frac{1-\nu_2^2}{E_2}\right)\frac{aP}{\alpha R^3}\right]^{1/3}}$$

Table 10 Allowable loads for mechanisms shown in Fig. 8

$$B9 = 32.07\left(\frac{1-v_1^2}{E_1}+\frac{1-v_2^2}{E_2}\right)^{5/4}\left(\frac{L}{R_2^{1/4}}\left[\frac{1}{1/R_2-1/R_1}\right]^{5/4}\right)\left(\frac{\gamma_R\tau_{y1}}{K(1+\mu)}\right)^{9/4}\left(\frac{1}{xyn_r}\right)^{1/4}$$

$$B10 = 27.39\left(\frac{1-v_1^2}{E_1}+\frac{1-v_2^2}{E_2}\right)\left(\frac{L}{1/R_2-1/R_1}\right)\left(\frac{\gamma_R\tau_{y2}}{K(1+\mu)}\right)^{2}\left(\frac{1}{xyn_r}\right)^{2/9}$$

$$B11 = 6.848\left(\frac{1-v_1^2}{E_1}+\frac{1-v_2^2}{E_2}\right)\left(\frac{1}{0.25+\mu^2}\right)\left(L\right)^{11/9}\left(\frac{1}{1/R_2-1/R_1}\right)\left(\frac{\gamma_R\tau_{y1}}{K}\right)^{2}\left(\frac{1}{xyzn_o}\right)^{2/9}$$

$$B12 = 5.870\left(\frac{1-v_1^2}{E_1}+\frac{1-v_2^2}{E_2}\right)\left(\frac{1}{0.25+\mu^2}\right)\left(\frac{L}{1/R_2-1/R_1}\right)\left(\frac{\gamma_R\tau_{y2}}{K}\right)^{2}\left(\frac{1}{xyn_o}\right)^{2/9}$$

$$B13 = 23.48\left(\frac{\gamma_R\tau_{y1}}{(1+\mu)}\right)^{2}\left(\frac{L_2R_2}{K^2}\right)\left(\frac{1-v_1^2}{E_1}+\frac{1-v_2^2}{E_2}\right)\left(\frac{1}{xyn_o}\right)^{2/9}$$

$$B14 = 50.86\left(\frac{\gamma_R\tau_{y2}}{(1+\mu)}\right)^{9/4}\left(\frac{L_2^4R_2^5}{K^9}\right)^{1/4}\left(\frac{1-v_1^2}{E_1}+\frac{1-v_2^2}{E_2}\right)^{5/4}\left(\frac{1}{xyzn_o}\right)^{1/4}$$

Stress-concentration factor for B9-B14:

$$K = \left[1+\frac{1/a}{1/R_2-1/R_1}\right]\left[\frac{2}{m^2n}\right]$$

$$\cos\theta = \frac{1/a+1/R_1-1/R_2}{1/a-1/R_1+1/R_2}$$

Table 11 Allowable loads for mechanisms shown in Fig. 9

$$B15 = 52.80\left(\frac{\gamma_R \tau_{y1}}{\beta}\right)^3 \left(\frac{m^3 n^3 R_1^2 R_2^2}{(R_1+R_2)^2}\right)\left(\frac{1-\nu_1^2}{E_1}+\frac{1-\nu_2^2}{E_2}\right)^2 \left(\frac{1}{xyn_o}\right)^{1/3}$$

$$B16 = 153.4\left(\frac{\gamma_R \tau_{y2}}{\beta}\right)^{27/8} (m^{27/8} n^{15/4})^{3/8} \left(\frac{R_1 R_2}{R_1+R_2}\right)^{19/8} \left(\frac{1-\nu_1^2}{E_1}+\frac{1-\nu_2^2}{E_2}\right)^{19/8} \left(\frac{1}{xyzn_o}\right)^{3/8}$$

$$B17 = 29.57\left(\frac{\gamma_R \tau_{y1}}{\beta}\right)^{27/8} (R_1)^{19/8} \left(\frac{1-\nu_1^2}{E_1}+\frac{1-\nu_2^2}{E_2^{19/8}} \left(\frac{1}{xyzn_o}\right)\right)^{3/8}$$

$$B18 = 13.20\left(\frac{\gamma_R \tau_{y2}}{\beta}\right)^3 (R_1)^2 \left(\frac{\gamma-\nu_1^2}{E_1}+\frac{1-\nu_2^2}{E_2}\right)^2 \left(\frac{1}{xyn_o}\right)^{1/3}$$

$$B19 = 76.99\left(\frac{\gamma_R \tau_{y1}}{\beta}\right)^{27/8} (m^{27/8} n^{15/4})\, R_2^2 \left(\frac{R_1}{2R_2+R_1}\right)^{19/8} \left(\frac{1-\nu_1^2}{E_1}+\frac{1-\nu_2^2}{E_2}\right)^{19/8} \left(\frac{1}{xyn_r}\right)^{3/8}$$

$$B20 = 66.53\left(\frac{\gamma_R \tau_{y2}}{\beta}\right)^3 (mn)^3 \left(\frac{R_1 R_2}{2R_2+R_1}\right)^2 \left(\frac{1-\nu_1^2}{E_1}+\frac{1-\nu_2^2}{E_2}\right)^2 \left(\frac{1}{xyn_r}\right)^{1/3}$$

$$B21 = 77.03\left(\frac{\gamma_R \tau_{y1}}{\beta}\right)^{27/8} (m^{27/8} n^{15/4}) (R_2)^2 \left(\frac{R_1 R'_2}{2R_2 R'_2 + R_1 R'_2 - R_1 R_2}\right)^{19/8} \left(\frac{1-\nu_1^2}{E_1}+\frac{1-\nu_2^2}{E_2}\right)^{19/8} \left(\frac{1}{xyn_r}\right)^{3/8}$$

$$B22 = 66.56\left(\frac{\gamma_R \tau_{y2}}{\beta}\right)^3 (mn)^3 \left(\frac{R_1 R_2 R'_2}{2R_2 R'_2 + R_1 R'_2 - R_1 R_2}\right)^2 \left(\frac{1-\nu_1^2}{E_1}+\frac{1-\nu_2^2}{E_2}\right)^2 \left(\frac{1}{xyn_r}\right)^{1/3}$$

For B15-B22, β = the greater of μ or 0.31

For B15 and B16, $\cos\theta = \dfrac{R_1 - R_2}{R_1 + R_2}$

For B17-B20, $\cos\theta = \dfrac{R_1}{2R_2 + R_1}$

For B21 and B22, $\cos\theta = \dfrac{R_1 (R_1 + R_2)}{2 R_2 R'_2 + R_1 R'_2 - R_1 R_2}$

Note: The relationship between cos θ and values for *m* and *n* is shown in Fig. 10.

Note: The relationship between cos θ and values for *m* and *n* is shown in Fig. 10.

Fig. 10 Plot of *m* and *n* vs. cos θ. Values for *m* and *n* appear in the stress-concentration factor (*K*) expression in Fig. 8 and in some of the allowable-load expressions in Fig. 9. Source: Ref 28

The wear design method is to evaluate a proposed design by using the relationships shown in Fig. 7, 8, and 9 to determine an allowable load. The allowable load is then compared with an estimate of the actual load. If the allowable load is significantly higher than the estimated actual operating load, the design is accepted and is given further consideration only if problems develop in subsequent functional tests.

If the allowable and estimated loads are comparable, changes to the design are considered to improve the safety margin. If this cannot be done, the wear of the device is closely monitored in life and functional tests to verify adequate performance.

If the allowable load is less than the estimated load, design changes are explored to obtain a condition in which the allowable load exceeded the estimated load. Typical changes that are considered in this approach are dimensional and material changes, as well as any changes that would affect the loading situation.

This wear design method is a conservative approach, because most applications can tolerate wear depths one to two orders of magnitude above the CLA value. In situations where an acceptable "zero wear design" cannot be found because of cost or technical reasons, a less conservative approach is then used. In this situation a more realistic failure criterion is used for the amount of wear that can be tolerated. Generally this is the amount of wear that would cause functional problems. A combination of the zero wear model for sliding and the measurable wear model for sliding is then used to project wear and evaluate potential designs. Examples of this method can be found in Ref 21, 30, 31, and 32.

Properties Needed for Electronic and Magnetic Applications

Eugene J. Rymaszewski, Rensselaer Polytechnic Institute

Introduction

PROPERTY can be defined as a quantitative response to a stimulus. In the context of electronic and magnetic applications, such a response usually has two aspects: another stimuluslike parameter and one or, more likely, several attributes of a physical body responding to the stimulus. For example, a voltage V applied to both ends of a wire causes an electrical current I to flow through the wire. The value of the current can be expressed as (Ohm's Law):

$$I = \frac{V}{R} \quad \textbf{(Eq 1)}$$

$$V = IR \quad \textbf{(Eq 2)}$$

$$R = \frac{\rho l}{A} \quad \textbf{(Eq 3)}$$

$$\rho = \frac{RA}{l} \quad \textbf{(Eq 4)}$$

where R is the electrical (Ohmic) resistance of the wire, in Ω; ρ is the electrical resistivity of the wire material, in $\Omega \cdot$ m; A is the cross-sectional area of the wire, in m^2; and l is the wire length, in m. Note that A and l are the dimensions--structural parameters--of the wire and ρ is the property of the wire material. The wire is directly involved in the voltage/current interaction, as opposed to a structure supporting the wire, which may be involved indirectly.

The physical dimensions of this structure and its mechanical and thermal properties may also be relevant, albeit indirectly, to the numerical determination of ρ. For example, sufficiently high values of V and I generate enough heat to raise the wire temperature and, consequently, alter the value of R and, therefore, ρ. The temperature rise will depend on the thermal path (cooling) between the wire and its environment determined by the structure. The temperature rise causes expansion in most materials that can lead to mechanical stresses in the wire and/or its support structure. Thus, there are mechanical and thermal interactions to be considered. Such interactions, if not properly considered, may lead to wrong conclusions. For example, if one were to measure the voltage or current dependency of ρ and not factor in the temperature rise and its effect, then an excessively high positive value of $\Delta\rho/\Delta V$ would be "measured." In reality, it may be zero (or even negative); or the presumed resistor stability, which neglects its thermal coefficient of resistivity (TCR) and temperature rise, will not occur, and the design may fail to perform as expected.

The nonelectromagnetic parameters fall into two distinctly different categories: those involved in fabrication (melting solder, making thermocompression bond, sputtering or evaporating film, diffusing impurities into semiconductors, sintering ceramics), and those involved in operation of the equipment, such as the wire example described above. This article focuses, as its name indicates, on this second category of properties.

Properties Needed for Electronic and Magnetic Applications

Eugene J. Rymaszewski, Rensselaer Polytechnic Institute

Background Information

Classes of Materials. The value of electrical resistivity of materials, ρ, and its inverse, the electrical conductivity, σ, vary over almost 24 orders of magnitude at or near room temperature. Its subranges classify the materials as conductors, semiconductors, and insulators. Conductors are typically metals with ρ ranging from 10^{-8} to 10^{-4} $\Omega \cdot$ m. The electrical conductivity results from the presence of "free" electrons, that is, free to move in response to the presence of an electric field.

No "free" electrons are present in the insulators, and consequently, their ρ is from 10^{4} to 10^{16} $\Omega \cdot$ m (Ref 1). Insulating materials fall into two major categories, the organic (polymers)--pure, as in polymers, or composite, as in epoxy-impregnated fiberglass cloth--and inorganic, usually ceramics.

The gap in the values of ρ between the conductors and insulators is filled by the semiconductors whose electrical conductivity mechanism is best explained by the band-gap theory (Ref 2). The ρ of semiconductors is in the 10^{-4} to 10^{4} $\Omega \cdot$ m range. The semiconductors are either group IV elements, silicon (Si) and germanium (Ge), or composite--formed by two or more group III-V or group II-VI materials, such as GaAs (Ref 3).

The magnetic materials can be metals, alloys, and ceramics. They all have the ability to carry high magnetic flux in response to applied magnetizing force. Their broad classification is based on the atomic structure and values of relative permeability. The high-permeability materials fall into two distinct groups, the magnetically hard and magnetically soft. The hard materials have high coercivity; once magnetized, they resist demagnetizing forces caused by any applied or stray magnetic fields (Ref 4).

The electronic and magnetic applications cover a very wide span of generating and processing information: from placing a telephone call (in a house, on the road, in an airplane) to watching TV from the air, cable, or satellite, to using computers of various sizes and performance capabilities, to remotely interacting with a space ship, and so forth. Many, probably most, of these applications entail generation, processing, transmission, and storage of information, as well as using information to initiate an action--creation of sound, light, or mechanical force, for example. All of the above material categories are used in the electronics hardware in various structures, with widely varying structural dimensions and demands on their properties. As a rule, mutually compatible sets of materials must be employed, placing further demands on their properties.

Small, inexpensive items, such as handheld calculators, are designed for the lowest manufacturing cost, which often precludes repair (a "throwaway" product). The more expensive, and more complex, products usually consist of several subassemblies that are semipermanently joined. These joints are either solder or connectors, a technology in itself to provide satisfactory performance and reliability at affordable cost (Ref 5).

Electronic Applications. The semiconductors play a pivotal role in electronics for processing and storing data and in interfacing the electronic circuits with their exterior, for example, fiberoptic interconnections, optical scanners, displays and, ultimately, humans. The metals and insulating materials (organic and/or inorganic) are directly involved in electronic circuit embodiments by providing interconnections. They also provide mechanical support, environmental protection, and facilitate heat transfer (Ref 5).

Magnetic materials play a key role in permanent storage and retrieval of information. Furthermore, their use in transformers enables more than just changing magnitude of the voltage. A current transformer reduces high current values to make them more suitable for an ammeter. Transformers (both voltage and current) also isolate the output circuit(s) from the input,--which is important for a multitude of reasons, such as keeping away very high powerline voltages from the instrument panel or separating the telephone line from the interior circuitry of a modem.

The materials properties, such as ρ, are customarily given for the "bulk" materials--those having similar order-of-magnitude cross-sectional dimensions, on a macroscopic scale. The numerical values of these properties may change

when the dimensions are reduced to submicron range, as is the case with thin films which see an increasing use in electronic applications (Ref 6). Another factor influencing the numerical values is the microstructure of the material: totally amorphous, crystalline regions within an amorphous matrix, polycrystalline, or monocrystalline. Chemical composition of some amorphous structures may deviate from the stoichiometric, with the resultant alterations in their properties. Figure 1 shows an example of near-zero dispersion of amorphous $Ba_xTi_{2-x}O_y$ thin films and still very low dispersion of partially and fully crystallized barium-titanate films (Ref 7, 8). Properties of the crystalline materials may be direction dependent. As already indicated above, a materials property is often temperature dependent.

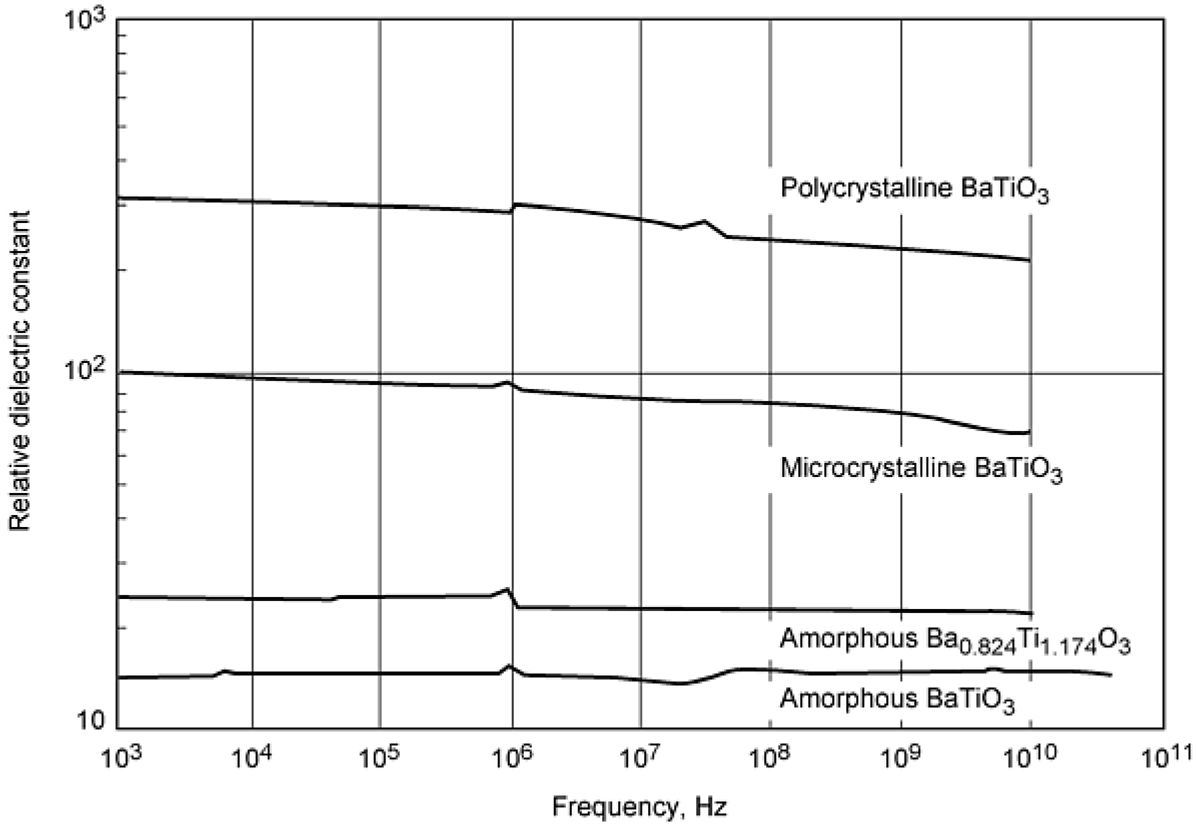

Fig. 1 Frequency dependency of dielectric constant for selected dielectric materials

The Ohm's law equations (Eq 1, 2, 3, 4) indicate that either a voltage *V* or a current *I* can be the stimulus that, through the geometry and resistivity/conductivity of the material will determine the value of the response. An underlying assumption is the independence of $\rho = 1/\sigma$ on either voltage or current. This is not always the case, even at a constant temperature. Perhaps the most striking example is the *V-I* (voltage-current) characteristic (interdependence) of a semiconductor diode, formed at the junction of two oppositely doped regions. In addition to being highly nonlinear, it is very strongly polarity dependent, as shown in Fig. 2 (Ref 9). Such nonlinear response is pivotal to the very existence of all digital electronic circuits.

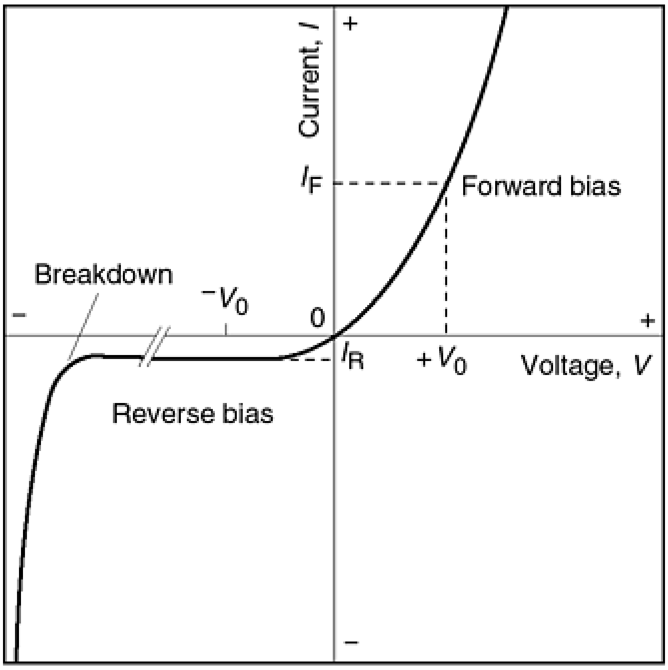

Fig. 2 Voltage-current characteristic of a semiconductor junction. Source: Ref 9

Information-handling applications require periodic or, at least, occasional changes in the values of voltages and currents. Consequently, dependency of the materials properties on such changes must be known and considered for a particular application. For example, the resistivity equations (Eq 1, 2, 3, 4) imply uniform current density throughout the cross-sectional area *A*. However, as the frequency of the current increases, the current penetration depth decreases (skin effect), causing the resistivity to increase. In the time domain, the skin effect manifests itself as time-dependent resistance: high shortly after start of the current flow and decreasing to its DC value. The time it takes depends on the dimensions of the conductor (Ref 10).

Materials may be stressed beyond their mechanical limits, with the resultant permanent deformation. An equivalent situation may occur with the excessive electric stresses that can affect insulators (dielectric breakdown) and conductors (melting, electromigration, void migration) (Ref 11, 12).

Properties of Interest. In this section, an overview of the electric and magnetic parameters is followed by detailed discussion of the significance of these parameters for electronic applications. Many applications prescribe particular values and tolerances of such parameters, and significant efforts are still underway to achieve a particular combination of values of several properties in a particular material. Increasingly, they have to be engineered because such combinations of properties are not available in the existing materials.

Some of these parameter values or properties are not desired because they have deleterious impacts. In such cases they are considered parasitic and, consequently, attempts are made to keep them small, below or within acceptable limits. For example, a particular resistor value is required in a circuit. By contrast, resistance of an interconnection should be low to avoid excessive values of voltage drop. Also, resistance of an insulator, for example, dielectric of a capacitor, must be high enough to prevent excessive leakage currents.

As is shown at the end of the section "Power and Energy Conversion, Storage, and Transmission," some sets of values cannot be altered beyond certain limits for a given set of structural dimensions regardless of the materials properties, only appropriate dimensional changes will produce the desired results. The most notable example is the product of inductance and capacitance of an interconnection (a pair of electrodes, such as wires). This product reaches a minimum for nonmagnetic materials (μ = 1) with low dielectric constants $\varepsilon_r \approx 1$ (e.g., air). Any further reduction is possible only with a shorter length of the interconnection. Such reduction can easily lead to a complete structural redesign.

An analogous situation may occur when the heat generated by electronic circuits is within a small area, causing high values of heat flux, often expressed in W/cm^2. The heat flowing to its environment encounters thermal resistance, causing

the temperature to rise. The thermal conductivity of the materials in the heat-flow path and their structural geometries (cross-sectional area and path length) control the thermal resistance. As shown in Fig. 3, the power densities on the order of 100 W/cm^2 and higher--not unusual in some aggressive initial electronics designs--are likely to cause excessively high operating temperatures. The limited thermal conductivities of materials used often require close attention to the structural dimensions. Some relief may soon be provided from development of affordable exotic materials with high thermal conductivity, for example, diamond films. An alternative is the use of Peltier-junction based (Ref 13) thermoelectric coolers.

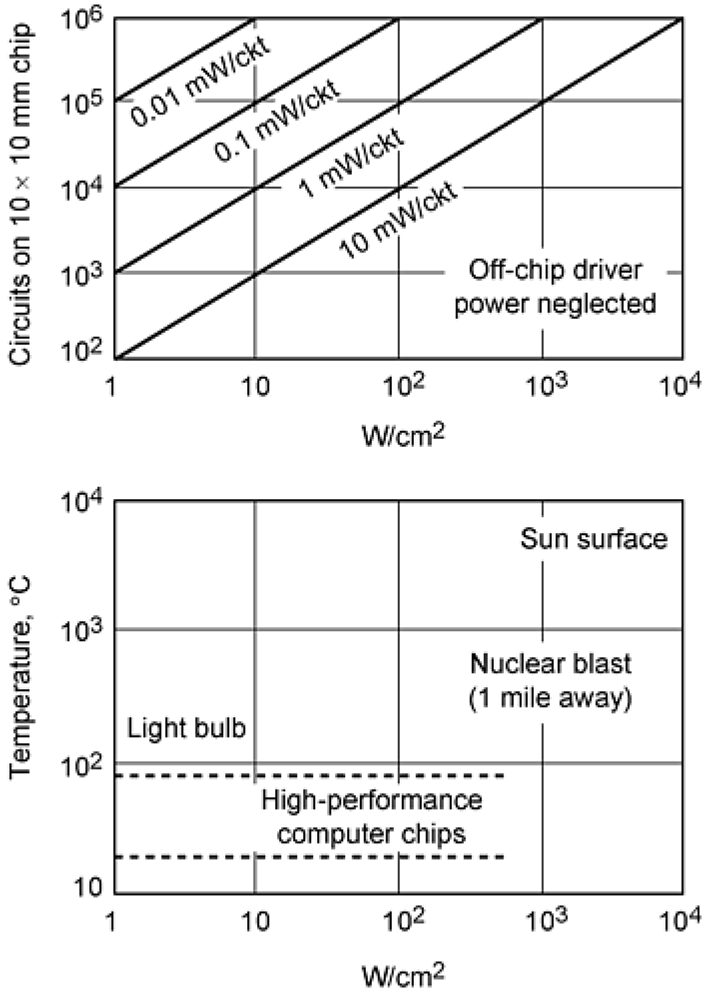

Fig. 3 Temperature versus power density. Source: Ref 5

Most electronic structures, whether integrated circuit (IC) interconnections or packaging, are multilayer structures, with conducting layers alternating with the insulating layers. All layers are appropriately patterned and bonded by a variety of processing techniques. The interlayer bonds are part chemical, part mechanical. The bond strength is often of concern, as delamination can have disastrous reliability consequences. Inadequate bond strength and excessive shear forces (caused, for example, by mismatched thermal coefficients of expansion and large temperature variations) are of prime concern.

Important Trends and Considerations Not Addressed in Detail. The trend in electronic applications is toward increasing density--more functions per unit area or per unit volume. Figure 4 shows dramatic reductions in the volume required for 1 MB (megabyte) of electronic memory storage from 1950 to 2010, a sixty-year interval during which the technology changed from small magnetic (ferrite) cores to IC chips (Ref 13). Packaging had evolved as well and contributed to the volumetric improvements beyond those that would have been possible with just the magnetic core and semiconductor chip technologies which are basically planar, two dimensional.

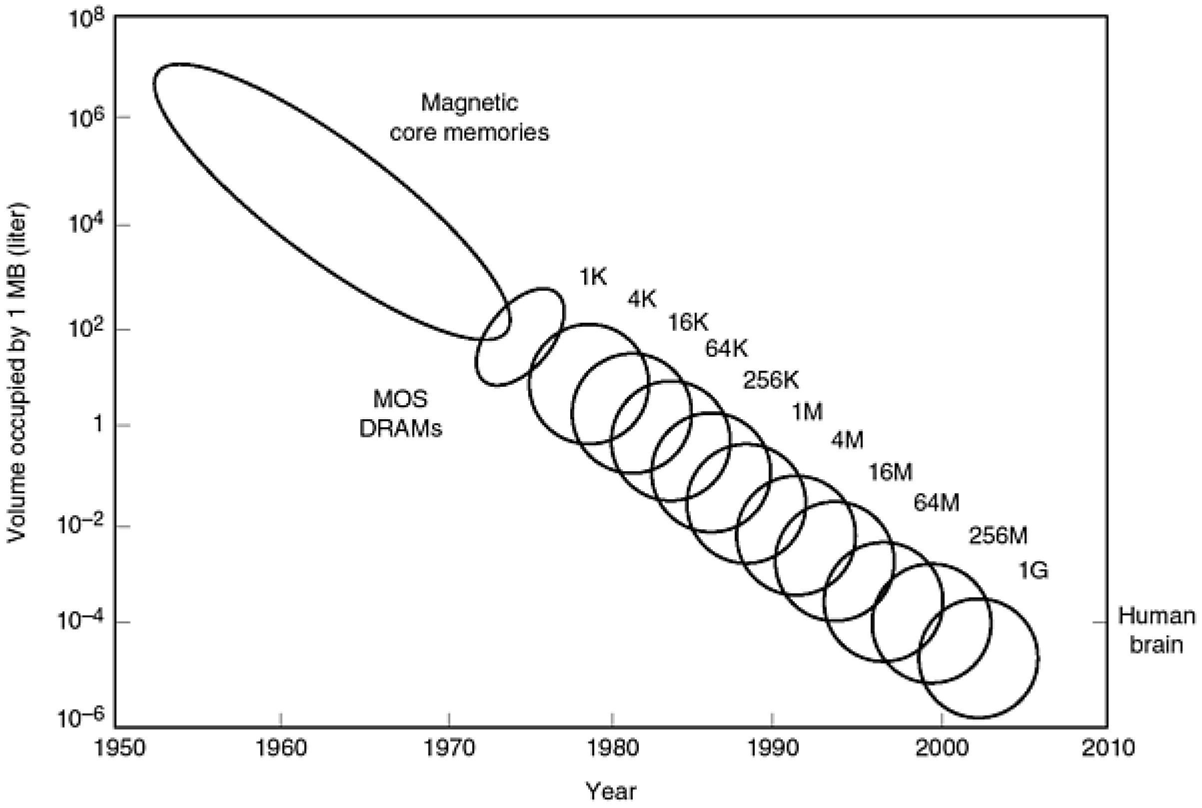

Fig. 4 Memory density trends. Source: Ref 5

At the same time, the trend is often toward increasing the area of the IC chips, multichip modules (MCMs) and printed wiring boards (PWBs). Thus, the number of pixels per each subassembly is steadily increasing (Ref 14). This trend taxes the capabilities of design support systems and, especially, the defect-free manufacturing processes. There is a strong competitive pressure to balance the design of leading-edge products against the expense of establishing, maintaining, and improving defect-free manufacturing environment. Consequently, a certain percentage of the product, especially during its early manufacturing phase, is likely to be defective. It has to be weeded out prior to the final assembly, or even sooner. Sophisticated testing facilitates the weeding out. However, nonkiller defects escape detection, are shipped, and contribute to failures early in the life of the products. A prestress process, known as "burn-in," endeavors to enhance the weeding-out of defects (Ref 11, 15).

Properties Needed for Electronic and Magnetic Applications

Eugene J. Rymaszewski, Rensselaer Polytechnic Institute

Overview of Electric and Magnetic Parameters and Materials Properties

Electric voltage, current, and power are fundamental electrical units--*V, I,* and *P*. They are measured in volts (V), amperes (A), and watts (W), respectively. A potential difference, or electromotive force, of 1 V exists between two points of a conductor carrying a constant current of 1 A when the power dissipated between these points equals 1 W (Ref 16). Note that implicit to this definition is the electrical resistance of 1 Ohm (Ω) present between these points.

Power and Energy Conversion, Storage, and Transmission. The very definition of fundamental electrical units invokes power dissipation, that is, the conversion of the electrical energy into thermal. The energy can also be temporarily stored, either in the electric field associated with a voltage between two or more conductors, or in the magnetic field caused by and associated with the current flowing through a conductor. Changes in the field energies are linked with the corresponding temporary flow of current and appearance/application of voltage. Electric permittivity, a materials property, is the proportionality constant that directly relates the voltage and structural geometry to the electrical field energy. Magnetic permeability is its magnetic field energy counterpart.

The static (constant with time) magnetic and electric fields may and do exist independent of each other. The dynamic (changing with time) fields do not: a charge must be transported to alter the electrical potential between any two (or more) electrodes, such as capacitor plates or electrical connections. Note that $I(t) = dQ/dt = C(dV/dt)$. Such current $I(t)$ creates a magnetic field associated with it. This current will in turn cause a voltage $V = L(dI/dt)$. Thus, the dynamic voltages and currents are interdependent and interlinked in space. An interconnection consisting of two wires of uniform cross-sectional geometry has an inductance per unit length, L_0, and a capacitance per unit length, C_0.

The ratio of the above V and I on an infinitely long interconnection (no reflections) with a uniform cross-sectional geometry is referred to as the characteristic impedance Z_0:

$$Z_0 = \frac{V}{I} = \sqrt{\frac{L}{C}} = \sqrt{\frac{L_0}{C_0}}$$

The value of Z_0 and, therefore, the ratio $L/C = L_0/C_0$ depend on cross-sectional geometry, magnetic permeability, and electric permittivity of the material(s) surrounding the interconnection conductors. The geometry dependence for some selected geometries is shown in Fig. 5; this dependency as well as very detailed data are presented in Ref 17. The detailed theory is discussed in many texts, such as Ref 18 and 19.

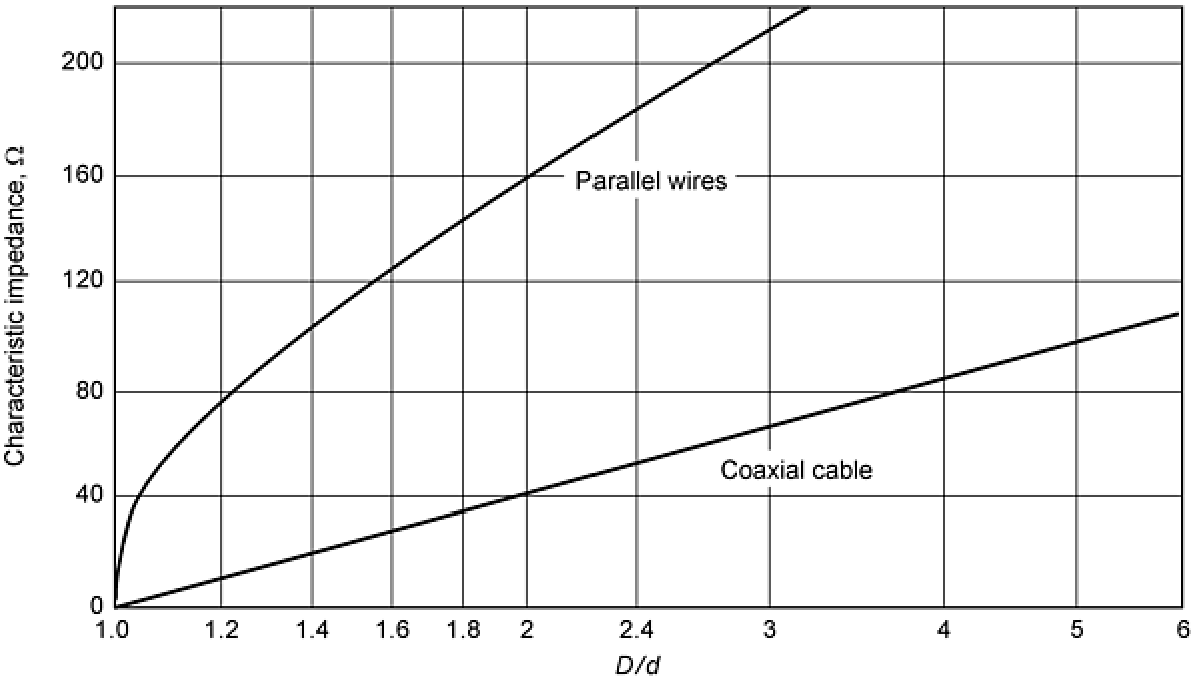

Fig. 5 Characteristic impedance versus cross-sectional geometries of two parallel wires and coaxial cable

The velocity of propagation *v* of the "interlocked" voltage *V*(*t*) and current *I*(*t*) waves does not depend on the cross-sectional geometry, only on the permeability μ and permittivity ε of the insulating material between the conductors,

$$v = \sqrt{L_0 C_0} = \frac{c}{\sqrt{\mu\varepsilon}}$$

where *c* is the velocity of light in free space. Thus, *for a given length, the product LC is fixed* and reaches a minimum for $\mu = \varepsilon = 1$. To reduce the value of *LC*, the interconnection length must be reduced--often a difficult task.

Capacitance and Dielectric Materials. An ideal capacitor has no electrical conduction between its plates; it only stores any amount of electrical energy and returns it in full. The dielectric material between the capacitor plates largely determines the degree to which these ideal characteristics are met. It has four key properties--the dielectric constant, the dielectric leakage, the dielectric breakdown, and the dielectric loss--which limit the ideal behavior of a capacitor. The leakage current drains the charge and may be very detrimental in applications in which the capacitor is expected to separate (block) dc circuits or to maintain its charge, as in dynamic random access memory (DRAM) chips.

The dielectric leakage depends on the electric field strength. It is commonly normalized to the electrodes area. Its metric is then the current density *J*, often given in μA/cm^2. In many applications, it is very important to keep the capacitor area *A* to a minimum. Two factors determine the capacitance density (for example, expressed in nF/cm^2): the dielectric constant ε and the thickness of the dielectric, *d*. Thinner dielectric produces higher electric field *E* = *V*/*d*, often measured in MV/cm, for the same applied voltage *V*. Usually, it increases the value of *J*. Figure 6 shows examples of the leakage currents *J* versus capacitance densities for some recently developed thin films, with the values of *d* well into the submicron range (Ref 13).

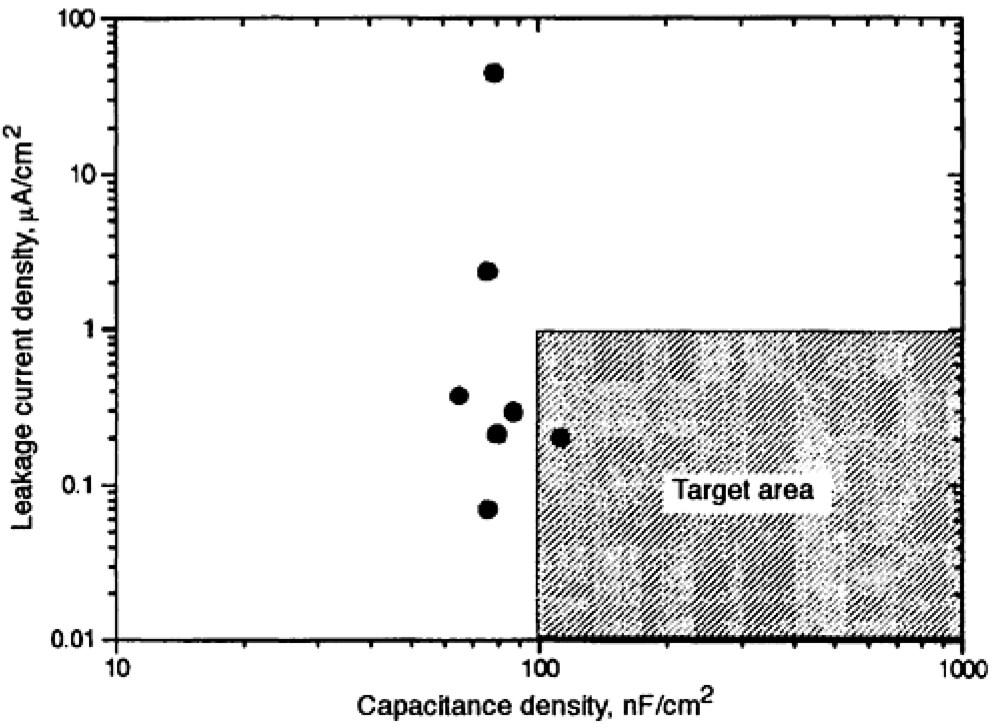

Fig. 6 Leakage current densities versus capacitance densities of new dielectric thin

There is another limitation to the voltage between the capacitor plates--the dielectric breakdown, a situation caused by excessive electric field strength and manifested by avalanching current, often producing permanent destruction (Ref 10). The breakdown field strength is inversely dependent on the dielectric constant, as illustrated in Fig. 7, breakdown field versus permittivity (Ref 13). It must be noted here that very thin films may well have disproportionately low breakdown voltages (and average fields) because the dielectric will first break down at locations of reduced thickness caused, for example, by microroughness of the metals onto which the dielectric was deposited or by presence of small particles.

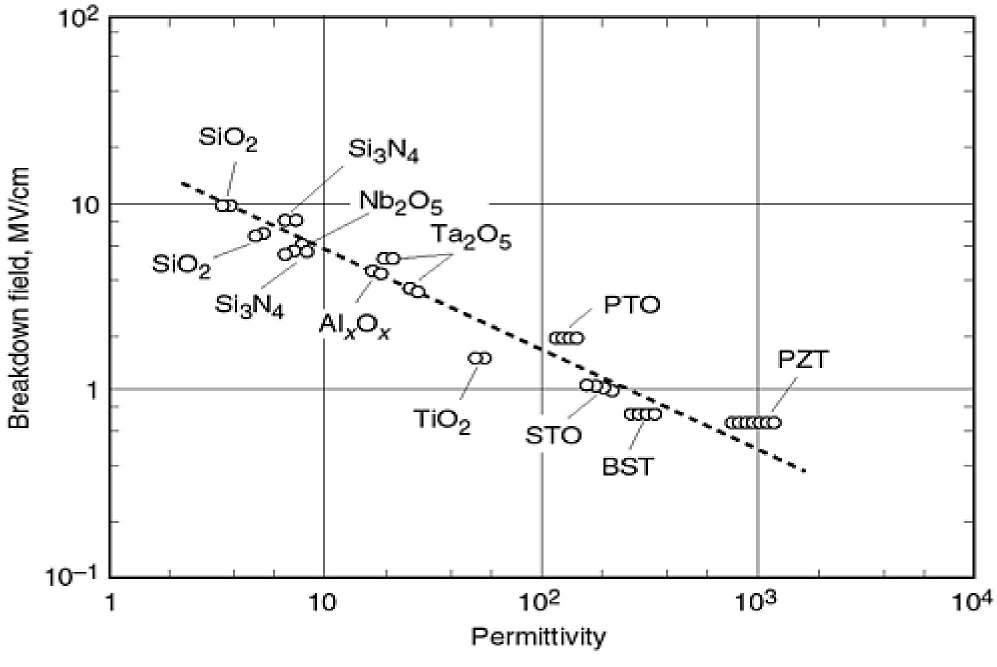

Fig. 7 Breakdown field dependency on the dielectric constant

Unlike the leakage currents and breakdowns that occur at dc, the dielectric losses are an ac phenomenon. In an ideal capacitor, there is a 90° phase shift at the angular frequency $\omega = 2\pi f$ between the applied ac voltage vector V and the vector I of the ac current flowing through the capacitor C; $I = V \times j2\pi fC = V \times j\omega C$, with $C = \varepsilon A/d$. With all real materials, the dielectric constant is a complex number $\varepsilon = \varepsilon' + j\varepsilon''$. As a rule $\varepsilon' \gg \varepsilon''$. The ratio of ε'' to ε' is often referred to as the "loss-angle tangent," tan δ. For the most insulating materials, it remains relatively constant and small at all frequencies at which ε' remains constant. A change (reduction) in ε' with frequency is known as dispersion and is associated with rising ε'' and, therefore, a higher value of tan δ that fairly accurately tracks $d\varepsilon'/df$ ($d\varepsilon'/d\omega$) (Ref 4, 10, 12, 20).

The onset of dispersion occurs at lower frequencies for the higher values of ε. This is another factor to be considered, in addition to the lower breakdown field strength shown in Fig. 7. As shown in Fig. 1, minimum dispersion, if any, occurs with the amorphous thin films. Another property of higher dielectric constant materials to consider is the temperature dependency of ε.

Inductance is conceptually related to the resistance in the sense that a change in the current flowing through it is resisted by appearance of voltage $V = L(dI/dt)$ or, in case of a steady alternating current of frequency f, $V = I \times j\omega L$. The term ωL is called reactance, the positive counterpart to reactance of a capacitor $1/j\omega C$ or $-j/\omega C$. Again, an ideal inductor temporarily stores energy in its magnetic field and returns all of it. In the real world, this is never fully the case (except in superconductors) because of the Ohmic wire resistance and, if magnetic materials are used, because of their losses caused by the remanence (area within the hysteresis loop).

Signal Transmission. Unlike water flow from a hose or light emitted by its source, the electric current can flow only in a circuit (containing resistances and reactances) that forms a closed loop, that is, with connections to both terminals of the source. It is common among electronics engineers to imply presence of a "return" current path, without being explicit about it. In most situations, it works well and justifies the simplification. The return current path is usually formed by the "ground": the body (chassis) of equipment or planes used to deliver the power (see the next section "Mutual Inductance"). However, such a design has a poorly controlled return-current path, which can cause performance problems (Ref 5). Characteristic impedance and signal velocity of propagation along such lines are briefly covered in the section "Power and Energy Conversion, Storage, and Transmission." Ideal transmission lines preserve the amplitude and transition time of the signal. The inevitable losses occur due to the interconnection resistance (particularly troublesome in the small cross-section lines of high density ICs and packages) and, to a much lesser degree, in the insulating dielectrics.

Mutual Inductance. If a second conductor is present in the magnetic field associated with the current through the first conductor, it induces a voltage proportional to the ratio of the field common to both conductors to the total field of the first conductor. This phenomenon is the base for various transformer designs which, as a rule, seek "tight coupling" between the first (primary) and second (secondary) wires. This coupling is further enhanced by use of ferromagnetic flux concentrators. A second, less desirable, effect occurs when two or more signal transmission lines are in proximity of each other. The mutual inductance between them is, as a rule, accompanied by mutual capacitance. The combined effect is known as "crosstalk." Typically, it is very small (close to zero) at the far end (away from the driver of the first line) and sizeable at the near end. A "directional coupler" utilizing this phenomenon permits separation of two waves propagating in opposite directions along the first line (Ref 5).

Properties Needed for Electronic and Magnetic Applications

Eugene J. Rymaszewski, Rensselaer Polytechnic Institute

Overview of Parameters and Materials Properties Other than Electric and Magnetic

As already briefly indicated, the temperature dependence of many properties, singly and in the context of an electronic structure, is of paramount importance to proper functioning of devices, circuits, and equipment. The malfunctions can be immediate, for example, caused by the drift of device characteristics outside of design limits, or they can be the result of failures caused by time or cycle-dependent disruptions of the structural integrity, for example, cracking of the solder joints. The mechanical stresses can also originate from a hostile operating environment: shocks and vibrations being the major ones. A hostile operating environment (salt water, for example) may chemically attack the electronic components.

Temperature and Temperature Dependencies. An important consideration, especially in semiconductor-based components and ICs is the strong temperature dependency of the conduction mechanism; it often limits the temperatures at which a circuit functions reliably. There are several other temperature considerations, temperature values, and their effects:

- Temperatures required for processing (manufacturing) of the semiconductor devices and IC chips, such as diffusion or sputtering
- Temperatures required for packaging (assembly) of the electronic equipment, for example, solder
- Environmental temperatures encountered during the product life, for example, transportation in an unheated compartment of a jet plane, products under the hood of a vehicle in tropic and arctic environments
- Temperature rise above the environment caused by power dissipation

The effects of these temperature variations are many:

- Shift in the electrical characteristics already mentioned
- Shift in the device switching speed (bipolar digital circuits are faster at higher temperatures, complementary metal-on-silicon, or CMOS, circuits are slower)
- Excessive mechanical stresses caused by mismatches in the thermal coefficients of expansion
- Instability of the materials such as decomposition of polymers and melting of solder

The designs for temperature control become increasingly difficult with wider range of operating temperatures (e.g., in automotive applications from arctic to tropic) and greater power densities. Thermoelectric coolers/heaters may be required. They increasingly employ Peltier-effect junctions.

Interface Adhesion. Essentially all electronic structures have thin-film layers of insulators and conductors. The interlayer adhesion is, as already mentioned, an extremely important design consideration that often requires compromises in the choice of materials, their deposition/lamination techniques, and surfaces treatments to facilitate the adhesion.

An additional consideration is the quality and integrity of the vertical electrical connections between two or more conducting layers. Such connections require creation of apertures in the insulating layer, commonly called vias or via holes, and their subsequent filling with conducting materials. Additional challenge results from diminishing dimensions, currently in the submicron range. The integrity of the via connections requires sufficient removal of the insulating material and metal deposition that has a good bond to the conductor at the via hole bottom as well as to the via hole sides. This integrity is threatened during the subsequent product manufacturing and through its life in the field, mainly by mechanical stresses.

Stress-Strain, Creep, and Fatigue. There is an unavoidable mismatch in the thermal coefficients of expansion (TCE) between the semiconductor IC bodies, the aluminum and insulator thin films on them, and the packaging to which the chips are attached. The need for low thermal resistance further compounds the challenge of providing adequate stress relief. The packaging structures usually employ copper conductors and various organic and inorganic insulators, each with their own challenges. Creep is often relied upon to provide stress relaxation. However, repeated temperature cycling fatigues the bonds and, thus, limits the product life. The mechanism is sufficiently understood (Ref 5) to offer design guidance. The failures may result from structural damage that disrupts either electrical or thermal conduction paths.

Properties Needed for Electronic and Magnetic Applications

Eugene J. Rymaszewski, Rensselaer Polytechnic Institute

Electronic Applications

The electronic applications (as opposed to electric power) are still growing rapidly, doubling in dollar volume every decade. They seem to penetrate every appliance and gadget, and even go beyond dreams of science-fiction writers; just think of cell phones, personal digital assistants, and small, easily portable geopositioning equipment. Yet, many of these applications share the same basic technologies: semiconductor IC chips, packaging (supporting chips and other components, such as resistors, capacitors, and inductors), source(s) and distribution of electric power, and means of interfacing with humans and other equipment. This section deals with the components of the electronic circuits--analog and digital. The next section discusses the augmenting technologies: magnetic and special technologies such as electrooptical.

Semiconductors. Understanding of the operational principles of a semiconductor junction is barely half a century old; the IC technology is two decades younger. Yet the progress has been spectacular, as demonstrated in Fig. 4. The fabrication of ICs is a highly specialized, still rapidly evolving field (Ref 3, 21, 22). The IC chips consist of two major domains: the semiconductor devices and the thin-film interconnections (conductors, insulators, and interlayer connections) for signal and power distribution. An integration of IC chips with the rest of the components occurs in the packaging, the task of which is to provide mechanical support and protection, signal and power connections, and to conduct away the inevitable heat. Thus, sufficient electrical, thermal, and mechanical interfaces must be established during manufacture and assembly and maintained through the useful product life. Depending on the application, there may be a need to disassemble the package in order to remove and replace one or several of the failed chips.

Resistors. The very definition of electrical parameters (Ohm's law) includes the resistor. Yet, the real-life realization of just about any resistor has several challenges, made especially severe in demanding applications. The thermal coefficient of resistivity had been already mentioned, the value and sign of which are controlled by the composition of materials and by the physical dimensions. The range of resistor values of interest extends over at least 6 to 10 orders of magnitude. The additional considerations are the variation of the value when first manufactured and within the operating temperature and frequency ranges, and the power-handling capability. The very recent challenges are presented by the quest for the lowest manufacturing and assembly costs and smallest area or volume. Such challenges drive development of "embedded" resistors, as well as capacitors and inductors, labeled imbedded passives (Ref 13). They are produced with thin films of

proper composition, dimensions, and processing. In addition to determining the power-handling capabilities, the structural dimensions of resistors control their high-frequency characteristics. The impedance of low-value resistors (below 100 Ω) has the tendency to acquire a sizeable series inductance, and high-value resistors (above 1 kΩ) tend to have a parallel capacitor component. The skin effect is less pronounced in thin-film resistors, but its effect should at least be considered.

Capacitors. The range of capacitance value is even greater than those of resistors, from fraction of a picofarad (pF) to one or several Farads, or at least 12 orders of magnitude. Some of the applications require tight tolerances (initial value, throughout the life, versus temperature and frequency) while others are open-ended toward higher values requiring only some minimum value. The operating and breakdown voltage and leakage currents are another important consideration that may dictate the choice of materials, as, for example, shown in Fig. 7. The embedded capacitors often require compatibility with organic materials used in packaging structures. This need rules out many excellent processing techniques that require high temperatures.

The series inductance of the capacitor with its connections, L_s, affects the high-frequency behavior in a peculiar way--there is an apparent increase in the capacitor value because total $X_c = (1/\omega C - \omega L_s) < 1/\omega C$. To make matters worse, above the resonance frequency, at which $1/\omega C = \omega L_s$, the inductance dominates the total impedance (plus the losses represented by a series resistance R_s). Just as with the resistors, careful control of geometry is required to push the resonance frequency to values higher than the highest operating frequency (Ref 23).

Signal Transmission. Transmission of electrical signals tolerates only relatively minor distortion, be it injected noise or signal amplitude degradation. The signal delay is unavoidable and is factored into designs, but it is often required to be as small as achievable as well as to remain constant. The signal transition time limits the maximum transmittable data rate. It is controlled by the losses in the conductors (series resistance) and insulators (dielectric losses and, in extreme situations, leakage currents). The quest for higher densities (Ref 14) drives cross-sectional geometries toward smaller values, requiring low-loss materials. For example, aluminum served the IC industry well since its inception a third of a century ago. While copper offers lower losses, and will eventually replace aluminum, the IC industry will use it with greatest reluctance. By contrast, the electronic packaging industry has been copper based from the start. Both are seeking dielectric materials with permittivities below 2 to minimize signal delay time and degradation of the signal transition time. Nonisometric values of permittivity are of concern.

Power Distribution. The power distribution system resides between the source of power--a battery or power supply circuits that convert the power line ac voltage into appropriate value dc voltage--and the power users: a multitude of circuits connected to the distribution at a multitude of locations. Ideally, all power users should have the same voltage (within tight tolerance) free of superimposed ac noise. The conductivity is, again, a key parameter, along with proper geometries. Suppression of the ac noise (decoupling) is usually accomplished with discrete capacitors whose high-frequency behavior sets the limits (Ref 5, 23).

Magnetic Applications

Some of these applications are as old as the electromagnetic technology, or even its precursor, the electricity and magnetism branch of physics. The unwanted (parasitic) effects of magnetic field energy associated with a current flow are described elsewhere in this section. The desired effects can be classified into several major groups: those requiring flux enhancers--such as ferromagnetic cores--and those without, sometimes referred to as having an air core. Some applications require conversion of the magnetic energy into energy other than electrical, for example, mechanical or thermal.

Inductors and transformers require no energy conversion. Some conversion is unavoidable and is considered parasitic. The inductors have only one set of terminals and one coil associated with the magnetic flux. The transformers have at least two coils (primary, to which the input voltage or current are applied, and the secondary) that provide isolation and, depending on the ratio of the turns in the coils, a voltage or current transformation. The volume of magnetic core is determined by the transmitted power.

Electromagnets, relays, motors, and activators utilize the magnetic field(s) to exert mechanical force either by interaction with the field of a permanent magnet, or between two electromagnets or (in most relays) by the attractive force between a solenoid core and the structure carrying contacts.

Magnetic storage requires initial magnetization and subsequent interrogation (readout) that causes minimum alteration of the magnetization to enable multiple readouts. The main advantages of the magnetic storage are the permanence--ability to store without continued application of electric power--and high storage capacity and essentially an unlimited number of the write/read cycles. The main disadvantage is the need to move the storage elements with respect to the readout head, by either a moving tape or a spinning disk. Another disadvantage is a relatively long read-out time.

Properties Needed for Electronic and Magnetic Applications

Eugene J. Rymaszewski, Rensselaer Polytechnic Institute

Special Applications

These applications augment the mainstream electronic and magnetic applications by utilizing materials properties such as piezoelectric, optoelectric, optomagnetic, superconducting, and so forth.

Piezoelectric applications are similar to magnetic transducers, sometimes serving the same purpose, for example, in phonographic pickups. The amount of mechanical displacement is very small--an advantage when minute, well-controlled movements are the goal, as in microscopic positioning mechanisms. The piezoelectric crystals have very constant frequencies of mechanical oscillation. They are popular in applications requiring generation of accurate ac signals, such as watches and tuning circuits for radio receivers and transmitters.

Optoelectronics are gaining in popularity because modulated coherent light enables very high data transfer rates over large distances. The transmission medium is a fiber light guide whose refraction coefficient confines the light beam to the interior and transmits it with very low losses. However, generation and modulation of light at the sending end still poses challenges, and these challenges are greater than those at the receiver: the wide-band demodulation of light and conversion to electrical signals.

Display panels use two types of technology: the well-established cathode-ray tubes (CRTs) used in most television sets and desktop computers, and flat-panel displays, which begin to challenge the bulky and heavy CRTs in area and are far superior in total volume and mass.

Optoelectronic storage applications are best known by the compact disc (CD), its bigger cousin, laser disc (LD), and the emerging DVD, which originally stood for a digital video disc. All offer a very low-cost, high-capacity storage, mostly for read-only use--the information is permanently embedded during the manufacturing. These discs supplement the magnetic storage and, to a degree, compete. Write/read variants are also available, but at high cost.

Properties Needed for Electronic and Magnetic Applications

Design with Brittle Materials

Stephen F. Duffy, Cleveland State University; Lesley A. Janosik, NASA Lewis Research Center

Introduction

BRITTLE MATERIALS (e.g., ceramics, intermetallics, and graphites) are increasingly being used in the fabrication of lightweight components. From a design engineer's perspective, brittle materials often exhibit attractive high-strength properties at service temperatures that are well beyond use temperatures of conventional ductile materials. For advanced diesel and turbine engines, ceramic components have already demonstrated functional abilities at temperatures reaching 1370 °C (2500 °F), which is well beyond the operational limits of most conventional metal alloys. However, a penalty is paid in that these materials typically exhibit low fracture toughness, which is usually defined by a critical stress intensity factor, and typically quantified by K_{Ic}. This inherent undesirable property must be considered when designing components. Lack of ductility (i.e., lack of fracture toughness) leads to low strain tolerance and large variations in observed fracture strength. When a load is applied, the absence of significant plastic deformation or microcracking causes large stress concentrations to occur at microscopic flaws. These flaws are unavoidably present as a result of fabrication or in-service environmental factors. Note that nondestructive evaluation (NDE) inspection programs cannot be successfully implemented during fabrication. The combination of high strength and low fracture toughness leads to relatively small critical defect sizes that cannot be detected by current NDE methods. As a result, components with a distribution of defects (characterized by various sizes and orientations) are produced, which leads to an observed scatter in component strength. Catastrophic crack growth for brittle materials occurs when the crack driving force or energy release rate reaches a critical value and the resulting component failure proceeds in a catastrophic manner.

The emphasis in this article is placed on design methodologies and characterization of certain material properties. Of particular interest to the design engineer is the inherent scatter in strength noted above. Accounting for this phenomenon requires a change in philosophy on the design engineer's part that leads to a reduced focus on the use of safety factors in favor of reliability analyses. If a brittle material with an obvious scatter in tensile strength is selected for its high-strength attributes, or inert behavior, then components should be designed using an appropriate design methodology rooted in statistical analysis. However, the reliability approach presented in this chapter demands that the design engineer must tolerate a finite risk of unacceptable performance. This risk of unacceptable performance is identified as the probability of failure of a component (or alternatively, component reliability). The primary concern of the engineer is minimizing this risk in an economical manner.

This article presents fundamental concepts and models associated with performing time-independent and time-dependent reliability analyses for brittle materials exhibiting scatter in ultimate strength. However, the discussion contained within this article is not limited to materials exposed to elevated service temperatures. The concepts can be easily extended to more mundane applications where brittle materials such as glass or cements are used. Specific applications that have utilized ceramic materials at near-ambient temperatures include wear parts (nozzles, valves, seals, etc.), cutting tools, grinding wheels, bearings, coatings, electronics, and human prostheses. Other brittle materials, such as glass and graphite materials, have been used in the fabrication of infrared transmission windows, glass skyscraper panels, television cathode ray tubes (CRTs), and high-temperature graphite bearings. Thus, in this article the design methodologies used to analyze these types of components, as well as components exposed to elevated service temperatures, are presented. Reliability algorithms are outlined, and several applications are presented to further illustrate the utilization of these reliability algorithms in structural applications. For further background material on statistical methods, see the article "Statistical Aspects of Design" in this Volume.

Time-Independent Reliability Analyses

An engineer is trained to quantify component failure through the use of a safety factor. By definition, the safety factor for a component subjected to a single load *L* is given by the ratio:

$$\text{Safety factor} = \frac{R}{L} \qquad \textbf{(Eq 1)}$$

where *R* is the resistance (or strength) of the material from which the component is fabricated. Making use of the concept of a safety factor, the probability of failure (P_f) for the component where a single load is applied is given by the expression:

$$P_f = \text{Probability}\left(\frac{R}{L} \geq 1\right) \qquad \textbf{(Eq 2)}$$

In making the transition from a deterministic safety factor for a component to a probability of failure, for the most general case, the assumption is made that both *R* and *L* are random variables. Under this assumption P_f is the product of two finite probabilities summed over all possible outcomes. Both probabilities are associated with an event and a random variable.

The first event is defined by the random variable *L* taking on a value in the range:

$$\left(x - \frac{dx}{2}\right) \leq L \leq \left(x + \frac{dx}{2}\right) \qquad \textbf{(Eq 3)}$$

The probability associated with this event is the area under the probability density function (PDF) for the load random variable (f_L) over this interval, i.e.,

$$P_1 = f_L\,(x)\,dx \qquad \textbf{(Eq 4)}$$

The second event is associated with the probability that the random variable *R* is less than or equal to *x*. This is the area under the probability density function for the resistance random variable (f_R) from $-\infty$(or an appropriate lower limit defined by the range of the resistance random variable) to *x*. This second probability is given by the cumulative distribution function (CDF) for the resistance random variable (F_R) evaluated at *x*, that is:

$$P_2 = F_R(x) \qquad \textbf{(Eq 5)}$$

With the probability of failure defined as the product of these two probabilities, summed over all possible values of *x*, then:

$$P_f = P_1 P_2 = \int_{-\infty}^{+\infty} F_R\,(x)\, f_L\,(x)dx \qquad \textbf{(Eq 6)}$$

To interpret this integral expression, consider the graphs in Fig. 1. In this figure, the graph of an arbitrary PDF for the resistance random variable is superimposed on the graph of an arbitrary PDF for the load random variable. Note that *R* and *L* must have the same dimensional units (e.g., force or stress) to superimpose their graphs in the same figure. A

common misconception is that P_f is the area of overlap encompassed by the two probability density functions. Scrutiny of Eq 6 leads to the appropriate conclusion that the probability of failure is really the area under the composite function:

$$g_{RL}(x) = F_R(x) f_L(x) \quad \textbf{(Eq 7)}$$

which is also illustrated in Fig. 1.

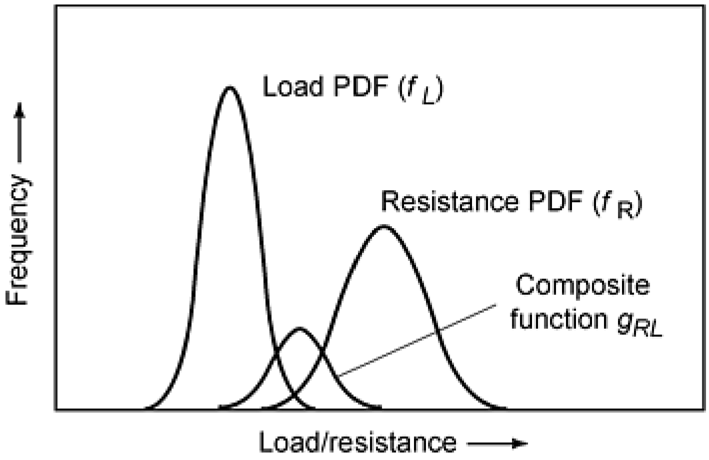

Fig. 1 Interference plot for load and resistance random variables

Next, consider the situation where the load random variable has very little scatter relative to the resistance random variable. For example, if a number of test specimens were fabricated from a brittle material (a monolithic ceramic), the ultimate tensile strength can easily vary by more than 100%. That is, the highest strength value in the group tested can easily be twice as large as the lowest value. Variations of this magnitude are not typical for the load design variable, and the engineer could easily conclude that load is a deterministic design variable while strength is a random design variable. This assumption can be accommodated in this development by allowing the PDF for the load random variable to be defined by the expression:

$$f_L(x) = \delta(x - x_o) \quad \textbf{(Eq 8)}$$

Here δ is the Dirac delta function defined as:

$$\delta(x - x_o) = \begin{cases} \infty & x = x_o \\ 0 & x \neq x_o \end{cases} \quad \textbf{(Eq 9)}$$

Note that the Dirac delta function satisfies the definition for a PDF; that is, the area under the curve is equal to 1, and the function is greater than or equal to 0 for all values of *x*. The Dirac delta function represents the scenario where the standard deviation of a random variable approaches 0 in the limit, and the random variable takes on a single value, that is, the central value identified here as x_o. Because the Dirac delta function is being used to represent the load random variable, then x_o represents the deterministic magnitude of the applied load. Keep in mind that the applied load can have units of force or stress. However, load and resistance are commonly represented with units of stress. Thus x_o is replaced with σ, an applied stress, and the probability of failure is given by the expression:

$$P_f = \int_{-\infty}^{+\infty} F_R(x)\delta(x - \sigma)dx \quad \textbf{(Eq 10)}$$

However, with the Dirac delta function embedded in the integral expression, the probability of failure simplifies to:

$$P_f = F_R(\sigma) \qquad \textbf{(Eq 11)}$$

Thus the probability of failure is equal to the CDF of the resistance random variable evaluated at the applied load, σ. The use of the Dirac delta function in representing the load design variable provides justification for the use of the Weibull CDF (or a similarly skewed distribution) in quantifying the probability of failure for components fabricated from ceramics or glass.

System Reliability

A unique property of most brittle materials is an apparent decrease in tensile strength as the size of the component increases. This is the so-called size effect. As an example, consider a simple component such as a uniaxial tensile specimen. Now suppose that two groups of these simple components have been fabricated. Each group is identical with the exception that the size of the specimens in the first group is uniformly smaller than the specimens in the second group. The mean sample strength from the first group would be consistently and distinctly larger in a manner that cannot be accounted for by randomness. Thus Eq 11 must be transformed in some manner to admit a size dependence. This is accomplished through the use of system reliability concepts. (See the article "Reliability in Design" in this Volume for details on formulating the basic equations for system reliability.) After the following discussion the reader should be cognizant that the expression given in Eq 11 represents the probability of failure for a specified set of boundary conditions. If the boundary conditions are modified in any way, Eq 11 is no longer valid. To account for size effects and to deal with the probability of failure for a component in a general manner, the component should be treated as a system, and the focus must be directed on the probability of failure of the system.

The typical approach to designing structural components with varying stress fields involves discretizing the component in order to characterize the stress field using finite element methods. Because component failure may initiate in any of the discrete elements, it is convenient to consider a component as a system and utilize system reliability theories. A component is a series system if it fails when one discrete element fails. This type of failure can be modeled using weakest-link reliability theories. A component is a parallel system when failure of a single element does not cause the component to fail. In this case, the remaining elements sustain load through redistribution. This type of failure can be modeled with what has been referred to in the literature as "bundle theories." Weakest-link theories and bundle theories represent the extremes of failure behavior modeled by reliability analysis. They suggest more complex systems such as "*r* out of *n*" systems. Here a component (system) of *n* elements functions if at least *r* elements have not failed. This type of system model has not found widespread application in structural reliability analysis. The assumption in this article is that the failure behavior of the brittle materials is sudden and catastrophic. This type of behavior fits within the description of a series system, thus a weakest-link reliability system is adopted.

Now the probability of failure of a discrete element must be related to the overall probability of failure of the component. If the failure of an individual element is considered a statistical event, and if these events are independent, then the probability of failure of a discretized component that acts as a series system is given by the expression:

$$P_f = 1 - \prod_{i=1}^{N} (1 - p_i) \qquad \textbf{(Eq 12)}$$

where N is the number of finite elements for a given component analysis. Here p_i is the probability of failure of the *i*th discrete element.

In the next section an expression is specified for the probability of failure (or alternatively, the reliability) of the *i*th discrete element for a simplified state of stress, that is, a uniaxial tensile stress. This expression allows the introduction of size scaling. Once size-scaling relationships are established for a simple state of stress, the relationships are extended to multiaxial states of stress.

Two-Parameter Weibull Distribution and Size Effects

In the ceramic and glass industry the Weibull distribution is universally accepted as the distribution of choice in representing the underlying PDF for tensile strength. A two-parameter formulation and a three-parameter formulation are available for the Weibull distribution. However, the two-parameter formulation usually leads to a more conservative estimate for the component probability of failure. The two-parameter Weibull PDF for a continuous random strength variable, denoted as Σ, is given by the expression:

$$f_\Sigma(\sigma) = \left(\frac{\alpha}{\beta}\right)\left(\frac{\sigma}{\beta}\right)^{(\alpha-1)} \exp\left[-\left(\frac{\sigma}{\beta}\right)^{\alpha}\right] \quad \textbf{(Eq 13)}$$

for $\sigma > 0$, and

$$f_\Sigma(\sigma) = 0 \quad \textbf{(Eq 14)}$$

for $\sigma \leq 0$. The cumulative distribution is given by the expression:

$$F_\Sigma(\sigma) = 1 - \exp\left[-\left(\frac{\sigma}{\beta}\right)^{\alpha}\right] \quad \textbf{(Eq 15)}$$

for $\sigma > 0$, and

$$F_\Sigma(\sigma) = 0 \quad \textbf{(Eq 16)}$$

for $\sigma \leq 0$. Here α(a scatter parameter, or Weibull modulus) and β(a central location parameter, or typically referred to as the Weibull scale parameter) are distribution parameters that define the Weibull distribution in much the same way as the mean (a central location parameter) and standard deviation (a scatter parameter) are parameters that define the Gaussian (normal) distribution. Note that in the ceramics and glass literature when the two-parameter Weibull formulation is adopted then "*m*" is used for the Weibull modulus α, and either σ_0 or $\sigma\theta$(see the discussion in the parameter estimation section regarding the difference between σ_0 and $\sigma\theta$) is used for the Weibull scale parameter. In this article, the (α, β) notation is used exclusively and reference is made to the typical notation adopted in the ceramics literature. The reason for this is the tendency to overuse the "σ" symbol (e.g., $\sigma\theta$, σ_0, σ_i-failure observation, and σ_t-threshold stress, etc.). Throughout this discussion the symbol "σ" implies applied stress.

If the random variable representing uniaxial tensile strength of an advanced ceramic is characterized by a two-parameter Weibull distribution, that is, the random strength parameter is governed by Eq 13 and 14, then the probability that a uniaxial test specimen fabricated from an advanced ceramic will fail can be expressed by the CDF:

$$P_f = 1 - \exp\left[-\left(\frac{\sigma_{max}}{\beta_\theta}\right)^{\alpha}\right] \quad \textbf{(Eq 17)}$$

Note that σ_{max} is the maximum normal stress in the component. When used in the context of characterizing the strength of ceramics and glasses, the central location parameter is referred to as the Weibull characteristic strength ($\beta\theta$). In the ceramic literature, this parameter can either be identified as the Weibull characteristic strength or the Weibull scale parameter. Because tensile strength is the random variable of interest, this parameter is referred to as a strength parameter throughout the rest of this article. The characteristic strength is dependent on the uniaxial test specimen (tensile, flexural, pressurized ring, etc.) used to generate the failure data. For a given material, this parameter will change in magnitude with specimen geometry (the so-called size effect alluded to earlier). The Weibull characteristic strength typically has units of stress. The scatter parameter $\alpha$is dimensionless.

With the tensile strength characterized by the two-parameter Weibull distribution, the discussion returns to the weakest-link expression for component probability of failure defined by Eq 12. Let $\Re_i$ represent the reliability of the *i*th continuum element where:

$$\Re_i = 1 - p_i \qquad \textbf{(Eq 18)}$$

The reliability of this continuum element is then governed by the following expression:

$$\Re_i = \exp\left(-\left(\frac{\sigma}{\beta_0}\right)^{\alpha} \Delta V\right) \qquad \textbf{(Eq 19)}$$

where σ is the principal tensile stress applied to the continuum element. The volume of this arbitrary continuum element is identified by ΔV. In this expression β_0 is the Weibull material scale parameter and can be described as the Weibull characteristic strength of a specimen with unit volume loaded in uniform uniaxial tension. This is a material specific parameter that is utilized in the component reliability analyses that follow. The dimensions of this parameter are stress × (volume)$^{1/\alpha}$.

The requisite size scaling discussed earlier is introduced by Eq 19. To demonstrate this, take the natural logarithm of Eq 19 twice, that is:

$$\ln \ln (\Re_i) = \ln\left(-\left(\frac{\sigma}{\beta_0}\right)^{\alpha} \Delta V\right) \qquad \textbf{(Eq 20)}$$

Manipulation of Eq 20 yields:

$$\ln (\Delta V) = -\alpha \ln (\sigma) + \ln \ln (\Re_i) + \alpha \ln (-\beta_0) \qquad \textbf{(Eq 21)}$$

with

$$y = \ln (\Delta V) \qquad \textbf{(Eq 22)}$$

$$x = \ln (\sigma) \qquad \textbf{(Eq 23)}$$

$$m = -\alpha \qquad \textbf{(Eq 24)}$$

and

$$b = \ln \ln (\Re_i) + \alpha \ln (-\beta_0) \qquad \textbf{(Eq 25)}$$

then it is apparent that Eq 21 has the form of a straight line, that is, $y = mx + b$.

Once again consider the two groups of test specimens fabricated from the same material mentioned at the beginning of the section on system reliability. Recall that the specimens in each group are identical with each other, but the two groups have different gage sections such that ΔV (which is now identified as the gage section volume) is different for each group. Estimate Weibull parameters α and β_0 from the failure data obtained from either group (parameter estimation is discussed in detail in a following section). After the Weibull parameters are estimated the straight line in Fig. 2 is located by setting $\Re_i$ equal to 0.5 (i.e., the 50th percentile) in Eq 21. This value for $\Re_i$ should establish a line that correlates well with the median values in each group.

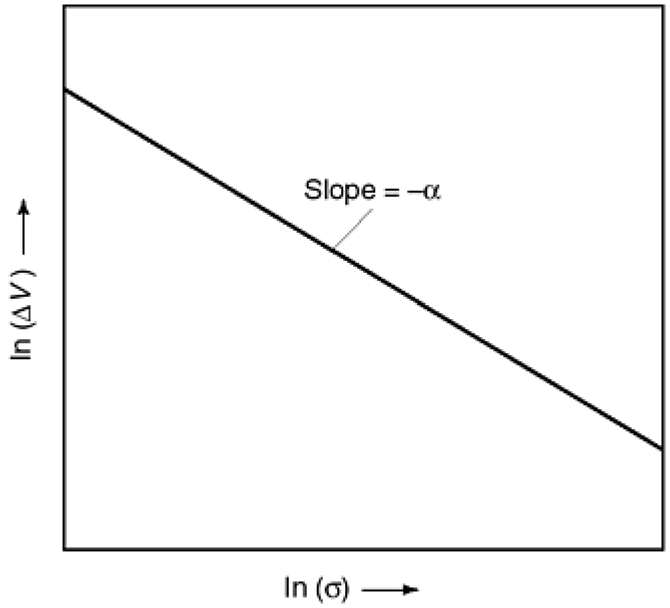

Fig. 2 Specimen gage volume plotted as a function of failure stress

Now return to the data sets mentioned above and establish the stress value associated with the median in each group. Plot the gage volumes (ΔV) of each group as a function of the median stress values in Fig. 2. If no size effect is present, the median failure strengths of the groups will fall close to a horizontal line. This would indicate no correlation between gage volume and the median strength value. Keep in mind that the discussion here could proceed using any percentile value, not just the 50th percentile. A systematic variation away from a horizontal line indicates a size effect exists that must be considered in engineering design. If the median values for each group follows the trend indicated by the solid line in Fig. 2 the design engineer should have no apprehensions using Weibull analysis with size scaling. Figures 1 and 3 in Ref 1 are two excellent examples of these types of graphs with actual data.

The ability to account for size effects of individual elements is introduced through the expression for $\Re_i$ given by Eq 19. A rational approach for justifying this expression is outlined above. Now a general expression for the probability of failure for a component (i.e., a general form for Eq 17) is derived based on Eq 19. Under the assumptions that the component consists of an infinite number of elements (i.e., the continuum assumption) and that the component is best represented by a series system, then:

$$P_f = 1 - \lim_{k \to \infty} \left(\prod_{i=1}^{k} \Re_i \right) \qquad \textbf{(Eq 26)}$$

Substituting for $\Re_i$ yields:

$$P_f = 1 - \exp\left(-\lim_{k \to \infty} \sum_{i=1}^{k} \left(\left(\frac{\sigma}{\beta_0} \right)^{\alpha} \Delta V \right)_i \right) \qquad \textbf{(Eq 27)}$$

Here ΔV once again represents the volume of an element. The limit inside the bracket is a Riemann sum. Thus:

$$P_f = 1 - \exp\left[-\int \left(\frac{\sigma}{\beta_0} \right)^{\alpha} dV \right] \quad \textbf{(Eq 28)}$$

Weibull (Ref 2) first proposed this integral representation for the probability of failure. The expression is integrated over all tensile regions of the specimen volume if the strength-controlling flaws are randomly distributed through the volume of the material, or over all tensile regions of the specimen area if flaws are restricted to the specimen surface. For failures caused by surface defects, the probability of failure is given by the expression:

$$P_f = 1 - \exp\left[-\int \left(\frac{\sigma}{\beta_0} \right)^{\alpha} dA \right] \quad \textbf{(Eq 29)}$$

which is derived in a manner similar to Eq 28. The segregation of defect populations into volume and surface-distributed flaws hints at the possibility of multiple defect populations. Reference 3 presents an in-depth treatment of this topic as it relates to ceramic materials.

The Weibull material scale parameter β_0 has units of stress × (volume)$^{1/\alpha}$. If the strength-controlling flaws are restricted to the surface of the specimens in a sample, then the Weibull material scale parameter has units of stress × (area)$^{1/\alpha}$. For a given specimen geometry, Eq 17 and 28 can be equated, yielding an expression relating β_0 and β_θ. Methods for converting β_θ to an equivalent β_0 value are addressed in ASTM Standard Practice C 1239-95.

Three-Parameter Weibull Distribution

The three-parameter Weibull PDF for a continuous random strength variable, denoted as Σ, is given by the expression:

$$f_\Sigma(\sigma) = \left(\frac{\alpha}{\beta} \right) \left(\frac{\sigma - \gamma}{\beta} \right)^{(\alpha-1)} \exp\left[-\left(\frac{\sigma - \gamma}{\beta} \right)^{\alpha} \right] \quad \textbf{(Eq 30)}$$

for $\sigma > \gamma$, and

$$f_\Sigma(\sigma) = 0 \quad \textbf{(Eq 31)}$$

for $\sigma \leq \gamma$. In Eq 30 α is once again the Weibull modulus (or the shape parameter), β is the Weibull scale parameter, and γ is a threshold parameter. The cumulative distribution is given by the expression

$$F_\Sigma(\sigma) = 1 - \exp\left[-\left(\frac{\sigma - \gamma}{\beta} \right)^{\alpha} \right] \quad \textbf{(Eq 32)}$$

for $\sigma > \gamma$, and

$$F_\Sigma(\sigma) = 0 \quad \textbf{(Eq 33)}$$

for $\sigma \leq \gamma$. The same reasoning presented in the previous section on size scaling utilizing a two-parameter formulation can be applied using the three-parameter formulation. The resulting expression for the probability of failure of a component subjected to a single applied stress σ is:

$$P_f = 1 - \exp\left[-\int \left(\frac{\sigma - \gamma}{\beta_0} \right)^{\alpha} dV \right] \quad \textbf{(Eq 34)}$$

if the defect population is spatially distributed throughout the volume. A similar expression exists for failures caused by area defects. The focus of the discussion in the next section turns to accommodating multiaxial stress states in Eq 28 and Eq 34. This involves the development of multiaxial reliability models.

The approach outlined in this section and previous sections to account for the scatter in failure strength and the size effect of brittle materials was first introduced by Weibull (Ref 2 and 4). The concepts were based on the principles of weakest-link theory presented earlier. A number of authors including Pierce (Ref 5), Kontorova (Ref 6), as well as Frenkel and Kontorova (Ref 7) have made contributions in this area. In fact, Pierce first proposed the weakest-link concept while modeling yarn failure. However, Pierce assumed a Gaussian distribution for the strength random variable of yarn, and Weibull developed the unique PDF for his work that now bears his name. Hu (Ref 8) explored the difficulties associated with parameter estimation when a Gaussian or log normal distribution is adopted for the strength random variable. Shih (Ref 9) has shown that the three-parameter Weibull distribution is a more accurate approximation of brittle material behavior (specifically monolithic ceramics) than the Gaussian or other distributions. However, most analyses incorporate a two-parameter Weibull PDF where the threshold stress (the value of applied stress below which the failure probability is 0) is taken as 0. The reliability predictions obtained using the two-parameter function are more conservative than those obtained with the three-parameter model.

Multiaxial Reliability Models

Over the years a number of reliability models have been presented that extend the uniaxial format of Eq 28 and 34 to multiaxial states of stress. Only models associated with isotropic brittle materials are presented here. Anisotropic reliability models are beyond the scope of this article. References 10 and 11 contain information pertaining to reliability models for brittle composites. The monolithic models highlighted here include the principle of independent action (PIA) model, the normal stress averaging (NSA) model, and Batdorf's model. A brief discussion is presented for each. A detailed development is omitted for the sake of brevity. In order to simplify the presentation of each model, recast Eq 28 as:

$$P_f = 1 - \exp\left[- \int \psi \, dV \right] \quad \textbf{(Eq 35)}$$

where ψ is identified as a failure function per unit volume. What remains is the specification of the failure function ψ for each reliability model.

Phenomenological Models (NSA and PIA). To predict the time-independent (also referred to as fast-fracture) material response under multiaxial stress states Weibull (Ref 2) proposed calculating a failure function per unit volume (Weibull identified the function as the risk of rupture) by averaging the tensile normal stress raised to an exponent in all directions over the area of a unit radius sphere for volume flaws. This is known as the NSA model where:

$$\psi = k\overline{\sigma}_n^{\alpha} \quad \textbf{(Eq 36)}$$

where

$$\overline{\sigma}_n^{\alpha} = \frac{\int_A \sigma_n^{\alpha} \, dA}{\int_A dA} \quad \textbf{(Eq 37)}$$

and

$$k = \frac{(2\alpha + 1)}{(\beta_0)^{\alpha}} \quad \textbf{(Eq 38)}$$

The area integration in Eq 37 is performed over the region of a unit sphere where σ_n (the Cauchy normal stress) is tensile. The reader is directed to Ref 12 for an in-depth explanation of the constants appearing in the equations above. Gross (Ref 13) demonstrated that for surface flaws this same averaging technique can be executed over the contour of a circle with a unit radius. Although the surface flaw technique is intuitively plausible for the NSA model, the approach is somewhat arbitrary. In addition, it lacks a closed-form solution, and therefore requires computationally intensive numerical modeling.

Barnett et al. (Ref 14) and Freudenthal (Ref 15) proposed an alternative approach usually referred to as the PIA model. Here:

$$\psi = \left(\frac{\sigma_1}{\beta_0}\right)^{\alpha} + \left(\frac{\sigma_2}{\beta_0}\right)^{\alpha} + \left(\frac{\sigma_3}{\beta_0}\right)^{\alpha} \quad \textbf{(Eq 39)}$$

where σ_1, σ_2, and σ_3 are the three principal stresses at a given point. The PIA model is the probabilistic equivalent to the deterministic maximum stress failure theory.

The NSA model, and in particular the PIA model, have been widely applied in brittle material design. The reader is directed to Ref 16, 17, 18, 19, and 20 for a more in-depth development and discussion of the merits of these two models. Historically, the NSA and the PIA models have been popular methods for multiaxial stress state analysis. However, the NSA and PIA models are in essence phenomenological and do not specify the nature of the defect causing failure. As a consequence, no foundation exists for extrapolating predictions made by these models to conditions different from the original test conditions. Other models that are rooted in the principles of fracture mechanics are discussed in the next section.

Batdorf's Theory--Mechanistic Model. The concepts proposed by Batdorf (Ref 21), and later refined by Batdorf and Crose (Ref 22), are important in that the approach incorporates a mechanistic basis for the effect of multiaxial states of stress into the weakest-link theory. Here material defects distributed throughout the volume (and/or over the surface) are assumed to have a random orientation. In addition, the defects are assumed to be noninteracting discontinuities (cracks) with an assumed regular geometry. Failure is assumed to occur when a far-field effective stress associated with the weakest flaw reaches a critical level. The effective stress is a predefined combination of the far-field normal stress and the far-field shear stress. It is also a function of the assumed crack configuration, the existing stress state, and the fracture criterion employed (hence the claim that the approach captures the physics of fracture). Accounting for the presence of a far-field shear stress reduces the far-field normal stress needed for fracture. This model is identified by taking:

$$\psi = \alpha\, k_B \int_0^{(\sigma_e)_{max}} \frac{\Phi(\Sigma, \sigma_{cr})}{4\pi}\, \sigma_{cr}^{\alpha-1}\, d\sigma_{cr} \quad \textbf{(Eq 40)}$$

where Φ is a solid angle that is dependent on the fracture criterion selected, the crack configuration, and the applied stress state. The maximum effective stress $(\sigma_e)_{max}$ is defined as an equivalent mode I fracture stress for mixed-mode loading. The crack-density coefficient k_B is obtained from the following expression:

$$k_B = \frac{\eta_v(\sigma_{cr})}{(\sigma_{cr})^{\alpha}} \quad \textbf{(Eq 41)}$$

Here σ_{cr} is defined as the critical far-field normal stress for a given crack configuration under mode I loading. Once again Ref 12 can provide a detailed interpretation of the parameters appearing in Eq 40. For the most part, the Batdorf model yields more accurate reliability analyses than those produced by either the NSA or PIA models.

Numerous authors have discussed the stress distribution around cracks of various types under different loading conditions and proposed numerous criteria to describe impending fracture. Specifically, investigators such as Giovan and Sines (Ref 23), Batdorf (Ref 21), Stout and Petrovic (Ref 24), as well as Petrovic and Stout (Ref 25) have compared results from the most widely accepted mixed-mode fracture criteria with each other and with selected experimental data. The semiempirical equation developed by Palaniswamy and Knauss (Ref 26) and Shetty (Ref 27) seemingly provides enough flexibility to fit to experimental data. In addition, Shetty's criterion can account for the out-of-plane crack growth that is observed under mixed-mode loadings. However, several issues must be noted. No prevailing consensus has emerged regarding a best probabilistic fracture theory. Most of the available criteria predict somewhat similar results, despite the divergence of initial assumptions. Moreover, one must approach the mechanistic models with some caution. The reliability models based on fracture mechanics incorporate the assumptions made in developing the fracture models on which they are based. One of the fundamental assumptions made in the derivation of fracture mechanics criteria is that the crack length is much larger than the characteristic length of the microstructure. This is sometimes referred to as the continuum principle in engineering mechanics. For the brittle materials discussed here, that characteristic length is the grain size (or diameter). If one contemplates the fact that most brittle materials are high strength with an attending low fracture toughness, then the critical defect size can be quite small. If the critical defect size approaches the grain size of the material, then the phenomenological models discussed above may be more appropriate than the mechanistic models.

Parameter Estimation

As indicated earlier, the distribution of choice for characterizing the tensile strength of brittle materials is the Weibull distribution. One fundamental reason for this choice goes beyond the fact that the Weibull distribution usually provides a good fit to the data. While the log-normal distribution often provides an adequate fit, it precludes any accounting of size effects. Reference 8 provides a detailed discussion on this matter. As it turns out, once a conscious choice is made to utilize the Weibull distribution, Eq 17 provides a convenient formulation for parameter estimation. However, one cannot extract the fundamental distribution parameters needed for general component analysis from this expression, unless the test specimen has the same geometry and applied loads as the component. The fundamental distribution parameters (identified previously as material specific parameters) were embedded in Eq 28. Thus, together Eq 17 and 28 provide a convenient method for extracting material specific parameters from failure data.

Tensile strength measurements are taken for one of two reasons: either for a comparison of the relative quality of two materials or for the prediction of the failure probability for a structural component. The latter is the focus of this article, although the analytical details provided here allow for either. To obtain point estimates of the unknown Weibull distribution parameters, well-defined functions are utilized that incorporate the failure data and specimen geometry. These functions are referred to as estimators. It is desirable that an estimator be consistent and efficient. In addition, the estimator should produce unique, unbiased estimates of the distribution parameters. Different types of estimators exist, including: moment estimators, least squares estimators, and maximum likelihood estimators. This discussion initially focuses on maximum likelihood estimators (MLE) due to the efficiency and the ease of application when censored failure populations are encountered. The likelihood estimators are used to compute parameters from failure populations characterized by a two-parameter Weibull distribution. Alternatively, nonlinear regression estimators (discussed later) are utilized to calculate unknown distribution parameters for a three-parameter Weibull distribution.

Many factors affect the estimates of the distribution parameters. The total number of test specimens plays a significant role. Initially, the uncertainty associated with parameter estimates decreases significantly as the number of test specimens increases. However, a point of diminishing returns occurs when the cost associated with performing additional strength tests may not be justified by improvements in the estimated values of the distribution parameters. This suggests that a practical number of strength tests should be performed to obtain a desired level of confidence associated with a parameter estimate. This point cannot be overemphasized. However, quite often 30 specimens (a widely cited rule-of-thumb) is deemed a sufficient quantity of test specimens when estimating Weibull parameters. One should immediately ask why 29 specimens would not suffice. Or more importantly, why is 30 specimens sufficient? The answer to this is addressed in ASTM Standard Practice C 1239-95 where the details of computing confidence bounds for the maximum likelihood estimates (these bounds are directly related to the precision of the estimate) are presented. Duffy et al. (Ref 28) discusses the reasons why these same confidence bounds are not available for the nonlinear regression estimators.

Tensile and flexural specimens are the most commonly used test configurations in determining ultimate strength values for brittle materials. However, as noted earlier, most brittle material systems exhibit a decreasing trend in material strength as the test specimen geometry is increased. Thus, the observed strength values are dependent on specimen size and geometry. Parameter estimates can be computed based on a given specimen geometry; however, the parameter estimates should be transformed and utilized in a component reliability analysis as material-specific parameters. The procedure for transforming parameter estimates for the typical specimen geometries just cited is outlined in ASTM

Standard Practice C 1239-95. The reader should be aware that the parameters estimated using nonlinear regression estimators are material-specific parameters. Therefore, no transformation is necessary after these parameters have been estimated.

Brittle materials can easily contain two or more active flaw distributions (e.g., failures due to inclusions or machining damage) and each will have its own strength distribution parameters. The censoring techniques for the two-parameter Weibull distribution require positive confirmation of multiple-flaw distributions, which necessitates fractographic examination to characterize the fracture origin in each specimen. Multiple-flaw distributions may also be indicated by a deviation from the linearity of the data from a single Weibull distribution (see Fig. 3). However, observations of approximately linear behavior should not be considered a sufficient reason to conclude a single flaw distribution is active. The reader is strongly encouraged to integrate mechanical failure data and fractographic analysis.

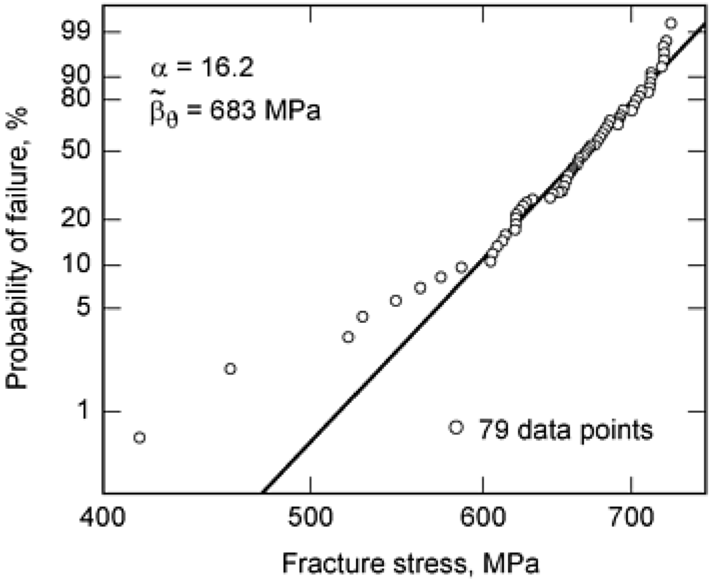

Fig. 3 Sample with multiple failure populations

As was just noted, discrete fracture origins are quite often grouped by flaw distributions. The data for each flaw distribution can also be screened for outliers. An outlying observation is one that deviates significantly from other observations in the sample. However, an apparent outlying observation may be an extreme manifestation of the variability in strength. If this is the case, the data point should be retained and treated as any other observation in the failure sample. Yet the outlying observation can be the result of a gross deviation from prescribed experimental procedure, or possibly an error in calculating or recording the numerical value of the data point in question. When the experimentalist is clearly aware that either of these situations has occurred, the outlying observation may be discarded, unless the observation (i.e., the strength value) can be corrected in a rational manner. For the sake of brevity, this discussion omits any discussion on the performance of fractographic analyses and omits any discussion concerning outlier tests.

Two-Parameter MLEs. With the above discussion serving as background, attention is now focused on obtaining estimated values of the Weibull parameters α and β_θ. This discussion focuses on MLEs because of their efficiency and ease of application when censored failure populations are encountered. When a sample containing ultimate strength observations yields two or more distinct flaw distributions, the sample is said to contain censored data. The maximum likelihood methodology accounts for censored data in a rational, straightforward manner. Other estimation techniques (specifically linear regression estimators) must appeal to ad hoc reranking schemes in the presence of censored data.

Johnson and Tucker (Ref 1), as well as others, have shown that the MLE method is more efficient in estimating parameters. Here, efficiency is measured through the use of confidence bounds. For an equivalent confidence level, the authors of these works have demonstrated that the confidence bounds for an MLE is always smaller than the confidence bound obtained using linear regression. For this reason the likelihood estimators should be used to compute parameters from failure populations characterized by a two-parameter Weibull distribution.

The parameter estimates obtained using the maximum likelihood technique are unique (for a two-parameter Weibull distribution), and as the size of the sample increases, the estimates statistically approach the expected values of the true population parameter. Let σ_1, σ_2, . . ., σ_N represent realizations of the ultimate tensile strength (a random variable) in a given sample, where it is assumed that the ultimate tensile strength is characterized by the two-parameter Weibull distribution. The likelihood function associated with this sample is the joint probability density of the *N* random variables and thus is a function of the unknown Weibull distribution parameters (α, β_θ). The likelihood function for an uncensored sample under these assumptions is given by the expression:

$$L = \prod_{i=1}^{N} \left(\frac{\tilde{\alpha}}{\tilde{\beta}_\theta}\right)\left(\frac{\sigma_i}{\tilde{\beta}_\theta}\right)^{\tilde{\alpha}-1} \exp\left[-\left(\frac{\sigma_i}{\tilde{\beta}_\theta}\right)^{\tilde{\alpha}}\right] \quad \textbf{(Eq 42)}$$

The parameter estimates (the Weibull modulus $\tilde{\alpha}$and the characteristic strength $\tilde{\beta}_\theta$) are determined by taking the partial derivatives of the logarithm of the likelihood function with respect to $\tilde{\alpha}$and $\tilde{\beta}_\theta$, and equating the resulting expressions to 0. Note that the tildes distinguish a parameter estimate from its corresponding true value. The system of equations obtained by differentiating the log likelihood function for a censored sample is given by:

$$\frac{\sum_{i=1}^{N} (\sigma_i)^{\tilde{\alpha}} \ln(\sigma_i)}{\sum_{i=1}^{N} (\sigma_i)^{\tilde{\alpha}}} - \frac{1}{N}\sum_{i=1}^{N} \ln(\sigma_i) - \frac{1}{\tilde{\alpha}} = 0 \quad \textbf{(Eq 43)}$$

and

$$\tilde{\beta}_\theta = \left[\left(\sum_{i=1}^{N} (\sigma_i)^{\tilde{\alpha}}\right)\frac{1}{N}\right]^{1/\tilde{\alpha}} \quad \textbf{(Eq 44)}$$

Equation 43 is solved numerically, because a closed-form solution for $\tilde{\alpha}$cannot be obtained from this expression. Once $\tilde{\alpha}$ is determined this value is inserted into Eq 44 and $\tilde{\beta}_\theta$is calculated directly. The reader is once again directed to ASTM Standard Practice C 1239-95 for the expressions corresponding to samples with censored data.

Three-Parameter Linear Regression. To date, most reliability analyses performed on structural components fabricated from ceramic materials have utilized the two-parameter form of the Weibull distribution. The use of a two-parameter Weibull distribution to characterize the random nature of material strength implies a nonzero probability of failure for the full range of applied tensile stress. This represents a conservative design assumption when analyzing structural components. The three-parameter form of the Weibull distribution was presented earlier in Eq 30 and 31. The additional parameter is a threshold stress (γ) that allows for zero probability of failure when the applied stress is at or below the threshold value. Certain monolithic ceramics have exhibited threshold behavior. The reader is directed to an extensive database assembled in Ref 29, the silicon nitride data in Ref 30, as well as data (with supporting fractography) presented in Ref 31 that was analyzed later in Ref 28.

When strength data indicates the existence of a threshold stress, a three-parameter Weibull distribution should be employed in the stochastic failure analysis of structural components. By employing the concept of a threshold stress, an engineer can effectively tailor the design of a component to optimize structural reliability. To illustrate the approach, Duffy et al. (Ref 28) embedded the three-parameter Weibull distribution in a reliability model that utilized PIA. Analysis of a space-shuttle main engine (SSME) turbopump blade predicted a substantial improvement in component reliability when the three-parameter Weibull distribution was utilized in place of the two-parameter Weibull distribution. Note that

the three-parameter form of the Weibull distribution can easily be extended to Batdorf's (Ref 21, 22) model, reliability models proposed for ceramic composites by Duffy et al. (Ref 32), or Thomas and Wetherhold (Ref 33), as well as the interactive reliability models proposed by Palko (Ref 34).

The nonlinear regression method presented here was first proposed by Margetson and Cooper (Ref 35). However, these estimators maintain certain disadvantages relative to bias and invariance, and these issues were explored numerically in Ref 28. The Monte Carlo simulations in Ref 28 demonstrated that the functions proposed in Ref 35 are neither invariant nor unbiased. However, they are asymptotically well behaved in that bias decreases and confidence intervals contract as the sample size increases. Thus, even though bias and confidence bounds may never be quantified using these nonlinear regression techniques, the user is guaranteed that estimated values improve as the sample size is increased.

Regression analysis postulates a relationship between two variables. In an experiment typically one variable can be controlled (the independent variable), while the response variable (or dependent variable) is not. In simple failure experiments the material dictates the strength at failure, indicating that the failure stress is the response variable. The ranked probability of failure (P_i) can be controlled by the experimentalist, because it is functionally dependent on the sample size (N). After arranging the observed failure stresses (σ_1, σ_2, σ_3, . . ., σ_N) in ascending order, and specifying:

$$P_i = \frac{(i - 0.5)}{N} \quad \textbf{(Eq 45)}$$

then clearly the ranked probability of failure for a given stress level can be influenced by increasing or decreasing the sample size. The procedure proposed in Ref 35 adopts this philosophy. They assume that the specimen failure stress is the dependent variable, and the associated ranked probability of failure becomes the independent variable.

Using the three-parameter version of Eq 34, an expression can be obtained relating the ranked probability of failure (P_i), to an estimate of the failure strength ($\tilde{\sigma}_i$). Assuming uniaxial stress conditions in a test specimen with a unit volume, Eq 34 yields:

$$\tilde{\sigma}_i = \tilde{\gamma} + \tilde{\beta}_0 \left[\ln \left(\frac{1}{1 - P_i} \right) \right]^{1/\tilde{\alpha}} \quad \textbf{(Eq 46)}$$

where $\tilde{\alpha}$, $\tilde{\beta}_0$ and **MATH OMITTED** are estimates of the shape parameter (α), the scale parameter (β_0), and threshold parameter (γ), respectively. Expressions for the evaluation of these parameters for a test specimen subjected to pure bending are found in Ref 28. Defining the residual as:

$$\delta_i = \tilde{\sigma}_i - \sigma_i \quad \textbf{(Eq 47)}$$

where σ_i is the ith ranked failure stress obtained from actual test data, then the sum of the squared residuals is expressed as:

$$\sum_{i=1}^{N} (\delta_i)^2 = \sum_{i=1}^{N} \left[\tilde{\gamma} + \tilde{\beta}_0 (W_i)^{1/\tilde{\alpha}} - \sigma_i \right]^2 \quad \textbf{(Eq 48)}$$

Here the notation of Ref 35 has been adopted where:

$$W_i = \ln \left(\frac{1}{1 - P_i} \right) \quad \textbf{(Eq 49)}$$

Note that the forms of $\tilde{\sigma}_i$ and W_i change with specimen geometry. This is discussed in more detail in Ref 28.

It should be apparent that the objective of this method is to obtain parameter estimates that minimize the sum of the squared residuals. Setting the partial derivatives of the sum of the squared residuals with respect to $\tilde{\alpha}$, $\tilde{\beta}_0$, and $\tilde{\gamma}$ equal to zero yields the following three expressions:

$$\tilde{\beta}_0 = \frac{N\left[\sum_{i=1}^{N} \sigma_i (W_i)^{1/\hat{\alpha}}\right] - \left[\sum_{i=1}^{N} \sigma_i\right]\left[\sum_{i=1}^{N} (W_i)^{1/\hat{\alpha}}\right]}{N\sum_{i=1}^{N} (W_i)^{2/\hat{\alpha}} - \left[\sum_{i=1}^{N} (W_i)^{1/\hat{\alpha}}\right]\left[\sum_{i=1}^{N} (W_i)^{1/\hat{\alpha}}\right]} \qquad \textbf{(Eq 50)}$$

$$\tilde{\gamma} = \left\{ \left[\sum_{i=1}^{N} \sigma_i\right]\left[\sum_{i=1}^{N} (W_i)^{2/\hat{\alpha}}\right] - \left[\sum_{i=1}^{N} \sigma_i (W_i)^{1/\hat{\alpha}}\right]\left[\sum_{i=1}^{N} (W_i)^{1/\hat{\alpha}}\right] \right\} \times \left\{ N\sum_{i=1}^{N} (W_i)^{2/\hat{\alpha}} - \left[\sum_{i=1}^{N} (W_i)^{1/\hat{\alpha}}\right]\left[\sum_{i=1}^{N} (W_i)^{1/\hat{\alpha}}\right] \right\}^{-1} \qquad \textbf{(Eq 51)}$$

and

$$\left| \sum_{i=1}^{N} \sigma_i (W_i)^{1/\tilde{\alpha}} \ln (W_i) - \tilde{\gamma} \sum_{i=1}^{N} \sigma_i (W_i)^{1/\tilde{\alpha}} \ln (W_i) - \tilde{\beta}_0 \sum_{i=1}^{N} \sigma_i (W_i)^{2/\tilde{\alpha}} \ln (W_i) \right| \leq \kappa_{conv} \qquad \textbf{(Eq 52)}$$

in terms of the parameter estimates. The solution of this system of equations is iterative, where the third expression is used to check convergence of an iteration. The initial solution vector for this system is determined after assuming a convenient value for $\tilde{\alpha}$, say $\tilde{\alpha}$= 1. Then $\tilde{\beta}_0$ is computed from Eq 50 and $\tilde{\gamma}$ is calculated from Eq 51. The values of these parameter estimates are then inserted into Eq 52 to determine if the convergence criterion is satisfied to within some predetermined tolerance (κ_{conv}). If this expression is not satisfied, $\tilde{\alpha}$ is updated and a new iteration is conducted. This procedure continues until a set of parameter estimates is determined that satisfy Eq 52.

The estimators perform reasonably well in comparison to estimates of the two-parameter Weibull distribution for the alumina data found in Table 1. Figure 4 is a plot of probability of failure versus failure stress for this data. The straight line represents the two-parameter fit to the data where $\tilde{\alpha}$= 143.2, $\tilde{\beta}_\theta$= 395 ($\tilde{\gamma} \equiv$0) using values from Ref 29 for the shape and scale parameters. The nonlinear curve represents the three-parameter fit to the data where $\tilde{\alpha}$= 1.22, $\tilde{\beta}_0$ = 389, and $\tilde{\gamma}$= 298. Note that the three-parameter distribution appears more efficient in predicting the failure data in the high-reliability region of the graph. This is a qualitative assessment. Goodness-of-fit statistics such as the Kolmogorov-

Smirnov statistic, the Anderson-Darling statistic, and likelihood ratio tests could provide quantitative measures to establish which form of the Weibull distribution would best fit the experimental data. These statistics are utilized in conjunction with hypothesis testing to assess the significance level at which the null hypothesis can be rejected. Comparisons can then be made based on the value of the significance level.

Time-Independent Reliability Algorithms

After a reliability model has been adopted and the failure function ψ has been specified, the primary task is the evaluation of the integral given in Eq 35. Closed-form solutions exist for only the simplest of component geometries and boundary conditions. Therefore, integrated computer algorithms have been developed that enable the design engineer to predict the time-independent (fast-fracture) reliability of components subjected to thermomechanical loading. Two algorithms are discussed here. One algorithm has been developed at the NASA Lewis Research Center and has been given the acronym CARES (Ceramics Analysis and Reliability Evaluation of Structures). This algorithm is widely discussed in Ref 12, 36, 37, and 38. The second computer algorithm, given the acronym ERICA, was developed by AlliedSignal (Ref 39, 40) with funding provided by the U.S. Department of Energy. Both algorithms are discussed briefly, and design examples are illustrated.

CARES Algorithm. The NASA Lewis Research Center CARES algorithm couples commercially available finite element programs, such as MSC/NASTRAN, ANSYS, or ABAQUS, with the probabilistic design models discussed previously. The algorithm contains three software modules that:

- Perform parameter estimation using experimental data obtained from standard laboratory specimens
- Generate a neutral database from MSC/NASTRAN, ABAQUS, and ANSYS finite element results files
- Evaluate the reliability of thermomechanically loaded components
